Loading. The instructions with most projectors indicate clearly how the film has to be threaded through the film path and the sound system, where applicable. Usually the projector also carries a threading diagram.

A number of modern projectors have an automatic threading feature. There the film end —which must be trimmed square—is pushed into a slot and automatically picked up by the sprocket. This drives the film through the loops, the film gate, and the various rollers and take-up sprockets. The main constructional feature of such automatic threading devices is a rigid loop guide through which the film must pass and which automatically ensures top and bottom loops of the correct size. Once the film has passed through the transport section, the loope guides are opened so that the film loops are free. Auto threading systems need an accurate construction, otherwise the perforations at the beginning of the film may become damaged. When the film leaves the last sprocket, it has to be attached to the take-up spool by hand; on some advanced auto-threading systems the film end is guided right into the take-up spool and picked up mechanically there.

Automatic film threading is rarer with sound projectors, since the film path round the sound system is more complicated.

A framing control is essential for professional requirements in order to correct any errors in threading the film into the projector. The frames of picture may not be in correct relation to the gate aperture and the effect on

the screen will be two incomplete portions of a scene. The framing control enables the projectionist to adjust the picture up or down correctly. The adjustment is of the optical type—that is, it does not change the alignment of the optical axis with the screen.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

When a framing control is fitted to narrow gauge machines it is usually of the non-optical type, its disadvantage being that operation of the control moves the projected area bodily up or down off the screen and it becomes necessary to use the tilting adjustment of the projector in order to bring the picture back into place.

ILLUMINATION AND OPTICAL SYSTEM

The optical system of a cine projector consists of the light source, the elements to concentrate the light on to the film image in the gate, and the projection lens which throws the enlarged image on the screen.

Light Sources. Most narrow gauge film projectors use high intensity tungsten filament lamps. Light powers range from 300 to 500 watts in 8 mm. projectors, up to 1,200 or even 1,500 watts in 16 mm. machines. Sometimes the lamps operate from 220 to 250 volt mains supplies; more often 110 volt lamps run via a transformer are used since at the lower voltage the light efficiency is better.

The complete optical arrangement consists of the lamp, a reflector behind it and two or three condensers in front. The latter focus the light beam on to the projector gate to provide a film image of maximum brightness. The lamps are usually designed to have as small a filament as possible, because the concentrated source gives the best results with the optical set-up. The projection lamp and the reflector must be carefully lined up to illuminate the image in the projection gate evenly.

Low voltage lamps with integral or proximity reflectors are also widely used in 8 mm. projectors. Here the lamp has the reflector built in to the bulb, or the rear surface of a bulb may be blown out in to the shape of an ellipsoid reflector. In either case the reflector is so arranged as to concentrate the light from the filament on to the image plane in the projector—often without the need for any condensers at all. This makes for a more compact lighting set-up. Low voltage lamps of this kind usually run at 8 or 12 volts, and come in powers of 50 to 150 watts. The light from the latter is equivalent to the illumination from a 500 watt mains voltage lamp with the more orthodox lighting set-up of a lamp and condensers.

Quartz-iodine lamps are also used in 8 mm. projectors, and have the advantage of being particularly compact as well as providing a light of constant intensity and colour temperature.

Professional motion picture projectors may have tungsten filament lamps, but the more usual light source is a carbon arc or a xenon arc. Carbon arc lamps are the most powerful illuminant, but require bulky lamp houses and automatic feeding gear for the carbons. The high-intensity xenon arc is a more modern light source, nearly as intense as a carbon arc, and easier to handle.

Xenon arc lamps are also used on a small scale in amateur 16 mm. and 8 mm. projectors. Here a 150-watt lamp corresponds in lamp output to about 500 to 750 watts of a mains voltage tungsten lamp.

Pulsed Light. In the usual projector the light source is continuous, and is interrupted by the shutter to produce the dark periods for the film pull-down and also to prevent flicker. The alternative method is to have an intermittent light source which pulses in synchronism with the film transport, and so provides the same effect without the need for a shutter. Pulsed light sources with a frequency up to 72 pulses per second are used in certain cinema projectors specially designed for such operation. The source is a high pressure xenon arc with a power rating of about 800 watts. Since this is the average power, the intensity of the pulses themselves is higher; hence the light output of the projector compares favourably with the light intensity of a conventional projector of twice the power.

Cooling. Some form of cooling device is incorporated in most projectors. Usually a fan, driven by the projector motor (or a separate motor) forces cold air past the film in the gate and past the projection lamp. The maintenance of the correct lamp temperature is important, otherwise the glass envelope may soften and distort.

The lamp and fan motor are generally controlled by separate switches, to enable the fan to be switched on before the lamp. On many projectors the switches are combined in such a way that the lamp can only be switched on once the fan is running.

Ventilation and forced draught can only remove the hot air from the lamp house; they cannot prevent the lamp from radiating heat through the condenser and on to the film. For this reason projectors may incorporate a heat filter in the optical path; more often such a filter comes into action automatically when the projector motor stops for projecting a still picture on the screen. As an alternative to heat absorbing glass, the filter may be a wire mesh or similar material.

35 mm. projectors with their much more intense lighting have a safety shutter which cuts the light off from the gate should the machine stop, otherwise the film would melt. In addition the film reels on a 35 mm. machine are enclosed in fire-proof housings. This is a safety precaution which was particularly necessary in the days when 35 mm. films were still on highly inflammable nitrate base.

Lenses. Normally a projector is fitted with a lens

twice the focal length of the standard camera lens; about 25 mm. for an 8 mm. projector and 50 mm. for a 16 mm. projector. This is suitable for home projection in fairly large rooms and projection in small halls. Modern 8 mm. projectors frequently come with a shorter focus lens about 15 to 20 mm. for bigger screen images in small rooms. Variable focus lenses are also popular; for instance a focal length range of 13 to 25 mm. on an 8 mm. projector covers everything from large images at short projection throws to medium screen sizes with longer throws. Typical projection lens apertures range from *f* 1·1 to *f* 1·8.

The focusing movement is a helical mount; sometimes the lens has a rack and pinion.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

SOUND PROJECTORS

The three main ways of projecting sound films are with an optical sound track, a magnetic track (stripe) on the film, and with a separate magnetic tape. The first is largely used for 16 mm. home and educational projectors (though there are also 8 mm. optical sound machines), while the second method is used for all three narrow film gauges. Sound projection with a separate tape is almost entirely confined to 8 mm. film.

With standard 35 mm. motion picture film the optical sound track is the most usual kind; for certain types of motion picture presentations (such as Cinemascope and similar systems) the sound may be recorded on a number of tracks on a separate magnetic film which runs through the projector in synchronism with the picture film.

PROJECTOR SOUND HEAD. The principal units of optical sound projection are: A, amplifier; B, reflecting prism; C, rollers to press film against drum; D, sound drum; E, loudspeaker; F, exciter lamp; G, film; H, photo-cell.

Optical Sound. In the optical sound projector the film passes intermittently through the picture gate and then runs over a system of rollers connected to a smoothing device. This ensures that it will move smoothly and continuously through the sound gate. Here light from an exciter lamp shines through the sound track at the edge of the film and falls upon a light-sensitive photo-cell.

The modulations on the sound track vary the intensity of the light falling on the photo-cell. This in turn varies the electrical output of the cell so that it transmits a greater or less current to the amplifier which operates the loudspeaker.

As the sound gate is mounted below, or in advance of, the picture gate, the sound is always printed on the film in advance of the frame of picture to which it refers. In standard practice the sound track starts twenty frames in advance of the picture, on 16 mm. film twenty-six frames in advance and on 9·5 mm. film twenty-five frames in advance.

The reason for this is the impossibility of combining the intermittent movement of the film for the image projection with the smooth movement necessary for the sound. For some special purposes film may also have edge-synchronization—with the sound next to the corresponding image. In this case, however, the sound has to be picked up before the film enters the picture gate in the projector, and then delayed by an interval corresponding to the travel time of the film from the sound pick-up to the picture gate.

Magnetic Sound. The arrangement of the sound head in a magnetic projector is similar, except that there is a magnetic play-back head in contact with the stripe on the film, instead of an exciter lamp and photo-cell. As 16 mm. sound films are available in various forms, with stripes of different widths and in different positions, many 16 mm. sound projectors have interchangeable plug-in magnetic heads for different stripe standards.

The magnetic head may be for playback only, or for recording and playing back. In either case appropriate switching converts the circuit from one mode of operation to the other. Magnetic sound projectors with the playback head only are used for educational and similar purposes where only pre-recorded films are shown.

Many 16 mm. projectors are equipped for showing optical and magnetic sound film. In this case optical and magnetic sound heads are arranged around the sound drum (or there may be two sound drums, one for each system).

Magnetic 8 mm. sound projectors may be of two types. The more advanced design is similar to the 16 mm. sound projector, with the sound drum and sound head built right into the pro-

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

MAGNETIC SOUND PROJECTOR. In addition to the optical soundhead (or instead of it) 16 mm. magnetic projectors carry a magnetic soundhead. A, base plate. B, magnetic head. C, roller. D, sound drum. E, flywheel. The film path is shown dotted.

jector housing. The film then follows the prescribed path around the sound drum and associated rollers.

The second system, utilized with less expensive 8 mm. machines, consists of a straightforward silent projector, plus a sound unit as a separate housing, carrying the amplifier and magnetic sound head. For projecting sound films, the projector is simply placed on top of the sound unit and the film threaded—after the film gate and lower sprocket—over the sound drum of the sound unit. Usually projector and sound unit are designed to clamp together to form a rigid combination.

Sound Adaptors for Magnetic Stripe. 8 mm. projectors designed as two separate units are derived from the idea of the independent stripe adaptor. The latter in fact appeared first and in early versions consisted of magnetic sound head and drum mounted on an arm fixed to an amplifier base. The projector stands on top of this and is positioned so that the film can pass over the sound head after going through the film part of the projector. An alternative system is to have the sound head and drum mounted on a separate panel which can be fitted to existing silent projectors, provided there is room for it.

Tape Synchronization. The second system of providing magnetic sound for silent films is the use of a separate tape. While striped film is suitable both for sound films with a pre-recorded track and for sound recording by the amateur himself, dual film-tape systems are mainly used for amateur-recorded sound tracks.

There are a number of ways of linking the tape and film: loop synchronization, mechanical coupling, tape recorder and film projector, electrical coupling and pulse synchronization.

Loop Synchronization. This involves a tape coupler which links the tape recorder with the projector. The coupler attaches to the tape recorder and takes the tape between the sound head and take-up spool. The tape runs over a capstan which is linked mechanically to the projector drive. The tape further runs over a loop connected to a variable resistance. If the projector speed and the tape speed are accurately matched, the loop stays constant in length. If, however, the projector runs faster than the tape recorder, the coupler pulls the tape through faster than the recorder is supplying it and the loop shortens. This moves the loop arm, increasing the resistance (which is wired in series with the projector motor), thus slowing down the projector. If the projector runs more slowly, the lengthening of the loop similarly results in increased current being fed to the projector, thus speeding up.

The mechanical connection is usually made to the sprocket of the projector, and can be arranged to suit any combination of tape recorder and projector speed. The tape and film remain in synchronism, unless the tape slips or stretches when running. This can be avoided by using perforated tape with a sprocket capstan.

Some 8 mm. projectors have a tape coupler of

SOUND STRIPE CONVERTER SYSTEMS. Top: Some 8 mm. projectors are designed for conversion to striped film projection through a specially constructed amplifier unit. The projector stands on the latter and the film runs through the sound head built into the amplifier. Bottom: A sound head unit can also be interposed in the film path of some projectors between the supply spool and the picture gate.

LOOP SYNCHRONIZER FOR TAPE RECORDER AND PROJECTOR. Top: The synchronizer takes the tape from the recorder and runs it over a tape capstan linked to the projector drive. The system is electrically coupled to the projector motor. Bottom: Synchronizer elements. A, mechanical interlock with projector. B, tape. C, tape capstan. D, electrical coupling to projector. E, loop arm. F, variable resistor.

this kind built into the machine. The tape from the tape recorder then passes over the capstan and other rollers mounted on the projector; the control units are also built into the latter so that setting up is greatly simplified.

Mechanical Coupling. Correct synchronization of the tape and the film—subject again to tape stretch and creep—is also possible by driving the projector and the tape recorder by the same motor. There are several ways of doing this.

First, the projector and tape recorder can be separate units but linked together by a rigid or flexible shaft. Since the one motor drives both units, any slowing down of the film also means a slowing down of the tape and vice versa. The projector in this case is a fairly simple 8 mm. machine, and can be used by itself for silent films or with the associated tape recorder for sound. The two units must be set up appropriately—usually in line with each other—to provide a smooth coupling of the drives.

Secondly, a number of 8 mm. projectors incorporate a tape recorder in the housing. Here again one motor drives both units; the film transport and spools on the one side and the tape reels on the other. This system is widely used also for perforated tape and even for magnetic film (in other words 8 mm. or 16 mm. film coated with a magnetic oxide layer).

Electric Couplers. Completely electric tape couplers can attach to the tape recorder in much the same way as a loop synchronizer. Here, however, the coupler is not linked mechanically to the projector. Instead, the tape —running over a capstan—drives a motor which transmits electric pulses at frequencies depending on the running speed of the tape recorder. These pulses are fed to the projector and automatically adjust the speed of the latter if the tape recorder runs faster or slower than the projector.

Amplifiers. Most 16 mm. sound projectors—optical and magnetic—have the amplifier built into the projector housing. The same applies to 8 mm. stripe projectors. Sound converter systems for striped film have the amplifier in a separate unit which also contains the sound unit through which the film is threaded. Tape coupling systems need no separate amplifier, since this is already built into the tape recorder.

For home projection an amplifier with a 6-watt output is perfectly adequate. Units with 12 watts and even 25 watts output are employed for educational purposes and projection in large halls; commercial and motion picture amplifiers are more powerful still. On modern projectors the whole amplifier system is made fairly compact by the use of transistors.

SPECIAL PROJECTORS

Compact Models. For sale representatives, travellers, etc., there exist specially compact 8 mm. projectors which are easy to carry around and set up at a moment's notice for demonstrations and instruction. They usually have a back-projection screen built into a portable carrying case. The screen is intended for daylight viewing by small audiences and the projector may be mains operated or even battery powered. In the latter case it is completely independent of available current supplies. The screen image is necessarily small, usually less than a square foot.

Projectors of this kind are mostly silent, though a few sound models—for 8 mm. striped film also exist.

Cassette Loading and Loop Systems. For showing short films over and over again, display projectors use a continuous film loop. Here the beginning and the end of the film are spliced together, and the film is wound up on a special spool. This feeds the film from the centre of the spool through the projector, and winds it up again around the outside.

Such loop systems may hold up to 100 feet or

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

DIRECT TAPE COUPLING SYSTEM. The tape from the tape recorder passes in a large loop over a capstan and tension regulator built on to the projector (right), thus governing the speed of the latter. Precision synchronizing systems of this kind may use perforated magnetic tape.

more of film, giving—in the case of 8 mm. silent film—a projection time of around 8 minutes per cycle. Once the film is threaded up, the projector needs no further attention. Loop systems can be used with silent or sound films.

A special development of this idea is the cassette projector. Here the film, again with its ends spliced together, is contained in a plastic cassette with a built-in film gate and a loop of film carried through this gate. The whole cassette is simply clipped into the projector and engages the film transport. The projector then starts running and can repeat the film indefinitely. The film may be stopped at any point by simply removing the cassette; no other threading or unloading (or rewinding) is necessary.

Cassette systems with automatic loading exist mainly for 8 mm. silent film, and projectors for such cassettes are available both for home projection and for audio-visual use. The idea can also be applied to 8 mm. sound films, but loading in this case becomes a little more complex since the film must be led past a sound head as well. This may be done by having the film run out of the cassette in the form of a loose loop which is then threaded through the film path of the projector. Such a system is adaptable to automatic loading, in which case pressure rollers automatically push the film against the gate and sound head.

Juke Box Projectors. Automatic screening systems are also the basis of coin-operated sound projectors set up in restaurants, coffee bars and similar places in the same way as juke boxes. The equipment consists of a cine projector with the usual optical elements, but a modified layout (to permit automatic placement of the films) and a back projection screen plus the amplifier and loudspeaker. The films are contained in a magazine from which they are brought into position for projection by a push-button selector device. In one system the films are pre-threaded from a feed spool to a take-up spool. The selected spool pair is brought into the projection path and the film then pressed into contact with the gate and sound head by a movable arm carrying sprockets and pressure rollers. At the end of the film-run an automatic rewinding mechanism comes into operation. Other juke box projectors may use continuous film loops in a cassette or other arrangement linked with the magazine selector.

Analysis Projectors. Their purpose is to permit the analysis of a cine film frame by frame at any required speed. Accordingly the projection speed is adjustable from about one frame every 2 seconds to the normal projection speed of 16 or 24 frames per second. The speed range is continuous, and the projector has an independently running shutter to prevent flicker at the slower projection speeds. Speeds of five or six frames per second also enable normal films to be shown in slow motion.

Analysis projectors need specially efficient heat filtering as individual frames remain in the picture gate far longer than they do otherwise. The projector may also have a loop film cassette or spool, to enable short film lengths to be projected over and over again without re-threading—a necessary part of movement analysis.

The film transport usually runs forward as well as in reverse at all speeds.

Wide-Screen Projectors. A few 16 mm. projectors incorporate a variable gate aperture. This enables the film gate to be reduced in height, thus providing an increased aspect ratio similar to that customary with wide-screen motion pictures. To obtain the wide screen effect it is necessary to project on the wide screen with a short-focus lens. Usually the cutting off of the top and the bottom of the image leads to unpredictable losses in the picture itself, unless the film was shot with such a restriction of the format in mind. The greater image enlargement is necessarily associated with a lower image quality.

An anamorphic attachment in front of the projector lens spreads out the normal frame into a wide picture. This of course is only possible when the film was shot in a camera fitted with a similar anamorphic attachment to compress the image sideways on the film.

Apart from anamorphic lenses, two other wide screen projection systems are used in commercial motion picture cinemas. The first utilizes a wider than normal film—65 or 70 mm. instead of the standard 35 mm.—with a long

horizontal image format. This gives the increased aspect ratio, but needs of course special projectors for this film size. The second way is to have three projectors linked up to throw three connecting images side by side on an extra-wide curved screen. The films are taken with a cross-coupled triple camera and projected in synchronism. The main technical problem is the hiding of the joins between the three images, various optical devices have been employed for this purpose. L.A.M.

PROJECTOR (STILL)

From the beginning of photography itself the projection of transparent images with the magic lantern was a popular form of entertainment. Fairly soon still projection became an important adjunct to lectures, both scientific and popular. Today the still projector is an important tool of audio visual presentations as well as being highly popular for private entertainment. Many photographers produce an appreciable proportion of their colour pictures in the form of transparencies for projection.

Still projectors can be divided broadly into slide projectors for individual transparencies in one of several current sizes, film strip projectors for still pictures assembled in the form of a strip of film, and special types such as overhead projectors and episcopes for opaque pictures.

SLIDE PROJECTORS

Projectors for slides can be grouped both according to the slide format they take and according to the degree of automation in loading and slide changing. The most popular slide format is 2 × 2 ins. (5 × 5 cm.) which may accommodate a range of picture formats from the sub miniature 10 × 14 mm. up to the $1\frac{1}{2} \times 1\frac{1}{2}$ ins. (40 × 40 mm.) super slide. However, sub-miniature slides of 3 × 3 cm., as well as larger formats of $2\frac{3}{4} \times 2\frac{3}{4}$ ins. (7 × 7 cm.) and $3\frac{1}{4} \times 3\frac{1}{4}$ ins. (8·5 × 8·5 cm.) to $3\frac{1}{4} \times 4$ ins. (8·5 × 10 cm.) are also used.

Handling differences range from manual loading of individual slides to magazine operation with manual slide change or remote or automatic control.

Optical Layout. The complete optical system of a slide projector consists of a lamp with reflector, a set of condensers, the slide stage and the projection lens. These elements are arranged along the optical axis of the projector, so that the lamp and the condenser system evenly illuminates the slide in the stage, which the lens then projects on to the screen.

For the greatest light efficiency the optical system of the lighting part should be designed for one particular image size. The use of larger slides leads to uneven illumination, while with smaller transparencies part of the light is lost through being masked off by the slide frame.

If a projector is designed for several transparency formats it is usually desirable to have at least one interchangeable condenser in the condenser set to concentrate the light on a larger or smaller image area as required. In practice this is used for multi size projectors, for example when projecting standard 24 × 36 mm. and half-frame 18 × 24 mm. transparencies. Some projectors also have interchangeable condensers for 24 × 36 mm. and 40 × 40 mm. super slide formats. Where,

CONSTRUCTION OF STILL PROJECTORS. Top: Miniature film strip and slide projector of older design. A, condenser system. B, ventilation baffles of lamp house (powerful projectors incorporate a blower unit). C, pre-focus lamp. D, pressure plates for film strips. E, film spools (the whole film strip unit is usually interchangeable against a miniature slide carrier). F, lens in helical mount. G, base. H, tilting adjustment. Bottom: Standard $3\frac{1}{4} \times 3\frac{1}{4}$ ins. projection lantern. I, lamp house. J, lamp reflector. K, projection lamp in adjustable lamp holder. L, tilting clamp. M, base. N, condenser system. O, slide carrier. P, square bellows. Q, lens. R, extension rails.

however mixed slide sets are likely to be projected, it is an acceptable compromise to have a condenser system which illuminates the largest format to be used and put up with the waste of light with the smaller sizes. Most miniature slide projectors therefore cover transparencies up to the super-slide area.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Usually the role of the condenser system is to focus an image of the light source into the back of the projection lens. There is thus a cone of light between the front condenser and the lens. The slide stage is positioned so that the transparency format just fills this cone. With multi-size projectors it is also possible to obtain the maximum light efficiency for different slide sizes, by placing them in different positions in this light cone. Thus at least one dual size projector positions $2\frac{3}{4} \times 3\frac{3}{4}$ ins. slides in a plane comparatively near the front condenser in the widest diameter of the light cone, and 2×2 ins, miniature slides in a second plane further forward where the cone is narrower. When changing over between the two slide sizes (or when projecting mixed slides) the lens must of course be refocused to preserve the sharpness of the image on the screen.

A few twin projector designs also exist. There the light from a single lamp is directed via mirrors into two optical paths (or two lamps may be used). So there really are two projectors side by side built into a single unit. A single magazine may feed slides alternately into the two paths, or two magazines may be fitted each feeding its own optical system.

Such projectors provide a smooth slide transition, since at the point of change the images of both transparencies appear on the screen simultaneously, with one fading away as the other gets more brilliant. This is achieved by linked shutters or iris diaphragms which gradually open in front of one lens while closing in front of the other. Such linked shutters are also available as separate accessories for fitting over the lenses of two projectors arranged side by side to project on to the same screen. The same dissolve-type transition then becomes possible.

Twin projectors may also be used for projecting stereo slides. In that case the two projection lenses are fitted with polarizing filters oriented at right angles to each other.

Single Slide Carriers. There are three main types. The most usual is the horizontal push-pull type, which consists of a double sided carrier sliding between runners. One side is pulled out and a slide is loaded into it. Then the carrier is pushed back so that the slide is in line with the optical axis of the projector. Another slide is loaded into the empty side and when this is being projected the previous one is changed, the carrier being pushed and pulled alternately from side to side.

Another form of slide changer also works horizontally, but instead of the slides being loaded from alternate sides, they are loaded on one side and ejected from the other. They are referred to as ejection carriers. The screen is blacked out while the change takes place.

SLIDE CHANGERS. Top: *Magazine changer taking slides preloaded into magazines. The slides are fed manually from the magazine into the gate and returned again when the magazine advances to the next compartment. This type of attachment can be fitted to most non-magazine projectors; built-in magazine systems work fundamentally in the same way.* Bottom: *The push-pull slide carrier slides from side to side. It carries two slides which are inserted into and withdrawn from the carrier from alternate sides.*

The third type is the vertical slide carrier. The slide is inserted into a slot from the top and pushed down a chute until it is level with the top of the carrier, when it is projected. When the next slide is loaded the previous one is pushed to the bottom of the slot and removed from the side. The slides are held in position by springs which allow slides of varying thickness to be used.

Slide changing with both ejection carriers and vertical chute type carriers can be mechanized and even motorized. For this purpose the slides are loaded into a container in a stack. A motor or a manual control feeds them through the slide stage one by one, restacking them in the original order in a second tray or container at the other side. To work reliably, the slides must not be too thin (e.g. in cardboard frames less than 0·05 ins. thick) otherwise they may be fed in in twos (so that a double image appears on the screen) or jam in the carrier.

Manual Magazine Changers. Although there are considerable differences in design, these carriers all work on the same principle. The slides are loaded into a slotted box, holding from 30 to 70 slides according to make. This box is normally called a magazine in Europe, and a slide tray in the United States.

The magazine is then placed in a channel or tunnel parallel with the optical axis and usually

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

PROJECTOR WITH SLIDE CHUTE. Top: *The slides pass down a vertical chute behind the lens. Each succeeding slide pushes out the previous one which may collect in a stack at the bottom of the projector.* Bottom: *On some machines a slide tray may be fitted on top of the chute and the slides fed through semi-automatically or by a motor drive.*

on the right hand side. Slides are shown by pushing in a lever or sliding bar and withdrawn by pulling the same lever, which returns the slide to its original position in the magazine. Sometimes the magazine jumps forward one slot automatically at this stage, sometimes a small knob at the end of the lever is turned one "click" (the other end has a ratchet which engages on tooth shaped slots on the magazine). A shutter masks off the light from the lamp while the change takes place. It takes only seconds to fit extra magazines, so that it is possible to show any number of slides without any appreciable lapse of time in between.

It is possible to fit separate magazine carriers to some types of projectors supplied originally with single slide changers. These work on the same principle as those built-in.

Editing. In a projector with single slide change the slides are accessible individually. So if one slide happens to be inserted in the carrier the wrong way up or the wrong way round, it can be removed again and turned round. In a magazine projector the slides in the magazine are not accessible unless the whole magazine is removed. Even where the magazine runs along an open track next to the projector, the opening through which the slides are removed faces the slide stage and no removal from above is usually possible.

Some projectors incorporate a so-called editing feature. Here the slide can be removed from the projector when it is in the slide stage. A lever or other control then raises the slide vertically being projected through a slot in the top of the projector housing.

Motorized Slide Change. On automatic slide projectors the transport of the slide from the magazine into the slide stage and back again, and also the magazine shift to the next slide are effected by a separate motor. This comes into action on pressing a switch on the projector (or at the end of a remote control cable—see below) and then goes through one slide changing cycle. Normally this advances the magazine step by step; on some projectors the motor can also go into reverse and go through the sequence backwards. This means that any slide just shown can be repeated by pressing the reverse transport button.

A few motorized projectors provide both manual and automatic slide changing, but usually the slides are brought into the optical path of the projector only by the operation of the motor. The magazine may be removed completely or shifted to a different position by

PRINCIPAL ELEMENTS OF MODERN AUTOMATIC SLIDE PROJECTOR. disengaging the motor drive, provided the changing cycle has stopped with the slide stage empty. Often this is achieved automatically on switching the motor off, when a shutter may close the slide stage to darken the screen.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The motorized slide change usually works with a push-pull arm which slides the transparency from the magazine into the optical path. Some projectors use alternative systems, such as a gripping device that lifts the slide out of its magazine compartment into the projection system, or a magnet that pulls the slide (fitted with a metal edge) into the projector.

Magazine projectors, whether manually operated or motorized, will only work with slides within certain dimensional tolerances. The maximum outside size for 2 × 2 ins. slides is 50·8 mm. Slides bigger than that or unevenly mounted ones with protruding bits of binding tape or not fully closed metal tabs (in the case of metal frames) may get jammed. The range of thicknesses accepted is usually between 0·02 and 0·125 ins.; thinner transparencies (in card mounts) may buckle and jam the projector.

If a motorized projector jams the slide change mechanism may have to be disengaged by turning the motor (or a milled wheel fitted somewhere—usually below the housing) to bring the slide changing arm fully out of the projector.

Remote Control. The slide change can on motorized projectors also be operated by remote control. In this case a remote control cable is plugged into an outlet on the projector, and buttons on the remote unit at the end of the cable then operate the slide change. Frequently there is also remote focusing provision (see below).

In some cases the unit has a built-in light pointer. Here a small lamp projects an arrowhead or similar symbol. This is sufficiently bright to be visible against the projected transparency when the light pointer is directed at the screen, and serves for drawing attention to specific image details.

Some projectors have a mechanical remote control linkage consisting of a Bowden cable with a plunger at the end, Pressing the plunger —like pressing a cable release—changes the slide and advances the slide magazine. This unit may also incorporate remote focusing.

With a remote control unit the projectionist can sit in the midst of the audience and operate the projector from there. The remote control cable may be 6 to 10 feet long.

For slide shows and lectures in large halls this is however not usually adequate, especially where the lecturer himself operates the projector. Cableless remote control units are therefore also available. These can operate either by ultrasonic sound signals or by a radio link.

For ultrasonic operation the slide changing signal is given by a small whistle or other generator producing an inaudible sound impulse of a frequency above 20,000 cycles per second. A sensitive microphone in a receiver unit next to the projector picks up this signal and closes a relay which then operates the slide change in the usual way. Signals of two different frequencies may be used for remote slide changing and focusing.

Radio links use a small battery-operated transmitter, sometimes no larger than a pack of cigarettes, and a battery or mains operated receiver. Here again the receiver actuates a slide changing relay in response to the wireless signal. In some countries (including Britain) the use of radio links of this kind requires licencing by the postal authorities.

The range of ultrasonic slide change systems is about 50 feet; radio control units can operate over 20 times this range—fully adequate even in very large halls.

Magazine Types. The normal long magazine, a metal or plastic container with compartments for the individual slides, exists in a number of forms. These fit projectors of various makes, and are provided with openings for the slide changing mechanism to push the slide into the picture stage of the projector. The compartments are numbered and the magazine also

MULTI-MAGAZINE TYPES. Some projectors are suitable for different magazine types. These may include long slide magazines of various capacities (for example from 30 to 50 or more slides) and drum type magazines for continuous projection and display.

carries a ratchet or other device to engage the transport mechanism. Usually, the magazines take 30 or 36 slides, though special long magazines for 50 or even 70 slides exist. The orientation of the slides in the magazine depends on the type of changing mechanism.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Since individual projector manufacturers develop their own magazine designs, there is comparatively little standardization. A few groups of manufacturers, especially in Germany, have, however, agreed on the use of a uniform design to fit a number of different projector models.

As an alternative to the usual long magazine, circular slide magazines are also used. These are drum shaped, and may hold 80 to 120 slides in compartments radiating outwards from the centre. There are three types, used with projectors specially designed for them.

Vertically mounted drum magazines are fitted to a horizontal axis alongside the projector, and the slides fed sideways into the projector gate. With this design it is possible to have projectors taking long and drum type magazines interchangeably.

Removable horizontal drum magazines sit on top of the projector, rather like a gramophone disc, and the slides are fed downwards by a gravity system. A special retaining spring inside the magazine prevents the slides from falling out when the magazine is lifted off the projector.

Fixed drum magazines are permanently built into the projector and loaded while on the latter. This type of projector is primarily intended for continuous display and advertising use. The layout is normally horizontal.

Continuous Projection. The projection sequence can be made fully automatic with a motorized slide projector, so that the latter projects one slide after another without attention from an operator. For this purpose some projectors have a built-in time switch which actuates the slide changing mechanism at pre-set intervals—usually from 3 to 60 seconds. Similar timer units are also available separately and can be connected to the projector through the remote control outlet.

If the projector has a drum type magazine, the time switch can repeat a slide series indefinitely, since the drum magazine can go round and round. With projectors having a long magazine some means of reversing the magazine travel is necessary. Special units are available which do this, and may work on two systems.

In one of the projector projects the odd numbered slides in a magazine while the latter goes forward, and then reverses to project the even numbered slides. When the magazine reaches the starting point it reverses once more and repeats the cycle. The magazines must be loaded accordingly.

The other and simpler continuous projection method is to run through the magazine, compartment by compartment, and reverse at the end of the run so that the slide series is then projected in backward order.

Random Selection. On some projectors it is possible to select any given slide in a magazine for projection, irrespective of the order in which the slides are loaded. This method works best with drum type magazines. A multi-channel remote control selector chooses any given slide number by means of digital buttons, a telephone type dial or similar device. This sets the transport motor going to rotate the slide magazine and stops it at the selected compartment number to project the slide in it. The magazine only rotates in one direction, and the slide selection may take from 2 to 8 seconds, according to how near the required slide is to the gate before pressing the selector buttons.

Focusing. The basic focusing system of the projector lens usually consists of a helical mount by which the lens is screwed in and out. This serves for both coarse and fine focusing.

During projection of card mounted transparencies re-focusing is, however, often necessary owing to the popping of the transparencies under the warmth of the slide stage. Where slides of different thickness are projected in a set, re-focusing is also necessary because the various slides may not have their image plane in the same position.

Projectors often have some sort of centring device—usually in the form of V guides—to locate all slides in the same plane. This, however, works efficiently only all slides are uniformly mounted with the front and rear halves of a transparency frame of the same thickness.

Slide projectors with remote control systems may incorporate remote focusing of the lens to take care of these variations in image position. The remote focusing may be driven by a separate motor, or the fan motor may be used. There are two basic modes of operation.

In the simpler system, invariably used where the fan motor drives the focusing, an eccentric gearing moves the lens forward and backwards through a short distance. On the screen the image—once reoughly focused with the helical mount—moves through a cycle of sharpness, unsharpness and sharpness as the remote focusing button is depressed. To find the sharpest point takes a little skill, since the motor must be immediately stopped. Otherwise the focusing cycle runs through the position of maximum unsharpness before returning to sharpness again.

The other mode of operation works with a reversible motor controlled by two buttons on the remote unit, These run the lens forward and back, usually through the full range of its travel. It is thus possible to reverse the motor instantly if the point of maximum sharpness has been passed, and the motor may even be used for coarse focusing.

Slide projectors with fully automatic focusing also exist. Here a photo-electric and optical sensing system operates the focusing motor via a

relay whenever the image plane of the transparency shifts forward or back. The first slide must be focused accurately by hand; after that the automatic system compensates for any movements or changes in sharpness.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Illumination. Apart from one or two exceptions, the illuminant is a Class A projector lamp with a compact tungsten filament. The lamp usually burns vertically, base down and may vary from 75 to 1,000 watts.

Two or sometimes three condensers are placed in front of the lamp, and they produce a concentrated beam which should just cover the corners of the transparency. Much depends on the design and quality of the condensers as a poor condenser system will lose a great deal of light.

Most projectors employ an asperic rear condenser, placed close to the lamp, with a biconvex front (or field) condenser a short distance in front, just behind the transparency. An aspheric condenser helps to reduce spherical aberration, so that more light can be made to enter the front condenser. The closer the condenser and the greater its diameter the bigger is the cone of light from the lamp filament so adding to the brilliance of the image. In better-class projectors the condensers are coated to reduce the amount of light lost by reflection.

A concave mirror is generally placed behind the lamp to utilize light travelling towards the back of the projector which would otherwise be wasted. The mirror is positioned so that the lamp filament coincides with its centre of curvature, thereby producing a virtual image of the lamp filament in almost the same place as the filament itself. The filament and its reflection do not coincide exactly but come slightly to one side. If the reflected image impinged on the filament of the lamp, this would cause it to overheat and reduce the life of the lamp.

Where the filament consists of several turns spread out in a plane, the ideal positioning of the reflector projects the filament image between the turns of the filament itself. This can be checked by covering the projector lens with a piece of ground glass or translucent paper; the direct image of the filament and its reflected image should just interlace. With compact source projectors the two images of the filament may have to be placed side by side.

Lamp Power and Voltage. The wattage of the lamp is another important factor governing the strength of illumination. Taken on its own, however, it can prove misleading. If everything else were equal, then a high wattage lamp would give a brighter light than one of low wattage, though the difference would not be by any means proportional.

The current flowing through the lamp, i.e. the amperage (watts divided by volts) is, however, equally important. The filament of a high-voltage lamp is thinner and longer than that of a low-voltage lamp of the same wattage. The luminous intensity of the glowing filament increases considerably when the filament consists of a small coil of thicker wire, so that for a given wattage, the light output of a low-voltage lamp is greater.

For this reason low voltage projectors have become popular. Here the filament can become very compact indeed, being sometimes made of a folded ribbon type wire. A 100 watt lamp running at 12 volts can produce light equal in intensity to a 250 watt lamp operating at 200 to 250 volts. In addition the low voltage lamp burns at a higher colour temperature so that it appears to the eye comparable to the light from a 300 watt mains lamp.

As the filament is so small it becomes practical to use a smaller reflector and even to build this into the lamp itself. Such a proximity reflector lamp has the advantage that the mirror is permanently adjusted during manufacture.

Quartz-iodine lamps have also been used in miniature slide projectors. Here the light source is smaller still, and this lamp type has the further advantage of constant light intensity and colour temperature throughout its life. The luminous efficiency of a low voltage quartz-iodine lamp is higher still than of a normal low-voltage tungsten lamp.

The actual lamp power desirable for projection depends on the intended use of the projector. Inexpensive home projectors for showing miniature slides on a small screen at close quarters usually have a 150 watt mains voltage lamp. They are inexpensive mainly because with this lamp power no force ventilation is normally required. That also makes the projector more compact.

Low power projectors need to be operated in complete darkness, especially when projecting colour transparencies. A short distance between projector and screen is advisable, and the transparencies should be kept as thin as possible consistent with good quality. Generally speaking a picture size of 30 × 40 ins. or 40 × 50 ins. is about the largest that projectors of this class will give with reasonably good illumination.

For more comfortable projection a 250 to 300 watt mains voltage lamp (or 100 watt low voltage) is desirable. For large rooms a projector with a 500 watt lamp (or 150 watt low voltage) may be preferable. For really large halls big projectors with 750 watt or more powerful lamps may be needed.

When used with colour slides under good conditions a screen size of 4 × 6 feet is usually well within the limits of a medium power projector and slightly larger picture can often be projected satisfactorily.

With black and white transparencies quite good results can be obtained in classrooms having only partial black-out.

Two other factors influence the image brightness. One is the aperture of the lens. Provided that the optical system of the projector has been carefully designed, so that the image of the

lamp filament formed by the condenser just fills the rear element of the lens, more light will come from the lens than from the aperture. But a wide-aperture lens, without appropriate illumination does not necessarily give more light than a smaller aperture lens.

When projecting mixed slide sets containing very dense and very thin transparencies it is often useful to be able to vary the strength of the illumination. The obvious way, regulating the voltage fed to the lamp, is not suitable for projection of colour pictures because it also changes the colour temperature. Some projectors, however, are, or can be, fitted with an adjustable iris diaphragm over the lens. This can be closed down or opened up to reduce the light for overexposed colour transparencies and to boost it for the denser slides.

In one or two projectors this iris diaphragm is controlled automatically from a photo cell system. This receives the light reflected from the projection screen and responds to the light intensity, adjusting the iris accordingly.

Heat Filter. The second factor is the thickness of the heat filter. This is a special glass which is inserted in the optical system to protect the transparency from the heat of the lamp, at the same time transmitting a high proportion of the light. It is usually placed between the condensers. Most heat filters in 300-watt projectors are 3 mm. thick. This transmits some 85 per cent of the light but only 8·5 per cent of the heat.

In 500 watt and more powerful models, two or even three heat filter glasses may be employed, making a total thickness of perhaps 9 mm. This tends to offset the extra illumination given by the bulb.

Cooling. Unless a projector is designed so that a great proportion of the heat generated by the lamp can escape, there is a danger that the bulb will blister and give an unduly short life. Even more serious, the transparency may be spoilt, and some of the optical components damaged.

The main problem is to provide adequate cooling without excessive light leakage. Too much light escaping from the projector reduces the effectiveness of the black-out and dulls the brilliance of the screen image.

Sometimes light can escape in certain directions and prove disconcerting to people sitting in certain parts of the room.

With low power projectors using lamps up to 150 watts at mains voltage the cooling afforded by the convection airstream is usually adequate. The design of the lamp house, must allow cool air to enter and the hot air to leave freely. More powerful projectors for the larger slide sizes are sometimes also convection cooled, since there the lamp house is big enough to dissipate the heat adequately.

Miniature projectors with lamps of 250 watts or over almost always required forced cooling.

Various types of motor driven fan are employed for this purpose. Some use normal fan blades rotating at high speed, some are turbine fans shaped like paddle wheels. Other machines use impellers and cylindrical cooling devices with lateral slots in them.

Some of the stream of cool air from the fan is normally used to help cool the transparency. In some cases the air is forced through a duct with a vent just underneath the slide carrier. In an endeavour to prevent popping several magazine type projectors direct the warm air coming from the lamp towards the magazine in order to warm the slides before they are projected.

The warmth of the projector to the touch is not a good guide to the efficiency of cooling. In fact, a cool lamphouse indicates good thermal insulation and nothing more. A hot lamphouse means that the heat at least is getting away somewhere.

As far as the transparency itself is concerned, it is the temperature in the slide stage which counts. This can be measured in various ways, ideally with a thermometer slide incorporating a very thin bi-metal strip with an attached pointer. This is bound up between two thin glass plates to produce a slide of the normal thickness. As the strip inside the slide gets warm, it expands and moves the pointer over a graduated scale indicating temperatures. An efficiently cooled projector should not have a gate temperature exceeding about 40°C.

2 × 2 ins. Projectors. This is the most popular size. Most of them are suitable not only for 24 × 36 mm. transparencies but also for larger ones up to superslide size (4 × 4 cm.) in 2 × 2 ins. mounts. Some models have movable condensers which can be altered to give coverage for all sizes with maximum light concentration. Sometimes extra condensers are available for 4 × 4 cm. slides, and these may add to the price. Users of this size of slide should satisfy themselves that the projector they purchase will give adequate coverage.

The lenses fitted as standard are usually 85 mm. or 100 mm. The shorter of these will give a 3 × 2 foot picture from a 24 × 36 mm. slide at about 8 feet from the screen. With a 10 mm. lens the same image size is obtained at about 9½ feet. These lenses are therefore suitable for home projection in the majority of living-rooms, though longer lenses are sometimes required if the rooms are larger than average.

When used with half-frame (18 × 24 mm.) transparencies—and even more so with sub miniature transparencies mounted in 2 × 2 ins. slide frames—these projectors need a shorter focus lens. The usual focal length for half-frame slides is 50 to 65 mm., and 35 to 40 mm. with sub-miniature transparencies.

Variable focus projection lenses are sometimes used, for example with a focal length range from 85 to 120 mm. These provide a range of screen image sizes from a given projection distance, or permit a variation of the

CC-0. Aligarh Muslim University Digital Preservation Foundation, Chandigarh

projection distance for a given screen image size. Variable focus lenses are particularly useful for multi size projectors, since they can keep the image size on the screen constant when projecting smaller and larger transparencies in mixed sets.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

2¾ × 2¾ ins. Projectors. These are suitable for 1⅝ × 2¼ ins. and 2¼ × 2¼ ins. transparencies made on size 120 roll film. They are also useful for technical lectures where it is necessary to show fine detail which cannot always be obtained on smaller slides. The 3¼ × 3¼ ins. slide size was at one time used for this type of subject but it is less convenient for the production of colour slides.

The standard focal length of lens for this size of projector is 135 mm. to 150 mm. (5½ to 6 ins.) The picture size is 3 feet square at roughly 8 feet and 10 feet from the screen respecitvely.

In specifications 2¾ × 2¾ ins. projectors are fairly similar to the 2 × 2 ins. models, being largely scaled-up versions. Thus there are models with manual slide change, magazine operation, remote control, etc. The range of models on the market is however rather more limited.

Lamp power usually ranges from 300 to 750 watts, and virtually no low power projectors of this kind are made. This is because a 150 watt lamp is not adequate to illuminate the full area of the transparency and still give a reasonably bright picture.

Converting to 2 × 2 ins. It is usually possible to project 2 × 2 ins. slides in a 2¾ × 2¾ ins. projector. This involves either mounting the 2 × 2 ins. slides in adaptors inserted in the slide carriers or the fitting of new carriers. Usually it is desirable to change to a shorter focus lens to increase the picture size from the smaller format without having to move the projector farther away from the screen. In certain machines the condenser can also be adjusted to concentrate the light over the smaller area.

Multi-size Projectors. A number of universal slide projectors can be used with both 2 × 2 ins. and 2¾ × 2¾ ins. slides. Changing over from one slide format to the other is fairly quick, and in at least one outfit both sizes can be projected more or less simultaneously. There are two main types of design: multi-magazine and interchangeable track.

The multi-magazine projector has a 2¾ × 2¾ ins. and a 2 × 2 ins. magazine running along the two sides of the optical system. There are two slide changing mechanisms, to move the slides into the optical path from alternate sides. Each slide format has its own picture stage, set at different distances from the condenser system to ensure full illumination of the transparency. The lens needs re-focusing when a small slide is projected after a large one, or vice versa. With a projection zoom lens, adjustment of the focal lengths can keep the image size the same on the screen.

DUAL SLIDE PROJECTORS. Top: Universal projector with two magazine tracks on each side of the optical system. A, miniature slide magazine. B, miniature magazine track. C, slide changer arm. D, large-size magazine with slides. E, large-size magazine track. Bottom: Dual projector with interchangeable magazine track. F, large magazine with slides. G, track for large magazine. H, miniature slide magazine. J, miniature magazine track, fits into larger track.

The interchangeable track system uses a single magazine track for the larger slide magazines. When the smaller magazine is to be used, a second track is inserted in the main one, to locate the alternative size in the correct position. The slide change mechanism is the same for both formats, and special guides are used to locate the larger and the smaller slide accurately in the film gate.

Since only one magazine can be used at a time, there is no possibility of mixing large and small slides.

Large Size Slide Projectors. Projectors for 3¼ × 3¼ and 3¼ × 4 ins. slides are very much more bulky and exist practically only with single slide changers. The range of models available is limited, since the demand is comparatively small. Many institutions are, however, compelled to continue using this size of projector as they have large numbers of 3¼ × 3¼ ins.

slides. Colour transparencies in $2\frac{1}{2} \times 3\frac{1}{2}$ ins. and larger formats are also projected with this slide size.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The projector usually has a big lamp house which is often spacious enough not to require forced cooling even with a 500 watt lamp. The focusing movement generally consists of a square folding bellows connecting the slide carrier to the lens panel which moves along two extending rods. The focal length of the lens is normally 8 or 10 ins., so that a fairly long bellows is needed.

Really powerful large size projectors—for example for cinema projection—may use a 1,000 watt tungsten lamp or a carbon or xenon arc.

Converting to Smaller Sizes. It is usually possible to convert a $3\frac{1}{4} \times 3\frac{1}{4}$ ins. projector to show $2\frac{3}{4} \times 2\frac{3}{4}$ ins. and 2×2 ins. slides by fitting alternative slide carriers. Some light is lost when showing $2\frac{3}{4} \times 2\frac{3}{4}$ ins. slides but results are generally satisfactory. For 2×2 ins. slides, however—especially 24×36 mm. or smaller transparencies—the loss of light is more serious, unless the condenser system can be modified. It is also necessary to replace the lens by one of much shorter focal length, otherwise, over a normal distance, the picture size will be too small.

When 2×2 ins. or other small slides are used in a large projector there is of course no possibility of automatic slide changing.

Sub-miniature Projectors. Transparencies produced with sub-miniature cameras in the 8×11 mm., 10×14 mm. or 12×17 mm. format can be mounted in 2×2 ins. slide frames. There are also sub-miniature projectors which takes these transparencies in 3×3 cm. frames. There are not very many on the market, and they are mostly scaled down versions of the normal miniature projector. They include models with manual or magazine slide changing as well as automatic versions. The slide magazine is similarly scaled down to take 30 or more 3×3 cm. slides.

Usually sub-miniature projectors have a low voltage lamp of 100 watts and a 35 or 40 mm. projection lens. Often a small table top screen is included in the outfit for close range projection at low magnifications. This is suitable for daylight projection as well, since the image brilliance on the screen is adequate not to be swamped by the prevailing light.

Stereo Projectors. These consist of two optical systems set up side by side. Usually there are two lamps, but sometimes one lamp only is used, the light being split to illuminate each of the frames. A polarizing filter is placed immediately in front or behind the transparencies, each filter being set at 90° to the other.

The images are projected on to an aluminized or silver screen (normal white or beaded screens are unsuitable) and the lenses adjusted to bring the images into register. Polarizing spectacles are worn by the viewer with the filters arranged at the same angle as the polarizers in the projector so that the viewer sees only one image with each eye.

A special stereo mounting jig may be used to mount the slides in correct alignment. This reduces the need for adjusting the lenses, and saves time and eye strain.

FILM STRIP PROJECTORS

The continuous film length of a film strip is projected in a film strip projector or a slide projector which can be fitted with a film strip carrier. This is usually the case only in slide projectors with a manual slide changing system, where the whole slide changer is removable and replaced by the film strip carrier.

Film Strip Carriers. The most common and the cheapest form of film strip carrier is the spool type. The film is wound from one spool to another across the film gate. Usually the film

OPTICAL LAYOUT OF FILMSTRIP PROJECTORS. Top: *Low-price film strip projector. This generally uses a low-voltage, compact source, filament lamp of the motor car head-lamp type, and is intended primarily for home use where a high light output is unnecessary.* Bottom: *Precision film strip projector for home and lecture hall use. It utilizes a high-power projection lamp, improved optical system, and incorporates at least a heat filter (often also a fan for forced cooling) to protect the transparencies. In both cases the components are* A, *lamp* B, *double condenser;* C, *film strip;* D, *projection lens;* E, *lamp reflector;* F, *heat filter;* G, *front condenser (may be aspheric).*

is held flat by two pieces of glass held together by a spring. The projectionist must watch the screen as the film is wound to see when to stop winding. In some cases the glasses must be separated as the film is turned on. In others, the glasses are fixed close enough to keep the film flat, while allowing it to travel freely.

A more elaborate form of carrier transports the film by means of a sprocket wheel which engages the perforations of the film. They normally advance the film four sprocket holes with one turn, that being the number of sprocket holes in a single (half) frame (18 × 24 mm.) Double frame (24 × 36 mm.) transparencies require two turns.

Linked with the sprocket wheel is a cam mechanism which separates the pressure glasses as the film is wound.

Single frame film strips are invariably shown with the film running vertically. Most, but not all, double frame strips are wound horizontally. For this reason, on a general purpose projector the carrier can be rotated at least through 90°. Carriers suitable for double frame strips can usually be masked down for single frames.

Automatic Film Strip Projectors. Some film strip projectors incorporate an automatic film transport which advances the film by one frame on pressing a button. This may be operated via a remote control cable. The film transport may go forward or backwards, but no separate focusing by remote control is usually necessary since the film is flat between the glasses of the carrier. Automatic transport systems are usually designed for film strips where all the images are of the same size and orientation, to avoid the need for manual rotation of the whole carrier.

Film strip projectors intended for display purposes may have a built-in timer (like display slide projectors). For continuous projection loop systems, with the ends of the film strip spliced together, are used.

Random selector devices are also available for film strip projectors. Since a film strip has a very much larger capacity (up to several hundred transparencies) than a slide magazine, the selector devices are accordingly more complex. They run the film strip through the picture stage at high speed until the required image is nearly reached, then they automatically slow down and at the appropriate point a locating pin accurately positions the image in the projector gate.

Like slide projectors, film strip projectors are also available with built-in tape recorders or gramophone turntables for combined sound and picture presentation (see below).

SOUND STILL PROJECTION

A slide show even at home is usually accompanied by some sort of running commentary for the benefit of the audience. Since tape recorders can record such commentary or even lectures, the idea soon arose of using a tape recorder to control the projector. In this way it is possible to organize a combined sound slide show, which virtually runs itself.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Equipment-wise there are three main possibilities: (1) normal automatic magazine slide projectors in conjunction with a tape coupler and tape recorder, (2) combined projectors with a built-in tape recorder; (3) with sound tracks recorded on the slide itself. Corresponding provisions exist for film strip projectors. Such specialized equipment is produced for a variety of audio visual training purposes.

Tape Synchronization. Where a tape recorder operates the slide changing mechanism of a projector, it does so with the aid of signals on the tape. These are inserted in suitable spots within the commentary or other background effects, where a slide has to be changed. There are various systems of doing this, working either with direct electrical contacts or with recorded signals.

Contact Synchronization. This is the older and also more cumbersome method. One procedure is to stick short strips of metal foil to the back of the tape or to splice it into the tape at the appropriate points. During playback the tape runs over a tape synchronizer attached to the recorder. There the tape itself touches a pair of contacts connected to the remote control system of the projector. When the strip of metal foil runs over the contacts, it closes the remote control circuit and the projector automatically changes the slide.

In another system the tape runs between two contacts bearing on opposite sides of the tape. At the required points narrow strips are trimmed out of the centre of the tape, so that there the two metal contacts touch and close the slide changing circuit.

Both these methods have the drawback that the tape is permanently marked, and can thus be used only for the particular slide show for which it has been prepared.

Cueing Signals. The more elegant and modern way is to record slide changing signals electronically on the tape itself. The signal may be an ultra-high frequency one, recorded on the same track as the commentary or lecture, but inaudible during playback through being filtered out. During the projection the tape here runs over a pick up head of the tape synchronizer, and this amplifies the signal, to actuate a relay which closes the slide changing circuit.

Alternatively a cueing signal can be recorded on the second track of a twin track recorder, so that it does not interfere with the commentary at all. Such a signal can be of a normal frequency (for example 1,000 cycles) and it can be erased and re-positioned at will without interfering with the sound effects.

Some tape recorders have a special cueing head built in, so that no separate tape synchronizer is required. In this case a control on the tape recorder records the impulse on the

cueing track, and the projector is connected directly to the tape recorder.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

Where a film strip projector is fitted with a remote control film transport system, this can also be actuated by cueing impulses from a tape recorder.

Combined Tape Projectors. Certain slide and film strip projectors designed especially for audio visual purposes have a tape recorder built in. In principle this is no different from the combination of a separate tape recorder, tape synchronizer or coupler and projector. When built into one unit it is however more compact and may even include its own projection screen for daylight table-top projection.

Film strip sound projectors sometimes work with gramophone records. Here the signal is an inaudible one, recorded on the disc together with the sound effects and commentary.This arrangement is practical only with film strips, since the sound, once recorded, is permanently keyed to a particular picture series. Since the film strip is also a more or less unchangeable picture sequence, this is a handy combination for mass-produced educational lectures, etc. which are to be widely distributed.

Sound Slides. This is an alternative method of recording a commentary to be played back with a projected picture. It is more flexible than a tape recording, since each slide carries its own associated commentary and can be switched round at will. On the other hand the length of commentary per slide is limited.

The system uses large card or plastic slide frames with a central aperture to take standard 2 × 2 ins. slides. The frame carries a circular magnetic sound track surrounding this aperture. On this the commentary is recorded (during a preliminary projection session) by a rotating sound head inside the projector. Each slide can accommodate about 15 to 20 seconds of speech. During projection the same head picks up the recorded sound and plays it back through an amplifier and loudspeaker system built into the projector. The slides may be changed automatically at the end of the commentary, or manually by remote control or by a time switch. The sound slides themselves are loaded into a magazine—a scaled-up version of the usual miniature slide magazine.

A corresponding system also exists for film strips. Here every other frame on the strip carries an optical sound track. In the projector this is scanned by a travelling sound head which moves back and forth along the track while the picture next to it is being projected.

SPECIAL PROJECTION SYSTEMS

Micro-projectors. Where microscope specimens are to be shown to a class or during a lecture it is sometimes feasible to insert the microscope slide directly in the projector. For some slide projectors special micro-attachments are available, which fit in place of the lens unit. They consist of a microscope slide holder plus a short focus projection lens. The microscope slide is in this case positioned in a narrow part of the projected light beam, so that the lens projects a greatly enlarged and brilliant image of the specimen itself. The complete attachment usually includes a supplementary condenser and may have provision for inserting filters, microcells and similar items. Micro-projection with this type of outfit can yield magnifications of 200 to 300 times on the screen.

More elaborate micro attachments may incorporate a complete microscope system in reverse, consisting of an objective and an eyepiece lens with the latter facing the screen. This makes magnifications of 2,000 times and more possible on the screen. An alternative form of micro-attachment uses a mirror housing plus a second mirror, so that the specimen is located horizontally on a microscope stage. Here the projection beam from the projector is deflected upwards through the microscope system, and forward again by the second mirror on to the screen.

Overhead projector. This is a projection unit designed mainly for educational and similar uses, and consists of a light box with an illuminated horizontal top surface. Above this box is a mirror and a projection lens which projects the illuminated area on to a screen behind the projector. The light box takes transparencies up to 10 × 10 ins.

As an alternative to large film transparencies or one-sided translucent documents, a transparent strip of film can also be tensioned across the illuminated area. On this the lecturer can write or draw while talking, and the material then appears on the screen in front of a class. In effect this is therefore an optical blackboard, except that the picture appears in black (or coloured) writing on a white background.

The writing film for this purpose is available as 10 ins. wide acetate strip in lengths up to

OVERHEAD PROJECTOR FOR LARGE TRANSPARENCIES. A, mirror unit. B, mirror. C, supporting arms. D, H, rollers for continuous strips of transparency film. E, lens. F, film. G, opal glass sheet. J, lamps inside light box.

50 feet. It can be rolled continuously from a feed to a take-up roller to bring new portions over the illuminated area for further writing or drawing.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Overhead projectors usually have a 500 to 1,000 watt lamp, and a projection lens with a focal length of 10 to 15 ins.

With a 14 ins. projection lens a 10 × 10 ins. transparency covers a $6\frac{1}{2} \times 6\frac{1}{2}$ feet area on a screen at a projection distance of 10 feet.

In addition to straightforward drawing and writing, various special effects can be obtained with the aid of polarizing screens, filters, etc.

Episcopes and Epidiascopes. An episcope will project images of opaque objects such as book pages, photographic prints, maps, diagrams and small solid objects. Most episcopes work on the following principle:

The object is placed on a platform which can be raised and clamped under a sheet of toughened glass to hold it flat. The object is illuminated from above by means of a lamp and a number of mirrors, and the light is reflected from the object to a surface silvered mirror (inclined at 45°) at the top of the lamphouse. An episcope lens is placed in front of the mirror, and focused so that an image of the object appears on the screen. Shown on an opaque screen, the image will appear the correct way round. In some episcopes, there is no 45° mirror, in which case the image will be reversed unless back projection is used on a translucent screen. Episcopic projection must normally be done in a darkened room, as reflected light is less intense than light transmitted through a transparency.

Most episcopes will be found to be fitted with a 500, 750 or 1,000 watt lamp, which is cooled either by a motor-driven fan or by convection.

An epidiascope is a combined episcope and diascope so that both opaque objects and lantern slides can be projected. The diascopic attachment can often be obtained separately

EPISCOPE LAYOUT. The episcope serves for projecting opaque originals which are illuminated by reflected light. A, projection mirror. B, condenser mirror. C, lamp. D, glass plate. E, tray on which items are placed. F, projection lens. G, lever for raising and lowering tray.

to convert an episcope into an epidiascope.

The attachment consists of a lens holder, slide carrier and condenser which are placed on the front of the lamphouse, in line with the lamp. The front mirror used to help illuminate the object when the machine is employed as an episcope must be moved clear of the lamp so as to cause no obstruction between lamp and slide.

The diascopic attachment may be for standard slides or miniature slides and film strips, and sometimes a micro-slide adaptor (for projecting microscope specimens) is also available as for miniature projectors.

PSEUDOSCOPIC PAIR. Pair of images which, when viewed by any of the normal methods of stereoscopy, give an impression which is the reverse of stereoscopic—i.e., the front of any object appears farther away from the observer than the back. The effect may be easily produced by viewing a normal stereoscopic pair with the left and right hand pictures transposed.

PSYCHICAL RESEARCH. Apart from the fraudulent practitioners of so-called "spirit photography", many investigators of psychic phenomena have used the camera in the effort to produce tangible evidence of the powers claimed for or by spiritualist mediums.

It is authentically reported by Sir William Crookes, that "in the full blaze of the electric light" Katie (a spirit form) and Miss Cook (a medium) were seen together by eight persons in addition to himself. Forty-four photographs were taken and all of these showed marked differences between the medium and the apparition. To the arguments of trickery Sir William replied: "To imagine the Katie King of the last three years to be the result of imposture does more violence to one's reason and commonsense than to believe her to be what she herself affirms."

Some of these photographs are still extant and show Sir William arm in arm with the fair apparition. The sceptics alleged that Katie and Miss Cook were one person and the photographic evidence serves but to confuse the issue.

It is now some eighty years ago since Sir William commenced his investigations into psychic phenomena and the general verdict

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

of experienced investigators is "not proven".

During the years 1908 to 1918, flash light (magnesium powder) photography was employed in France and Germany to a considerable extent in the study of the mediumship of a young lady who called herself Eva C.

Many experiments were conducted by Mme. Bisson and Baron von Schrenck Notzing, a practising physician in Munich.

The photographic exposures during the sittings were usually carried out by Schrenck Notzing. The medium occupied a curtained corner of the seance room and one or more cameras were trained on the curtain. The room was illuminated by dark ruby light only. The lenses were left uncapped in this light and remained open during the whole of the seance. The magnesium (about a tenth of an ounce) was ignited by mains electricity. It was only necessary to press the switch to make exposures of anything which appeared suitable to the experiment.

The value of the seances, which were recorded in *The Phenomena of Materialization*, rests mainly on the evidence thus obtained. The photographs reveal phantoms in varying stages of development but these tended rather to discount the evidence for their genuineness.

In 1920, Mme. Bisson and Eva C. spent two months in London. Out of forty seances arranged by the Society for Psychical Research more than half were complete blanks and the remainder gave very meagre results. A further fifteen sittings with Eva C. took place at the Sorbonne in 1922.

Thirteen of these sittings were entirely blank and the investigating Committee returned a negative report.

Infra-red illumination would appear to be particularly suitable for psychic investigation. It has long been claimed that white light and psychical phenomena are incompatible. Dark ness or the use of a deep ruby light is considered essential. It would appear, therefore, that infra-red radiation would in no way inhibit the production of photographic evidence. On the contrary, it should provide a strong weapon in support of the genuineness of these phenomena. It is unfortunate that infra-red photography has not been applied to any great extent to this end. This is probably due to the fact that for many years there has been little or nothing worthy of investigation. The physical phenomena of spiritualism—if they ever existed—would appear to be a thing of the past. F.B.

PULFRICH, CARL, 1858–1928. German mathematician and physicist. Produced a stereoscopic rangefinder and devised a stereocomparator in 1901, both for the Zeiss works. Developed stereoscopic measuring methods for photogrammetry. Also devised the well-known refractometer which bears his name.

PULSE LIGHT. Continuous light source which provides an increased light intensity for short times at regular or irregular intervals by applying a high voltage pulse to the circuit feeding the lamp.

Both tungsten and xenon arc lamps can be used for pulse operation. In the former the pulse may be a capacitor discharge through the already burning lamp. This produces a short high intensity flash, but not long enough to damage the filament significantly. Accordingly such a lamp can be used for a large number of such pulse discharges.

Xenon arc lamps can have their light output boosted by short high-power pulses—for example from 500 watts to 5 or 10 kilowatts. The lamp will only stand a pulse duration of a few seconds at this high level, but this is sufficient for high-speed photography or cinematography, where this type of lamp finds its main application.

Pulse xenon lamps have also been used in motion picture projectors. There the lamp, pulsing at 72 cycles per second, can be synchronized with the film transport movement in the projector. This arrangement then needs no rotating shutter as the light itself is already intermittent.

Electronic flash tubes, including stroboscopic flashes are not pulse light sources, but discharges where the current supply is discontinuous.

PUYO, E. J. C., 1857–1933. French Army officer until 1902, and amateur photographer from 1887 onward. With Robert Demachy, a leading spirit in the Photo-Club de Paris, cultivated the aesthetic movement in photography by means of gum prints and bromoil in the Impressionist style. A prominent member of the Linked Ring. In 1914, rejoined the service. Wrote a number of books on the aesthetics of photography.

PYRO. Developing agent, once the standard agent in plate developers. Very popular at one time, and still favoured by some photographers.

See also: *Pyrogallic acid.*

PYROCATECHIN. Catechol; ortho-dihydroxybenzene. Developing agent.

Formula and molecular weight: $C_6H_4(OH)_2$; 110.

Characteristics: White powder.

Solubility: Freely soluble in water at room temperature.

PYROGALLIC ACID. Pyro; pyrogallol; 1 : 2 : 3-trihydroxybenzene. Developing agent.

Formula and molecular weight: $C_6H_3(OH)_3$; 126.

Characteristics: White powder or needle crystals. Rapidly oxidized in alkaline or neutral solutions.

Solubility: Freely soluble in water at room temperature.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

PYROMETRY Measurement of the temperature of a hot body by studying the nature of its radiation photographically. Usually based on the fact that the brightness of the light emitted by a body hot enough to be self-luminous increases with its temperature.

Body temperatures can also be measured by photography on infra-red film, by photographing the body coated with a heat-sensitive paint, by projecting an image of the body on heat sensitive phosphors, and by electronic scanning techniques.

See also: *Heat recording.*

PYROXYLIN. Nitrocellulose; soluble gun cotton. Used for making celluloid (nitrate) film base and collodion.

Formula and molecular weight: Not constant, depending on origin. A mixture of cellulose nitrates.

Characteristics: Harsh white cottony substance.

Solubility: Insoluble in water or alcohol. Soluble in equal parts of alcohol and ether, and in amyl acetate, acetone, and glacial acetic acid.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Q

QUANTUM. Smallest and basic indivisible unit of radiant energy. It is inversely proportional to the wavelength of the radiation.

QUANTUM EFFICIENCY. Effect of exposure on a photographic emulsion, expressed in terms of the number of light quanta required to render a silver halide grain developable. With present day emulsions the quantum efficiency is about 2½ per cent (1/40), i.e., forty quanta are necessary to produce the slightest trace of developable image.

QUANTUM EFFICIENCY, EQUIVALENT. The scientist's definition of the speed-to-grain ratio. Like photographic granularity, light itself has associated fluctuations due to the quantum nature of radiation. The size of the fluctuations due to granularity can therefore never be less than the limit imposed by the exposing light. This limiting value corresponds to 100 per cent efficiency, and determines the maximum theoretical speed-to-grain ratio.

See also: *Information in the image; Sensitivity.*

QUARTER PLATE. Standard format for negatives and prints, measuring 3¼ × 4¼ ins. A quarter plate is exactly a quarter of a whole plate (6½ × 8½ ins.). Introduced by N. P. Lerebours in 1840.

See also: *Sizes and packings.*

QUARTZ-IODINE LAMP. Tungsten filament enclosed in a narrow quartz (or sometimes glass) tube containing also a trace of iodine. This inhibits the deposition of vapourized tungsten during the burning of the lamp. Quartz-iodine lamps can therefore burn at higher temperatures (and hence higher light efficiency) and have a longer burning life.

Both the colour temperature and the light intensity of these lamps remain constant to the end.

See also: *Filament lamp.*

QUICK-CHANGE BACK. Attachment for plate cameras (particularly those used by the press) which allows the plate holder to be changed quickly. Generally the plate holder is held in place by hinged grooves with a quick-release catch; this allows the plateholder to be lifted straight out instead of being slid out, which takes longer.

Special types of quick-change back are used for making colour separation negatives in the camera by successive exposures. In some designs the three plates are held in a long sliding attachment which moves across the camera back in three stages. Each section may incorporate a tricolour filter, or the back may be used in conjunction with a filter slide or filter turret over the lens. With such a device the three exposures can be made in rapid succession.

The movement may be hand-operated, or worked by a motor. This type of quick-change back is also known as a repeating back.

See also: *Repeating back.*

QUICK-FIRE CAMERA. Camera in which the operations of advancing the film and setting the shutter are coupled to a single control that is either operated by clockwork or by a trigger or lever. Some cameras of this kind incorporate an electric transport motor.

Cameras of the quick-fire type are useful for securing series of pictures of fairly fast movement—e.g., at athletics events—and for press photography where they give the picture editor a selection of photographs instead of one which may or may not have been taken at the best instant.

They are also ideal for taking self-contained picture sequences.

See also: *Film transport; Miniature camera.*

QUINOL. Hydroquinone. One of the most commonly used developing agents, usually combined with metol.

R

RACK AND PINION FOCUSING. Focusing mechanism used on most stand—and the larger hand—cameras. The lens panel is fixed to a slide fitted in guides on the baseboard of the camera.

A focusing wheel or knob at the side of the baseboard is joined to a pinion engaging with a rack on the slide. Turning the focusing wheel slides the lens panel along the baseboard to focus the lens.

See also: *Focusing mechanism.*

RADIATION MEASUREMENT. Applied to the measurement of X-rays, gamma rays and emissions from radio-active substances. Covers two kinds of measurement: intensity (determined by the ionizing effect of such radiations, and detected by an instrument like a Geiger counter); and measurement of dosage to check the exposure of human operators to such radiations. This is done by measuring the density produced on a photographic film carried by the operator while exposed to such radiations.

See also: *Dosimetry.*

RADIATION MONITORING FILM. Film sensitive to X-rays and other types of radiation, packed in a light-tight cassette and worn on the person by workers in radiographic and nuclear establishments. After a specified period the film is given a strictly controlled development and the density of the silver deposit is measured with a densitometer. From this figure it is possible to estimate the radiation dosage received by the film and to switch the wearer to other duties away from the risk of further exposure if the amount should be above an agreed safety level. Where the radiation level varies within wide limits, a double coated film may be used. This has a fast emulsion which responds to low radiation levels, and (on the other side of the support), a slow emulsion for the higher levels. When the radiation dose has been very heavy the fast emulsion is stripped off and the density of the slow emulsion measured. If the slow emulsion is affected only slightly—i.e. when the dose has been light—it is stripped off and the density of the fast emulsion measured. The sensitivities of the two emulsions overlap to give a continuous range.

See also: *Dosimetry.*

RADIOGRAPHY. Branch of photography in which an image is formed on a film or plate by exposure to X-rays. An opaque object—e.g., part of the human body or a metal casting—is placed between the source of the X-rays and the sensitized material; the resulting radiograph shows details of the internal structure which would otherwise be invisible.

Radiographs are widely used throughout industry for the inspection of raw materials, structures and finished products and in medicine and surgery.

See also: *Gamma radiography; Industrial radiography; Medical radiography; Mass miniature radiography; Microradiography; X-ray crystal analysis.*

RAIN. Rain in photographs is nearly always suggested by reflections in wet surfaces, puddles, and open umbrellas, and not by the presence of actual raindrops.

Raindrops in the Picture. Raindrops reproduce best when they are illuminated by the rays of the sun and seen against a background of dark cloud, trees, or buildings in shadow. This means that they must be photographed against the light and that the camera must have a good lens hood. No matter how short the exposure, the drops will register as streaks of light and not as points. And as the subject is being photographed against the light, it will call for a comparatively long exposure, so the streaks will generally be so long that they will tend to obliterate the subject. This is why it is unwise to include the actual raindrops in the picture.

One way, however, in which raindrops not only show up but also materially contribute to the pictorial content, is in shots through rain-

CC-0. Agadh Jain Digital Preservation Foundation, Chandigarh

washed windows. There are two possibilities: photographing from the outside, close to the window pane, and taking the outdoor view from inside. In either case, the window may be only spattered with raindrops, or show the water streaming down on the glass. (Both effects can of course, be produced artificially with a bucket of water or a garden spray.) When shooting out of the window from indoors, the outside view will be blurred by the water; the drops themselves should therefore be brought out sharp by accurate focusing. Often a foreground object will add strength to the picture; neither this nor the window frame must be too dark, and some fill-in lighting is desirable.

When photographing from the outside, a suitable subject behind the window is essential, and it should be as close to the glass as possible. This type of approach has been popular for pictures of children, etc.

Lighting. Showery weather offers best conditions for pictures during or after rain. There is more chance of sunshine and rain occurring simultaneously, thus lighting up the falling raindrops if you wish to record them. Side-lighting or oblique back-lighting shows them to best advantage, particularly when they are striking the ground with force.

Heavy thundery showers during hot weather may produce after-mist and haze which gives plane-separation and "atmosphere", otherwise the air is usually clearer and sunlight harsher after rain, with distant scenes more clearly visible.

There are occasions, however, when the dull monotony of a completely overcast scene expresses the mood that the photographer wants to create. This type of scene calls for a different technique, aimed at avoiding hard contrasts and leaning towards mistiness and soft definition.

Photographs taken on dull rainy days need to be processed so that the contrasts of the subject are retained or even increased. This can be done by extending the development time (up to 50 per cent longer than normal), or by using a suitably contrasty grade of printing paper.

Rain often improves photographs of street scenes taken after dark. When such pictures are taken in dry weather, the foreground is usually a featureless area of black paper. When the streets are wet the foreground becomes filled with reflections and it may even form the principal interest of the picture.

Rainy Reflections. The general impression of a rainy day is strengthened when there are pools and shining wet surfaces in the picture. At such times the reflections themselves may be interesting enough to form the subject. On the other hand, a pool that gives a perfect reflection is bad because it simply duplicates the scene and presents the eye with two identical pictures.

A photograph that looks the same when it is turned upside down is a freak and nothing more.

One way out of the difficulty is to throw a stone into the pool and take the photograph while the surface is still disturbed. Or a low viewpoint can be adopted to reduce the proportion of the picture space occupied by the reflecting surface. In this way the reflection is subordinated and the subject receives its due importance.

If the reflection of the scene is to form the item of principal interest, then the lens must be focused on the reflected image and not on the reflecting surface. The image is as far away from the camera as the subject, no matter how close the reflecting surface may be. If objects on the surface of the water—reeds, waterfowl, floating debris—are to be included, then the lens must be stopped down until the depth of field extends from the reflecting surface to the image.

Sometimes the reflections are not wanted; if they cannot be got rid of by a change of viewpoint, they can be minimized or even cut out altogether by using a polarizing filter. The effect of the filter on reflection can be checked beforehand by visual examination.

Exposure. Exposure for wet objects and scenes should never be greater than that indicated by a meter reading on a medium tone area. Medium or slow films are best for sunless conditions, as fast emulsions are too soft in gradation to suit a subject which is already lacking in contrast. In sunshine, particularly backlighting, the reverse is the case. No filter is needed unless there are blue sky patches present. A lens hood is essential to prevent stray rays from sparkling surfaces striking the lens and causing flare.

For the moody, atmospheric type of rainy landscape, exposure needs to be full enough to register all the shadow detail and flatten the tones of the picture generally. Development should be continued for the full time or—if the flatness is to be exaggerated—a little longer.

The brilliant type of treatment looks best on a glossy or glazed surface, while the atmospheric effect calls for a semi-matt surface.

Protecting the Equipment. No camera should be allowed to get wet. An umbrella held by a companion will prevent this, and the lens hood helps to stop stray drops falling on the lens. If the camera does accidentally get wet it should be dried immediately. The metal parts require particular attention. The lens should be wiped gently with a soft handkerchief or other soft, absorbent material.

Do not hasten drying by heat, especially if the camera is a folding bellows type.

If there is a risk of being caught far away from shelter in stormy weather, it is a good idea to carry a square of plastic material of the kind sold for bathroom curtains. The camera in its case can then be wrapped up and kept perfectly dry in the heaviest downpour. P.J.

RANGEFINDER

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

When a camera has a focusing screen, there is no need for the photographer to know how far he is away from his subject; he simply gets it sharp on the screen and makes his exposure. But as soon as the focusing screen is dispensed with and the camera is focused by a scale, the distance from the camera to the subject must be known. Estimation is usually unreliable, and measurement can be a nuisance; a third alternative is to use a rangefinder.

Principle. A rangefinder enables the photographer to measure the distance to his subject without moving from his position. There are several types of rangefinder, but they all rely on the same basic principle, that when an object is looked at from two separated positions the lines of sight converge. The angle at which the lines converge increases as the object approaches, and decreases as it goes farther away.

Construction. In the type of optical rangefinder used in photography the two viewpoints are provided by windows at opposite ends of a metal tube which is held horizontal and at right angles to the camera-subject line. One of the windows lies on the camera-subject line; the eyepiece of the instrument is opposite this window. When the eye looks through the eyepiece it sees one picture of the subject directly through the window in that end of the rangefinder, and another picture, reflected by two mirrors or prisms, through the window in the other end. Sometimes the windows and mirrors are masked so that the eye sees the top half of one picture and the bottom half of the other. Sometimes, the eye looks through a half silvered mirror and sees the direct and the reflected pictures superimposed.

Included in the optical make-up of the rangefinder is an adjustable device that can be made to deflect the light rays of the reflected picture to bring it into register with the directly-viewed picture. This can be done by altering the angle of one of the mirrors, but it is more satisfactory to interrupt the beam of light by a rotating wedge system or a pair of prisms.

The deflection of the beam is controlled by turning a setting control on the instrument. The amount of rotation that has to be given to the wheel to keep the two pictures of the subject in register is related to the distance of the subject from the rangefinder.

Thus the wheel can be calibrated to show directly the distance of the subject when once the two images have been adjusted to coincide.

Accuracy. The two lines of sight converge more for objects near at hand than they do for those farther away. Because of this, rangefinders of this type are more accurate for objects up to, say, 25 feet than beyond. But as the accuracy required in focusing a normal lens falls off in exactly the same way, the defect is unimportant.

Since however accurate focusing is important with long focus lenses at greater distances, the value of a rangefinder is distinctly limited with lenses of longer focal length. In that case a reflex camera or a reflex attachment is more reliable as a means of getting the image really sharp.

Base Length. The optical accuracy of a rangefinder depends on the base length and on the scale of the image. The longer the base of the rangefinder (i.e., the distance between the two windows) the greater will be the convergence on any given subject, and the greater will be the separation between the two part images for a given focusing error.

The larger the scale of the image, the greater will again be the image separation. In both cases a given focusing error will show up more.

RANGEFINDER SYSTEMS. Top: *Rotating mirror. One mirror is pivoted to alter the angle of deflection and superimpose images at different distances.* Bottom: *Swinging wedge. Sideways movement of the wedge controls the angle of the beams.*

SWINGING WEDGE SYSTEM. Can be used with interchangeable lenses. A, *eyepiece.* B, *semi-reflecting surface.* C, *prism block.* D, *lens mount gear.* E, *cam.* F, *focusing gear.* G, *focusing wheel.* H, *swinging wedge.* I, *cam lever.*

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

ROTATING MIRROR SYSTEM. Suitable for interchangeable lens cameras. A, semi-reflecting surface. B, magnifying viewing system. C, eyepiece. D, coupling lever bearing on lens barrel. E, pivoted reflector. F, lens barrel.

ROTATING WEDGE SYSTEM. Generally used with non-interchangeable lens. A, viewing system with eyepiece. B, semi-reflecting surface. C, prism block. D, skew gear driving wedges. E, rotating wedges. F, focusing lens mount.

Commercial camera rangefinders may either use as long a base as the camera body will accommodate, or go for a shorter base, coupled with a magnifier in the eyepiece to increase the image scale and so make up for the loss in accuracy.

A long base has the advantage of minimizing mechanical inaccuracies, but it has the drawback that at extreme settings one of the images may move out of the field of view altogether.

A short base with magnifier makes the instrument more compact but the optical system is more easily influenced by mounting errors.

Coupled Rangefinders. A coupled rangefinder is simply an adjustable optical system of the type described above which has been built into a camera so that the rangefinder and lens focusing work together. A single control operates both systems and when it has been adjusted to make the two rangefinder images of any object coincide, the lens is automatically focused on the object.

The principle can be applied to any type of camera, but it is particularly suited to the miniature where the lens mount is attached direct to the body. This arrangement makes it possible to house the rangefinder mechanism and the lens focusing mount in the same rigid casting. In one popular miniature of this type, the lens focuses in a helical mount and the rear face of the lens tube presses against the end of a spring-loaded lever which carries the tilting mirror on the moving or rotating wedge of the rangefinder system.

With rangefinder and lens focusing systems coupled in this way the lens can be focused without any reference to the actual measured distance from the camera to the subject. At the same time, it is useful to know the exact distance at which the lens is focused, and the system always carries a visible scale of distances.

WEDGE RANGEFINDER IN FOCUSING SCREEN. Many single-lens reflex cameras incorporate a crossed wedge system in the centre of the viewing screen to act as a split-image rangefinder. The image in the split section lines up to become continuous only when the picture is sharply focused. A grained ring surrounding the wedges may also act as a focusing screen for direct observation of the sharpness.

Focusing Screen Rangefinder. Many current miniature reflex cameras incorporate a rangefinder system in the focusing screen. This consists of a pair of crossed wedges recessed into the screen so that the wedges cross in the plane of the focusing surface. The optical principle is similar to parallax focusing of an aerial image, but the parallax effect appears as a split image which joins up across a dividing line when the lens is set to maximum sharpness. As the rangefinder uses the screen image, there are no moving parts and it is automatically coupled with any lens.

This system works, however, only with fairly large lens apertures.

Non-optical Rangefinder. A non-optical rangefinder can be made from two pointers mounted on a baseboard. The object is sighted along the right hand pointer by the right eye and along

the left hand pointer by the left eye. The whole arrangement is kept at a fixed distance from both eyes. The angle between the pointers is calibrated to give the distance of the object directly on a scale marked on the baseboard.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Rangefinders of this type are cumbersome and not very accurate and many people find it impossible to master them. L.A.M.

Book: *Photographic Optics*, by A. Cox (London).

RAPID ACCESS SYSTEM

Photographic camera and processing system that produces a usable picture in the order of a few seconds (in some cases even in a fraction of a second) for immediate evaluation. While normal rapid processing is concerned merely with speeding up conventional processing procedures by concentrated heated solutions, rapid access systems are more integrated set-ups involving special processing techniques—usually applicators for the solution, suitably designed machinery, etc.

Cell and Chamber Processors. These permit the contact of small amounts of processing liquid with the emulsion and the film. A narrow space is provided between the film emulsion and the processing device. In a processor of this type the film, after being located over the sealing frame, is held tightly against the seal by means of a pressure plate. Through the centre bore of the processing platen, metered volumes of processing solutions are brought into the capillary chamber. The liquid could freely overflow the platen but is held within the chamber by capillary forces. The chamber dimensions are critical. Good processing results have been obtained using a chamber depth from 0·010 to 0·030 in. A nearly square frame of 1·16 by 1·06 in. is preferable; however, equal success has been attained with a more rectangular frame of 1·16 by 0·92 in.

CAPILLARY CHAMBER PROCESSOR. Top: *Capillary chamber. A, chamber. B, sealing frame. C, heater block. D, pressure plate. E, film. F, emulsion. G, overflow. H, orifice.* Bottom: *Processing cycle. 1. Film moves into position at start of cycle. 2. Development. 3, Fixer introduced through the central orifice displaces the developer. 4. Washing water flushes out the fixer. 5. Drying the air blown into the capillary chamber. 6. The film is removed at the end of the cycle.*

The volume of processing liquid required to fill the chamber ranges from 0·3 to 0·5 c.cm., depending on the frame size. The figures given apply to the processing of a 35-mm. double frame. Since the processing solutions contact the emulsion side of the film only, this process is well suited to ultra-rapid processing.

After the development is completed, the fixing solution is introduced into the capillary chamber through the centre bore. This pushes the developer into the overflow and then into the waste container. Any intermixture of the two liquids is counteracted by the strength of the fixing solution, which not only rapidly stops the development but also completes the fixation of the image in the presence of traces of the developing solution. A wash follows the fixer, and a hot, high-velocity air stream which enters the chamber from the side and is directed evenly over the film surface dries the emulsion; drying air, which escapes through the waste spacing into the vented waste container, cleans and dries the chamber as well as the film.

The emulsion of the film and the desired image characteristics determine the selection of processing solutions. The capillary chamber system is flexible, for any wet process can be used. Monobath processing yields acceptable results, although for image requirements of high contrast combined with low fog level development and fixation are best separated. Emulsions especially designed by the manufacturers for rapid processing applications give best results.

A typical processing cycle with a capillary chamber may take 1½ seconds for development, ½ second for fixing, 1 second for washing, and 2 seconds for drying.

The processing platen, which is part of the heater block, contains heating elements and a temperature-sensing probe. The pre-selected processing temperature is automatically controlled and is maintained within ± 0·5°F. The processing temperature can be set for any point from ambient to 130°F. Although high-temperature processing is not essential for ultra-rapid processing, elevated processing temperatures can be maintained more easily in varying ambient conditions.

Another developing chamber with a cavity of

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

approximately 0·005 in. can deliver recorded photographic data 1/5 second after exposure. The 35 mm. film itself makes a seal with the lips of the chamber during processing. Pre-heated developer at 170 F. is sprayed on the film through a narrow slit and withdrawn through a second slit by a vacuum pump. After a 0·6 second development time hot air saturated with acetic acid vapour dries the film, neutralizes the alkaline developing solution and stabilizes the image. The stabilization, however, is not complete and a yellow light is used for projection to prevent fading of the image. The drying and stabilizing operation takes a little less than 1 second so that the image can be projected approximately 1·5 seconds after exposure.

Viscous Layer Applicators. In selecting a processing method for a machine to be designed for both rapid and simplified processing, the viscous technique has found commercial application on a large scale. A typical machine processes 16 mm. black-and-white positive films at 36 feet/minute, with a dry-to-dry time of 1 minute. The developer and fixing solutions are each coated on the emulsion surface as a viscous layer in an atmosphere saturated with water vapour at 125°F. The viscous processing solutions are packaged in disposable, polythene bags which can be changed without interrupting the processing operation.

The film enters the processing chamber and passes round the coating roller. A coating hopper (a special kind of nozzle) applies a 0·008 in. layer of viscous developer to the emulsion surface. Raising or lowering the roller adjusts the time the developer remains on the film (from 2½ to 7 seconds), to select a specified contrast. The developer coating is removed by a high-velocity water spray jet, and the surface water on the film by an air squeegee. The film then passes round a second coating roller where the viscous fix is applied by another coating hopper, and removed (after 12 seconds) by a second spray jet. The film then passes into the wash compartment for a spray wash of 13 to 17 seconds. After passing through a second air squeegee, the film goes into the impingement air dryer for 15 to 21 seconds.

VISCOUS SOLUTION APPLICATOR. The processing solution is here applied to the film as a viscous layer which is thin enough not to flow. A, solution reservoir. B, gear pump. C, hopper. D, backing roller. E, film. F, water jacket to control solution temperature.

POROUS PLATE APPLICATOR. The processing solutions emerge through a porous plate and form a meniscus in contact with the film passing within a few thousands of an inch of the porous surface. Several applicators may be arranged in series for different processing steps. A, backing plate. B, meniscus of solution. C, porous plate. D, wick. E, solution feed. F, thermostatic heater block. G, film. H, waste.

Porous Plate and Roller Applicators. Rapid access processors based on the application of thin layers of solution to the emulsion surface by means of porous rollers or plates provide another technique. Here thin porous plates, made from sintered stainless steel granules, and of the width of the exposed area on the film are in contact with the film surface. The plates are fastened to a manifold block which contains a feed pipe and a cavity with a wick to disperse the solution flow uniformly through the porous material.

The solution is pumped through each plate as the film moves past it, and different plates in a row can apply different solutions. Cartridge heaters maintain the manifold block—and hence the solutions coming into contact with the film—at the right temperature.

An applicator relying on a meniscus of solution formed between a porous roller and the film emulsion consists of a hollow stainless steel tube plugged at both ends. Small holes are drilled radially through the roller, and die-cut felt washers slipped on the tube and retained by axial pressure of a collar. The processing solution, preferably a monobath, is brought first to the required temperature and then forced under pressure into the applicator tube through small holes in the bearings that coincide with similar holes in the applicator tube. From there it flows out through the felt washers to contact the emulsion.

Jet Spray and Slot Processors. The Kelvin-Hughes system of rapid processing uses a Venturi-type jet spray system operated by

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

compressed air. Atomized droplets of the various solutions are sprayed on to the emulsion at high velocity and at an economical rate. As this is a "total loss system", results are constant and no replenisher system is required.

Jet spray techniques raise condensation problems in rapid access processors carried in aircraft. Slot processors are therefore used in such cases, consisting of a bar of material with three accurately machined slots. Two of these slots carry the processing fluids and, thus have an inlet and outlet feed and return. The centre slot separates the developing slot from the fixing slot by ensuring an area of ambient pressure between these. Each slot may be regarded in itself as an open weir, which, when placed close to the emulsion surface of the film, forms a closed channel through which the processing fluid is drawn in contact with the emulsion surface. Since this fluid is drawn through the channel by negative pressure, it becomes a leak-proof system, which is consistent with airborne requirements.

The film is transported past the slot where it is fully developed in 2 seconds at 40°C.; it then passes a narrow ambient air channel, after which it is fixed via a slot similar to the developer channel in a similar time. Thus, the record is available with an access time of only 5 seconds. This applicator is arranged transversely to the film motion and is so aligned that there is a small air cushion between the emulsion and slot surfaces, thus ensuring turbulent liquid flow in the slot channel and protecting the emulsion.

Roller Applicators. Processing solutions can also be applied to the emulsion surface by non-porous rollers or wheels. Each roller dips into a tank with the appropriate solution to carry the latter into contact with the film as the latter touches the top of the roller. The rollers are driven in a contrary direction to the movement of the film. Such processors permit continuous rapid processing at rates up to 100 feet per minute of cine film.

An alternative arrangement has the lower portion of the rotating drum suspended in the solution, while the drum rotates at 300 r.p.m., in this case, however, in the direction of film travel. A comparatively thick layer of solution is carried round the upper circumference of the drum over which the film is positioned by two small guide rollers. Normally two drums are used for the developer, and fixer respectively, after which the film passes over a spacer roller into a washing tank and finally past a squeegee into a simple drier. The speed of the operation is variable for treatment from 1–10 seconds.

Saturated Web Applicators. Saturated web processing involves the use of a suitable absorbent material acting as the intermediate carrier for the processing solution. Advantages claimed are that the volume of solution used is very small (approximately equal to the volume of the material to be processed), that each area of emulsion is processed with fresh solution, and

JET SPRAY PROCESSOR. A, pressure pad. B, film. C, jet introducing chemical solutions and air at different stages. D, jet chamber. E, waste flow.

WEB PROCESSOR. This type of arrangement is frequently used in aerial reconnaissance cameras for in-flight processing. A, roll of saturated paper web. B, take-up roll for web and film. C, film coming from exposure section of camera.

WEB PROCESSING SYSTEM FOR IMMEDIATE VIEWING. Here the exposed film remains in contact with the saturated web only during processing. The web is then re-spooled again separately and the film can pass on to a viewing unit for immediate evaluation. A, motor. B, film supply. C, web take-up. D, saturated paper web. E, supply spool of web. F, processed film proceeding to viewing unit. G, sandwiching rollers to press the film and web into contact. H, exposure station with camera lens system.

undesirable by-products of the reaction removed with the web upon its separation from the processed film. The web is adaptable to various processing formulations, i.e. monobath as well as standard two-stage processing. Equipment utilizing the saturated web is leakproof, requires no pumps, valves, metering devices or complex machinery.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

The web material is a special paper made of fine fibres (to avoid fibre markings) in a sheet of high porosity permitting uniform compression. For adequate wet strength the paper is bonded to a non-porous plastic film, which decreases also the chance of entrapping air and makes the processing solution available from one side only. It further serves as an evaporation- and oxidation-barrier.

In operation the web (pre-saturated with an aqueous processing solution such as a monobath) is brought into intimate contact with the emulsion surface of the film by winding the surfaces together in a roll or tensioning the sandwich of material around a portion of the periphery of a drum. After processing is complete, the web is stripped away from the developed film.

COMBINED CAMERA-PROCESSOR-VIEWER WITH POROUS APPLICATORS. The processing unit receives the film coming straight from the exposure station in the camera. The film then passes in front of a lamphouse for immediate viewing. A, motor driving film rollers. B, film supply. C, camera lens. D, developing unit. E, fixer supply tank. F, developer supply tank. G, processed film. H, lamphouse. J, fixing station. K, pump.

COMBINED CAMERA PROCESSOR AND PROJECTOR. The film is exposed through the base while it is in contact with a developer in a solution-tight chamber. From there it passes to a fixing chamber through which the projector lamp projects the image on to a screen. Pumps circulate the solutions through the two chambers. A, film supply. B, camera lens and system. C, developing chamber. D, fixing chamber. E, projection lens. F, film take-up. G, solution pumps. H, developer reservoir. J, projection optics. K, fixer reservoir.

Diffusion-Transfer. The diffusion-transfer process, as exemplified by the instant-picture camera, is also a rapid access system in the true sense. Here processing takes place inside the camera by spreading an activating reagent—carried in pods on the positive material, between the negative and positive layers of a picture roll or sheet. This yields black-and-white positive prints within as little as 10 seconds, or colour prints in about a minute after exposure. For document copying exposed negative sheets are fed through a roller processing machine in contact with a positive sheet and the sandwich then stripped apart.

Combined Camera-Processor-Viewers. In many cases it is important to shorten the time between photographic recording of information and its presentation for visual inspection either in a permanent or temporary form. This can be achieved with combined camera-processor-viewers or -projectors.

A typical system for projection of the photographic data recording within a fraction of a second after exposure takes a photograph from a cathode-ray presentation, processes it automatically and then projects it immediately. The machine uses two-solution processing to develop the film within 0·2 seconds at 185°F. and to fix it in approximately 0·2 to 0·3 seconds at 205°F. A similar device for radar recording employs a porous applicator which is inserted in a narrow space between a camera portion and the viewing

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

COMBINED CAMERA, PROCESSOR, PRINTER AND VIEWER. A, processing solution applicator. B, negative film roll. C, camera lens of exposure station. D, positive film roll. E, printing light; exposes developed negative image onto positive film. F, processing solution layer. G, positive image. H, viewer system.

station using a U-shaped film path in a relatively small piece of equipment. A machine has also been designed which provides both negative and positive in a rapid processing operation. A sandwich is formed between the exposed negative and a positive film with a monobath processing solution in between. This develops the negative which is immediately printed on the positive material and thus developed by the same monobath.

The processing solution develops and fixes the positive image almost immediately, after which the positive and negative films are separated. Either of them can then be used in the usual way.

Processing Chemistry. For rapid access processing, highly active developers are required making full use of all means of accelerating the developing process, such as high general concentration, pH and temperature. In cases where temperatures considerably exceed normal working temperatures special quick-finish (rapid access) films have to be used which stand temperatures up to say approximately 200°F. (93°C.). The emulsions of these films are specially hardened and also thinly coated. A typical formula for a highly active developer is the following:

Sodium sulphite (anhydrous	6 ounces	150	grams
Potassium carbonate (anhydrous)	4 ounces	100	grams
Hydroquinone	2 ounces	50	grams
Phenidone	20 grains	1·1	grams
Sodium hydroxide	175 grains	10	grams
Potassium bromide	280 grains	16	grams
Benzotriazole	20 grains	1.1	grams
Water to make	40 ounces	1000	c.cm.

This stock solution is normally diluted for use with equal parts of water.

Where machines use monobaths (combined developing and fixing solutions) these are usually based on the accelerating effect of phenidone in hydroquinone developers leading to developers of increased activity compared with the MQ type.

A formula for a suitable monobath as follows:

Sodium sulphite (anhydrous)	2½	ounces	60 grams
Hydroquinone	1⅛	ounces	30 grams
Sodium hydroxide	1	ounce	25 grams
Phenidone	55–90	grains	3·2–5 grams
Sodium thiosulphate (crystals)	3–10	ounces	75–250 grams
Water to make	40	ounces	1000 c.cm.
Formaldehyde (38%)	200	minims	10 c.cm

With two-solution techniques the fixing formula is usually based on ammonium thiosulphate.

Where the permanence of the photographic record is of less importance than utmost speed of processing, stabilization techniques are applied. Here a stabilizer renders the undeveloped silver halide relatively inert to heat, light or moisture.

The main stabilizing agents used for this purpose are ammonium thiocyanate in approximately 20 per cent solution or thiourea in about 3 per cent solution. Prints stabilized in this way are not washed. C.I.J.

RAPID CASSETTE. Name adopted jointly by a number of international camera and film manufacturers for a quick-loading 35 mm. film cassette.

The cassette contains a loose film length sufficient for 12 exposures 24 × 36 mm. (or larger numbers of smaller formats down to 18 × 24 mm.) and is inserted in the camera without any film threading. The film transport of the camera automatically feeds the film into a take-up cassette which is removed when all the frames are exposed. Rapid cassettes must be used in cameras specially designed to take them.

Models of this type have appropriate film chambers and transport systems, and need no film rewind.

RAPID PROCESSING

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

There are occasions when a photograph of a subject is required in the shortest possible time. The methods vary according to the time factor and the facilities available, and cover:

(1) Speeded-up normal production.
(2) Rapid production.
(3) Ultra-rapid production.

In general negatives require proper fixing and washing after the necessary results have been obtained.

Speeded-up Normal Production. The film is developed as laid down by the manufacturers of the developer in use, the negative is fixed in an ammonium thiosulphate rapid fixer until it has cleared, and then given a short rinse in running water or quick changes of water. Agitation of the negative material reduces the time of fixing and washing; a further shortening of the washing operation can be made by a preliminary washing in 0·01 per cent potassium permanganate solutions until the pink colour is no longer discharged, after which only a short wash is required.

For contact printing, any surplus water is removed from the negative by gentle swabbing off with a grit-free piece of chamois leather dipped in water and wrung dry. This is followed by soaking for 2–3 minutes in a solution of industrial methylated spirit with 20 per cent water added, after which the negative is waved gently in the air until thoroughly dry, the negative is then printed in the normal way, the print developed, fixed in a rapid fixer, rinsed for 1 minute in running water, and soaked in methylated spirit. After blotting off with fluffless photographic blotting paper, the print may be waved in the air until dry; or with a little practice a nimble fingered person can set fire to the wet print (without blotting off) thus burning the methylated spirit, being careful not to allow the print itself to burn.

For enlarging with a negative carrier of the glass sandwich type, the method is the same as for contact printing.

With a glassless negative carrier the negative can be enlarged whilst wet. To avoid the formation of droplets of water on the negative (giving unsightly marks on the enlargement) the final rinse of the negative should contain a little wetting agent. This rinse need only be a minute or so, and after draining off the surplus moisture the negative is placed direct into the enlarger, for the normal enlarging procedure.

Rapid Production. In some branches of photography (press work, medical radiography, etc.) it may be necessary to produce photographs in a shorter time than possible by the above methods. For this purpose special developers (in addition to the rapid fixer) are available. Where convenient they may be used for the rapid processing of prints as well as negatives.

The developing solution is reasonably stable and will keep well in a tightly stoppered bottle. Used developer must not be returned to the bottle.

The quick finish developer and fixer can be bought ready made up; alternatively the following formulae will be found suitable. A developer for commercial use is:

Metol	1¼ ounces	32 grams
Sodium sulphite, cryst.	8¾ ounces	220 grams
Hydroquinone	2½ ounces	62 grams
Potassium bromide	2½ ounces	62 grams
Sodium hydroxide	2½ ounces	62 grams
Water (distilled)	80 ounces	2,000 c.cm.

The chemicals are dissolved in warm water. The developer is used undiluted for negatives, development times being 15–30 seconds at 70° F. (21° C.). For papers, dilution of 1 : 1 will give times of 10–15 seconds.

The fixer may be one of the proprietary quick fixers or the following can be used for bulk processing:

Hypo	64 ounces	1,600 grams
Sodium sulphite, cryst.	1½ ounces	38 grams
Potash alum	1 ounce	25 grams
Acetic acid, glacial	1½ ounces	38 c.cm.
Water	80 ounces	2,000 c.cm.

Agitation during the whole process must be vigorous and continuous to avoid development marks and stained prints. Dish development is therefore preferable.

Because of the short time of processing it is advisable to add a few drops of wetting agent to the solutions thus ensuring even development and preventing the formation of clear spots due to air bells.

Negative materials and paper are best transferred without rinsing direct from the developing bath to the fixer hardening bath.

Fixing times at 70° F. (21° C.) are 40–120 seconds, after which the negative is ready for inspection or for printing whilst still wet in the enlarger. If permanence is required then fixing must be increased to twice the time taken for the emulsion to clear, or the negative must be refixed at a later date and thoroughly washed. With ammonium thiosulphate fixers the above times ensure complete fixation.

Bromide paper will fix in 10 seconds at 70° F. (21° C.) in a rapid fixer. After a short wash the prints can be dried by the methods already described.

Ultra Rapid Production. In some specialized jobs it is desirable to increase the speed of production even further. An example of this is the use of photography in race finish recording in which a method has been evolved to produce an 8 × 10 ins. enlargement within 90 seconds of the last competitor crossing the finishing line. To attain this speed the developing and fixing formulae mentioned above can be used, but specialized materials and chemicals have been manufactured for this type of photography.

Quick finish films have an emulsion which is

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

RACE-FINISH LABORATORY. Operating and processing room set up alongside race track for immediate photo-finish prints (short arrow indicates race direction, inside arrow routing of photos). A, camera platform. B, processing unit. C, negative viewer. D, enlarger. E, print processing bench with developer and fixer dishes. F, sink and draining board.

resistant to high temperature processing, and with special processing solutions such films can be developed and fixed in a matter of 30 seconds.

Producing a Photo Finish Print. This procedure is possible only with special pre-hardened film. The film is exposed in a race finish recording camera and varies in length according to the time that elapses between the first and last competitor crossing the finishing line; an average is between 12 and 32 ins. It is developed by hand in a dish of quick finish developer at a temperature of 110° F. (43° C.) for 12 seconds. Without a rinse the negative is then transferred to a dish of proprietary rapid fixer at a temperature of 110° F. (43° C.) for 10 seconds, keeping the negative continually agitated. The fixing will then be complete enough to allow visual inspection and enlargement whilst still wet. Owing to the softness of the emulsion great care must be taken not to touch it, but just allow the moisture to drain off. An 8 × 10 ins. enlargement is then made in the normal way on bromide paper and developed in a quick finish developer (diluted 1 : 1) at 70° F. (21° C.) for about 21 seconds then transferred without rinsing to a dish of rapid fixer. Fixation will take from 10 to 15 seconds. After blotting off any surplus moisture the enlargement is ready for inspection by the judge.

Apart from the special taking and processing materials used, an important factor in achieving speed is the layout of the darkroom and the efficient routing of the work from one piece of equipment to another. To attain the fastest time of production the equipment should be set up with each piece as near as possible to the next and in such a manner that the rotation of work is in one direction only, either left to right or right to left.

A camera operating room designed for photo finish recording uses some specialized equipment to assist still further in speed of production.

In such darkrooms the processing unit is a 12 × 12 × 6 ins. deep metal container, with a stainless steel top cut away to receive two stainless steel dishes 9 × 3 × 2 ins. deep, one for developer and one for the fixer. Inside the metal container is an enclosed heating element, with thermostatic control to enable the operator to keep the chemical solutions at the required temperature. Each dish is fitted with a stainless steel lid; the developing dish has a loose lid to be removed before switching off the light, and the fixing dish is a hinged lid which is kept closed until the film is developed. This prevents any possibility of placing the film in the fixing solution first.

The enlarger is a fixed enlarger, the degree of enlargement depending solely on the area of negative to be enlarged to a 8 × 10 ins. print; focusing is carried out by slight movement of the lens.

The paper is held in a shallow metal box in which there is a sprung platform enabling twelve or more sheets of double weight paper to be loaded at any one time. A white sheath slides over the paper, to make the carrier light-tight and serve as a focusing plate. In use, the negative is focused on the white plate, the light then extinguished, the plate withdrawn and an exposure made. The exposed bromide paper is then removed leaving the next sheet in position for the next exposure. This can be carried on until the paper is exhausted and the carrier reloaded.

An audible electric timer ensures accurate timing for developing and fixing the negatives. This is necessary because of the short duration of these processes. Thermometers are also essential.

A safelight fitted flush with the top of the bench serves as a negative viewer.

All other equipment is of standard design.

The layout of the darkroom is based on the fact that the starting point is the camera. Around the walls from this point is a bench 33 ins. high to take the various items of equipment. As near the camera as convenient comes the processing unit with the dishes one behind the other (the developing solution at the back). Above the unit is the switch that controls the negative viewers and safelight; next comes the negative viewer on which is set the enlarger negative carrier, followed by the

enlarger with the paper carrier immediately below and control switch near by, then the print developing and fixing dishes, a sink with a dish for water to rinse the print, and on the opposite side of the sink a small dry bench for blotting off the finished product. Over the print developing and fixing dishes is a 8 × 10 ins. safelight. All switches are placed at the same height above the bench. Finally in a convenient place on the wall at the starting point is fixed the audible timer. The room light switch is positioned as far away as possible from the operating switches to guard against accidental switching on of white light.

The operator proceeds as follows. First he checks all temperatures (for ultra speed work this is very important). He then starts the audible timer, removes the developer dish lid and switches off the light. He then develops the film, fixes it, and switches on the negative viewer and safelight, places the negative in its carrier in the enlarger, focuses, and makes the enlargement. The final stages are, to develop and fix the enlargement, give it a quick wash, and blot off the surface water. This method of working keeps the speed of production as high as possible.

The specialized equipment mentioned is only necessary in the case of constant ultra speed work. For the occasional worker ordinary photographic equipment is quite adequate, with the addition perhaps of a metronome or some such means for timing the processing, and an immersion heater or boiling ring for heating the solution. S.J.H.

RAPID RECTILINEAR (R.R.) LENS. Lens system made up of two identical doublet lenses mounted symmetrically about a stop with the negative elements facing out. Dallmeyer in England and Steinheil in Germany hit upon this combination at the same time, 1866. In this way they got rid of all the aberrations except spherical aberration and curvature of field.

When the lens is stopped down to *f*8 it will cover an angle of 40° but the definition near the edges of the field is always softer than at the centre. R.R. lenses went out of general use when genuine anastigmats arrived.

See also: *Lens history.*

RAYOMETER. Special type of density wedge made of graduated thicknesses of aluminium, used in radiography to measure the sensitivity of emulsions to X-rays and the emission of X-ray tubes.

READE, JOSEPH BANCROFT, 1801–70. English clergyman, microscopist and astronomer. Pioneer of photography. Early in 1839 made photomicrographs in the solar microscope on silver chloride paper which was moistened with an infusion of nut-galls (i.e., gallic acid) thereby using tannin as an accelerator. Also the first to use hypo as a fixing salt (1839). Made camera photographs in 1839. Biography by C. H. Oakden (1926).

RÉAUMUR. Name given to a system of thermometry invented by R. A. F. de Réaumur (1683–1757) in 1731 in which the freezing and boiling points of water are 0° and 80°. This scale was mostly used in Russia.

RECIPROCITY LAW. Photographic exposure is the result of allowing light of a certain intensity to act on sensitive emulsion for a specified time. According to the reciprocity law of photochemistry, so long as the exposure (light intensity × time) remains constant, the response of the emulsion is the same—i.e., if the intensity is doubled and the time halved, the blackening produced on development should be unaffected.

In practice, photographic emulsions do not strictly follow this law. A given emulsion is most sensitive to illumination of a particular intensity. When the intensity varies greatly from this ideal, then the reciprocity law no longer applies. Very low intensities of light with correspondingly long times, or very high intensities with very short times, produce less effect.

The resulting reciprocity failure may show itself with the very short exposure of electronic flash, or with very long exposures (e.g., in astronomical photography). In either case more than the calculated exposure (up to three times normal) may be required.

See also: *Latent image.*

RECORD PHOTOGRAPHY. Photography that sets out to state the facts about the subject without any regard for its pictorial qualities. In practice it is not always possible to draw a sharp dividing line between the two, since many photographs taken purely as records often have a strong pictorial appeal—e.g., certain botanical subjects and architectural photographs.

Even in a record photograph, the photographer's personality is bound to show itself in choice of viewpoint, lighting, placing of subject, and in many ways in the photographic treatment of negative and print.

Perhaps the nearest approach to pure record photography is to be found in such operations as aerial survey, document copying, identification photography, and mass radiography.

CC-0. Adamnigam Digital Preservation Foundation, Chandigarh

RECTIFIED SPIRIT. One of the many forms of alcohol, containing about 5 per cent water, but no other additions (unlike methylated spirit). Subject to heavy excise duty.

REDEVELOPMENT. Process of converting the silver salts of a bleached image back into metallic silver by a second development. Bleaching followed by redevelopment is a useful method of improving negatives and prints, particularly for softening over-contrasty negatives and improving the colour of prints.

Redevelopment of Negatives. The contrast, density, and graininess of the negative can be adjusted by first bleaching it in a halogenizing bleacher and then redeveloping it.

A suitable halogenizing bleacher is:

Potassium permanganate	27 grains	1·5 grams
Sodium chloride	2 ounces	50 grams
Sulphuric acid, concentrated	100 minims	5 c.cm.
Water to make	40 ounces	1,000 c.cm.

Instead of the sodium chloride and sulphuric acid, 50 c.cm.—2 ounces—of concentrated hydrochloric acid may be used.

The negative is immersed in this solution until it is completely bleached. It is then transferred to a 5 per cent solution of sodium bisulphite, containing 0·1 per cent sodium hydroxide. The negative is then ready for redevelopment.

An alternative halogenizing bleacher is:

Copper sulphate, crystals	4 ounces	100 grams
Sodium chloride	4 ounces	100 grams
Sulphuric acid, concentrated	1 ounce	25 c.cm.
Water to make	40 ounces	1000 c.cm.

The negative is immersed in the bleaching solution until the whole image is white, after which it must be well washed before redevelopment.

The negative is redeveloped in a soft metol developer by white artificial light, or daylight. When the image is dense enough the negative is fixed and washed in the usual way.

The final image can be made softer and thinner than the original by removing the negative from the solution before it is fully developed.

The image may also be converted into one of finer grain by redeveloping the negative to the required density in a para-phenylene diamine, instead of a metol developer.

Again, the over-all contrast range can be reduced without greatly affecting individual highlight or shadow gradation. The negative is first partially bleached in one of the above bleachers. Bleaching is stopped when the shadows and lower half-tones are completely white, but the highlights are still partially black. The highlights are then reduced in a permanganate reducer which does not affect the bleached shadows. Finally, the whole negative is redeveloped in a normal developer.

Redevelopment of Prints. The object in redeveloping prints is usually to improve the image colour. This may be desirable if the prints were originally processed in stale developer. They may be bleached in the solution given for negatives, above, or in a bath consisting of equal parts of potassium ferricyanide and bromide in about 20 parts of water.

As soon as most of the image has disappeared, the print is thoroughly washed for about half an hour in running water. It is then developed in any fresh print developer by weak white light. Finally the print is fixed and washed in the usual way.

L.A.M.

See also: *Contrast control.*

REDUCER. Photographically, a solution which is capable of dissolving silver in a negative or positive image, thus decreasing its density. Chemically, a reagent (such as a developer) which increases the proportion of the metallic or electropositive component of a compound—e.g., by converting a metal salt into the metal. A photographic reducer is generally the opposite of a chemical reducing agent—i.e., it is an oxidizing agent.

See also: *Development theory; Reducing.*

REDUCING. Method of lowering the densities in a negative or print. Although this can be done by physical means (Baskett's reducer) it is more common nowadays to use chemical reducers.

Before starting to reduce a negative or print it should be well soaked in water. This ensures that the solutions used will act evenly.

Negatives. All negative reducers decrease the density of the image. At the same time they may also affect the image contrast. There are thus three kinds of reducer.

(1) Subtractive or cutting reducers which remove equal densities of silver everywhere. These decrease density but do not affect contrast.

(2) Proportional reducers which decrease

REDUCTION. Top: *Subtractive reduction decreases density with or without increase of contrast.* Centre: *Proportional reduction reduces density and contrast evenly.* Bottom: *Superproportional reduction mainly affects highlights.*

the image density in proportion to the amount of silver already there. These decrease density and reduce the over-all image contrast of the negative image.

(3) Superproportional reducers which hardly attack the shadow densities, but considerably reduce the highlights.

Subtractive Reducers. Potassium permanganate and concentrated potassium ferricyanide (Farmer's reducer) are both subtractive reducers.

The formula for potassium permanganate reducer is:

Stock solution A		
Potassium permanganate	1 ounce	25 grams
Water to make	20 ounces	500 c.cm.
Stock solution B		
Sulphuric acid, concentrated	1 ounce	25 c.cm.
Water to make	20 ounces	500 c.cm.

The concentrated sulphuric acid must be slowly poured into the water and the solution should be stirred all the time.

Water must never be poured into concentrated acid.

For use, 1 part each of A and B are added to 200 parts of water.

The soaked negative is immersed in this solution until it is sufficiently reduced. It is then rinsed in a 2 per cent potassium metabisulphite solution to remove the purple brown stain, and washed.

The formula for Farmer's reducer is:

Stock solution A		
Potassium ferricyanide	2 ounces	50 grams
Water to make	20 ounces	500 c.cm.
Stock solution B		
Sodium thiosulphate	8 ounces	200 grams
Water to make	40 ounces	1,000 c.cm.

For use, 1 part of A and 5 parts of B are made up to 30 parts with water. This mixture does not keep, and becomes useless in about 15 minutes. Its life can be prolonged by adding about 12 grams (½ ounce) of anhydrous sodium carbonate to every 250 c.cm. (10 ounces) of working solution.

The soaked negative is immersed in the solution and when reduction has almost gone far enough it is taken out and washed. Reduction still carries on during the first few minutes of washing.

A number of other reducers act in the same way—for example, a mixture of equal parts of 0·2 per cent iodine (with enough potassium iodide added to dissolve it) and 0·1 per cent potassium cyanide.

An alternative formula is known as Belitzki's reducer. This is a solution of ferric potassium citrate or oxalate in an acid fixing bath. The Kodak version of this is:

Ferric chloride	1 ounce	25 grams
Potassium citrate	3 ounces	75 grams
Sodium sulphite, anhydrous	1½ ounces	40 grams
Citric acid	¾ ounce	20 grams
Sodium thiosulphate	8 ounces	200 grams
Water to make	40 ounces	1,000 c.cm.

The chemicals must be dissolved in the above order.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Proportional Reducers. Dilute Farmer's reducer acts proportionally. The standard formula given above is used, but the working solution is made up with only about one-tenth the amount of potassium ferricyanide.

The Farmer's reducer may also be used in two separate baths. The negative is first immersed in a 1 per cent potassium ferricyanide solution until sufficiently reduced, and then transferred to a 10 per cent sodium thiosulphate bath for 5 minutes.

An alternative proportional reducer can be made up from equal parts of the potassium permanganate reducer (above) and the ammonium persulphate solution (below).

Superproportional Reducers. A common superproportional reducer is ammonium persulphate.

Ammonium persulphate	60 grains	3·3 grams
Sulphuric acid, 10 per cent solution	200 minims	10 c.cm.
Distilled water to make	4 ounces	100 c.cm.

The ammonium persulphate must be pure; the crystals should crackle as they dissolve. The made-up reducer does not keep, and must be used immediately.

The negatives are immersed in the solution until they have almost been reduced enough. They are then immersed in an acid fixer or a 5 per cent sodium sulphite solution.

When the reducer solution begins to go milky, it should be thrown away and a fresh lot made up.

An alternative superproportional reducer consists of a 0·1 per cent solution of benzoquinone containing 0·3 per cent of sulphuric acid.

Prints. The methods and formulae suitable for print reduction are much the same as used for negatives. The solutions are generally used rather more dilute, because the amount of silver deposit that forms the image in a print is much less than that needed to form a negative.

The action of the reducer must be carefully watched and arrested before it bleaches out all the detail in the highlights and leaves only blank white paper.

Usually badly over-exposed or over-developed prints cannot be saved by reduction, nor is it worth the trouble. It is nearly always quicker and more effective to make a fresh print. Farmer's reducer can, however, be used to clear slightly veiled highlights by immersing the print in a dilute solution for about five to ten seconds.

Another clearing bath which acts more slowly consists of three parts ferrous sulphate and one part each of potash alum and citric acid in twenty parts of water.

Local Reduction. Certain reducers, among them Farmer's, may be applied locally with

a brush to lighten small areas of the print or to pick out highlights. They may even be used to "paint" clouds into an otherwise empty grey sky.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Chemical Spotting. Local reduction is also useful for removing small black spots, etc., as an alternative to scraping them out with a knife. Chemical removal does not damage the print surface in any way, whereas scraping always leaves a roughened patch. Small spots can be erased in this way with a mixture of equal parts of a 5 per cent solution of iodine in alcohol (with a little potassium iodide added to help it to dissolve) and of 10 per cent thiocarbamide in water.

The print is first swabbed over with a plug of cotton wool soaked in alcohol, to remove surface grease. It is then wiped dry with another piece of cotton wool. The reducing solution is applied with a brush, and immediately wiped off with a piece of cotton wool soaked in alcohol.

The process is repeated until the reduction has gone far enough, and the print is finally fixed in an ordinary hypo fixer.

Bleaching. The print image can be completely bleached out—as in making bromoil prints and also in making pen-and-ink drawings from photographs. L.A.M.

See also: *Bleach-out process; Retouching.*

Books: *The Complete Art of Printing and Enlarging*, by (O. R. Croy (London); *Developing*, by C. I. Jacobson (London).

REDUCTION. Term applied to certain chemical reactions in which the electro-positive (usually metallic) component is increased—e.g., exposed silver bromide in a film is reduced by the developer (a reducing agent) to form metallic silver.

In practical photography the same term is also applied to any operation on a negative or print which lowers the contrast of the image or decreases the density of the silver deposit. The object of reduction is to make a very dense negative easier to print, or to lighten undesirably black areas of a print.

Finally, reduction in printing, in copying and graphic arts work applies to reproduction at a scale of less than 1 : 1 or same size. Thus a three times or 1 : 3 reduction means that the copy is $\frac{1}{3}$ the linear size of the original.

The three uses of the term are unconnected.

See also: *Development theory; Latent image; Reducing; Scale.*

REFLECTANCE. The reflecting power of any surface is measured by comparing it with a perfectly white surface such as magnesium oxide which has been deposited as smoke on a polished silver surface. The ratio of the brightness of a given surface to that of magnesium oxide under the same conditions of illumination is called the reflectance value. In calculations it is treated in the same way as transmission—i.e., it may be quoted as a reflection factor or as a percentage reflection or as a reflection density (the negative logarithm of the reciprocal of the reflectance).

REFLECTION. When rays of light fall on a polished surface like that of a mirror or a pool of still water, they are reflected. The optical laws of reflection are important to the photographer who wants, for example, to take pictures in a mirror, or a scene reflected in water. The same laws apply to the use of a reflector for brightening up shadows.

There are three principal laws of reflection:

(1) The angle of incidence is equal to the angle of reflection.

(2) The incident and reflected rays are in the same plane as the normal at the point of reflection.

(3) The image is as far behind the mirror as the object is in front.

Angle of Reflected Ray. A ray of light striking the reflecting surface bounces off the surface and goes away in a new direction. The angle which it makes with the perpendicular to the surface of the mirror before reflection—angle of incidence—is the same as the angle it makes with the same perpendicular after reflection—angle of reflection.

If the ray of light falls on the mirror at an angle of 45°, it will be reflected at the same angle. It will, in fact, be turned at 45° + 45° = 90° to its original direction. (This is the principle of the reflex viewer in which a 45° mirror is used to swing the light coming through the lens from the subject through 90° to make it form an image on a horizontal focusing and viewing screen.)

This law decides the angle at which a reflector must be placed to throw light from a lamp or the sun into the shadow areas of the subject. Although the matt white surface of reflectors used for this purpose scatters much

REFLECTION. A, image. B, reflecting surface. C, object R, angle of reflection. I, angle of incidence. The angle of incidence is always the same as the angle of reflection, and the image is as far behind the mirror as the object is in front.

of the light in all directions, most of the rays behave roughly as though they had been reflected from the polished surface of a mirror.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

To arrive at the correct angle for a reflector, one imaginary line is visualized as coming from the light source to the reflector and another from the shadow area to the reflector. To throw the maximum amount of light into the shadow area, the reflector must be fixed so that both imaginary lines make the same angle with its surface. In addition, the surface of the reflector must be at right angles to the plane in which both imaginary lines lie.

Position of Reflected Image. When photographing an image reflected in a mirror or a sheet of water, the lens must be focused on the image and not on the reflecting surface. And the image lies as far behind the reflecting surface as the mirrored object lies in front of it. So that the actual distance on which the lens must be focused to reproduce the image sharply is the sum of the distance from the camera to the mirror and the mirror to the object.

A photographer may want to make a self portrait by taking his reflection in a mirror. If he and his camera are 4 feet in front of the mirror, his image in the mirror will be 4 feet behind the mirror, and he will have to focus at 8 feet. F.P.

See also: *Mirror photographs.*

REFLECTIVITY. Term applied to the ability of a surface to reflect light incident on it—the ratio between the intensities of the light before and after reflection. The figure varies with the nature of the surface and also with the direction in which the intensity of the reflected light is measured.

REFLECTOR

A lamp normally gives out light in all directions and unless something is done to control it, only a part of the light falls on the subject while as much, or more, is wasted. In practice the lamp is equipped with a suitably-shaped reflector which intercepts most of the rays of light travelling away from the subject and sends them back and distributes them in the desired direction.

According to the shape and size of the reflector, the light may be spread to give general illumination or concentrated to brighten a small area of the subject.

Surface. Reflectors are usually made of metal to withstand the heat of the lamp.

The surface may be highly polished, in which case it behaves like a mirror, or matted. A polished surface gives a hard light which casts sharp-edged shadows; a matted surface gives a soft diffused light with blurred and more luminous shadows.

Shape. The shape and size of the reflector decide how much of the light is concentrated usefully on the subject. A flat surface simply throws back the light in a spreading beam radiating outwards as though from an imaginary lamp as far behind the reflector as the real lamp is in front. Reflectors of this kind, consisting of a flat, white-painted or silvered board or stretched sheet are used near the subject for lighting up shadow areas; they are not used as lamp reflectors. Flat reflectors of this type are used outdoors in motion film production.

Lamp reflectors are always curved towards the light source. Three principal types of curve are employed—spherical, parabolic, and elliptical. In each case, the name indicates the shape of a cross section through the middle of the reflector.

A spherical reflector is used to produce a broad spreading beam for general illumination of the subject. This is the form chosen for flash and Photoflood lamps used as flood or fill-in lights.

A parabolic reflector is mostly used to give a fairly parallel beam of light for illuminating only a part of the subject or for illuminating the whole of a distant subject. Theoretically, a point source of light placed at the focus of a parabolic reflector gives a parallel beam of light of the diameter of the reflector.

An elliptical reflector gives a converging

REFLECTOR SHAPES. The lamp in each case is at the focal point. **Left:** *Spherical reflectors diverge and to some extent diffuse the light.* **Centre:** *A parabolic reflector produces a parallel beam.* **Right:** *An elliptical reflector produces a converging beam. In practice reflectors do not behave in this precise fashion, because of the finite size of the light source.*

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

REFLECTOR EFFICIENCY. The efficiency of a reflector depends on the angle subtended at the lamp. As the focus increases, the collection angle drops, and to maintain the same efficiency a larger reflector is required.

beam when the lamp is placed at one of its focal points (the light converging to the other focus). This type of reflector is used for concentrating the light on to a relatively small area, e.g., for illuminating the negative in an enlarger or projector.

But the performance of any one of these reflectors depends on a number of other factors. If the distance of the light source from the reflector is increased, the reflected beam tends to become narrower; if it is shortened, the beam tends to broaden. And even when a beam converges to a point in front of the reflector, it crosses and spreads out after passing through the point, so that although the reflector is of the converging type, the beam it finally produces may be diverging.

Size. The amount of light thrown back by the reflector depends upon how much of the light emitted by the lamp it intercepts. A reflector close to the lamp will intercept more of the light than one farther away.

So the closer the lamp is to the reflector, the smaller will be the reflector needed to throw back a given proportion of the light emitted by the source.

But there are disadvantages in using a small reflector with a short focal length close up to the lamp. A curved reflector will not give evenly distributed illumination unless it is used with a point source of light. The source provided by the normal filament lamp is either an incandescent ring (sometimes a grid) at least 1 in. across (if the bulb is clear) or a luminous opal or frosted bulb of 2 ins. or more in diameter.

Neither of these can be regarded as a point source, but for practical purposes they can be treated as such so long as the focal length of the reflector is large in relation to the size of the source. But as the focal length of the reflector is reduced, the effect of the size of the light source becomes more and more noticeable.

In general, the size of the light source is kept as compact as possible and used in conjunction with the largest convenient reflector. These dimensions are only important for the type of hard lighting given by an approximately point-sized light source and a highly polished curved reflector, e.g., as in projectors, spotlights, and some types of enlarger. Where the light can be more or less diffused however—e.g. for general subject lighting—it is easier to obtain an even flood of light by using frosted or opal lamps in matted reflectors. With this kind of set-up, there is no need for accurate centring or focusing of the lamp, and the exact shape of the reflector is less critical.

In enlarging and projecting apparatus, the reflector is usually a separate (often optically worked) component of silvered glass or metal, but in units for general lighting it is usually shaped to incorporate the lampholder, No adjustment of the relative positions is then possible.

The shape of the reflector as seen from the front is not always a circle. Other shapes are also used—e.g. the square types made to work

LAMP POSITION. Left: When the lamp is moved away from the reflector, the rays converge. Right: Moving the lamp towards the reflector makes the rays diverge. When the lamp is at the focal point of the reflector, the rays are more or less parallel. In practice the effect is less precise, and converging rays cross and produce a diffused light.

side by side, and the long, trough-shaped reflectors made to house tubular lamps.

Folding and Collapsible Types. Reflectors are always a problem when lighting equipment has to be carried about, and several attempts have been made to make them fold or collapse into a smaller space.

One form of collapsible reflector is constructed in the form of an umbrella top without a stick, silvered on the inside. This is commonly used by cinematograph crews on location work; it is too heavy and bulky for normal photographic use.

The normal studio lighting reflector is too awkward for use with small portable flash units so accessory manufacturers have developed various types of collapsible miniature reflector. The simplest of these are the folding reflectors made from segments of stiff card faced with metal foil. These open out to form a shallow cone which reflects a broad flood of light from a lamp mounted at the approximate focus. More accurate reflectors are made from thin blades of polished metal pivoted at one end so that they open up and close like a fan. The blades are shaped and bent in a curve so that they form a fair imitation of a parabolic or spherical reflector.

Large reflectors of this type are expensive to make but they are a practical proposition in the small sizes fitted to the miniature flashguns made for midget flashbulbs. Some cameras with built-in "pop-up" flash guns may use this type of reflector; others house the bulb in a small box-shaped reflector which retracts into the camera body without folding or collapsing.

Quartz-Iodine Lamp Reflectors. Quartz-iodine lamps have a much smaller diameter than a normal filament lamp of the same power and the light source itself is much more concentrated. With a source of this type it is possible to mount a small, deep and accurately shaped reflector close to the source. Accuracy of positioning is important, for maximum efficiency, so some manufacturers market quartz-iodine lamps complete with reflectors in a sealed beam unit. This kind of reflector directs the light with much greater precision so that it spreads evenly over the subject area without spilling a large proportion of it uselessly outside the field of the lens. In addition the whole lamp-reflector assembly is so much more compact that it can even be mounted on the camera accessory shoe. However, the lamp and reflector get very hot and need to be handled with respect after being switched on for even a short time.

Multiple and Special Types. For studio flood lighting whole banks of lamps are often fitted inside a large trough-shaped reflector. This gives even and well diffused over-all illumination.

Where highly localized light is required without the harsh character of a spotlamp, a deep reflector may be employed. That consists in effect of a normal spherical reflector with a long tube added to it (although in fact the whole unit may be made in one piece). The tubular part confines the light to a small area, the size depending on its distance from the source.

A series of separate reflectors arranged in a ring round the camera lens and pointing at the subject will yield completely shadowless illumination. As an alternative the individual

SPILL RINGS. Two or three concentric rings, painted dead black and placed in front of the lamp, intercept and cut out angular rays. This produces a well-defined beam.

lamps can be fitted in a ring-shaped reflector. Similar ring reflectors are available for quartz-tubular lamps.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Spill Rings. The shape and position of the reflector can be arranged to produce a more or less concentrated area of light on the subject, but the lamp itself sends out direct rays that spread over a much bigger area.

These direct rays are often undesirable but they can be controlled by mounting concentric "spill rings" of blackened metal in front of the lamp.

Spill rings, in proportion to their number and depth, absorb the undesirable wide angle rays emitted by the lamp but allow the useful direct and reflected rays to shine on to the subject. Occasionally a hemispherical metal cap is mounted in front of the lamp. It serves a similar purpose except that it cuts off all the direct rays from the lamp whether they are useful or not, and allows only a flood of reflected light to reach the subject. F.P.

REFLEX ATTACHMENT. Focusing device available as an accessory for certain miniature cameras which take interchangeable lenses. It converts the camera into a single lens reflex camera, and thus permits direct focusing of the image on a ground glass screen. This is of great assistance in telephoto work, close-up photography, and photomicrography where accurate focusing is essential.

Separate reflex viewing and focusing units are also available for cameras with non-interchangeable lenses; these are, however, independent viewfinders and not reflex attachments proper, nor do they necessarily show the exact image as seen by the camera lens.

Construction. The reflex attachment is constructed on the lines of a single lens reflex camera but without provision for holding any film. It fits on to the front of the camera and incorporates a movable mirror which deflects the light forming the image on to a ground glass screen in the top of the housing. The distance from the mirror to the screen is exactly equal to the distance from the mirror to the focal plane of the camera. For that reason a reflex attachment has to be specially designed or adapted for use with a particular camera. The front of the attachment carries a bayonet or screw mount for the lens.

REFLEX VERSATILITY. For maximum adaptability, some reflex attachments provide for interchangeable viewing eyepieces. These permit waist-level or eye-level examination of the image, and may incorporate a pentaprism unit to present the screen picture the right way round. Magnifiers up to 30× are also available for specially exact work.

Viewing. The image on the ground glass screen is observed through a focusing magnifier. Several types are often interchangeable on one and the same reflex housing. The usual magnification is 4× to 5×, but special fine focusing magnifiers are also available with a magnification of 20× to 30×. Other types are:

Vertical magnifiers which serve for observation of the image from above, i.e. for waist-level viewing. These form an upright but laterally reversed image.

Inclined 45° magnifiers for eye-level viewing which incorporate a second mirror or a prism system above the ground glass screen. These form an upright image which may be laterally reversed or (if a pentaprism is used) right-way-round.

Right-angle 90° magnifiers are similar to 45° magnifiers in principle, but suitable for eye-level viewing only. The reflecting system above the screen may be a simple mirror forming a laterally reversed image, or a pentaprism to show a right-way-round image.

Exposure. For exposure, the mirror of the housing is swung out of the way, and the camera shutter released. Some reflex housings use a prism which is moved vertically out of the way.

The movements of the mirror and the camera shutter can be coupled to a common release cable by a special link, or by a cable coupler which takes two separate cable releases and operates them together. The release must be so adjusted that the mirror swings completely clear of the optical path before the shutter starts to open.

On some attachments the mirror swings out

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

REFLEX VIEWING. of the way on pressing the release, and moves back again after the exposure. On others the mirror has to be re-tensioned or brought back to the focusing position every time.

Some reflex attachments incorporate special refinements, such as filter turrets and rapid focusing mounts. The former consists of a large rotating disc carrying several filter-apertures which are switched into the optical path between the lens and the reflex housing. This has two advantages. Firstly, it permits the use of one set of filters with a range of lenses. Secondly, changing filters becomes a much quicker matter than attaching them and detaching them in turn from the front of what may be a fairly long lens barrel.

The rapid focusing mount is a device for moving the lens in and out in a sleeve by means of a lever or other system. It provides a quick transition from sharp to unsharp and also enables the lens to be focused much more rapidly than with the usual screw mount. Preset click stops in this focusing movement may be provided to set the lens instantly to any preselected distance.

Close-up Work. The reflex attachment occupies some space between the camera flange and the lens mount, and so acts as an extension tube. It is thus specially suitable for close-up work with the standard, medium long focus, and wide angle lenses of the miniature camera to which it is fitted. The image is focused in the normal way by means of the lens mount, as on the camera.

As the extension is fixed, the range of subject distances is limited. It may however be increased by additional extension tubes, or by adding a bellows extension unit.

The image scale depends on the focal length of the lens and on the depth of the reflex housing.

Telephoto Work. Long-focus and telephoto lenses have to be specially matched to the reflex housing to allow for the depth of the housing and thus permit focusing at infinity. Most telephoto lenses designed for use with such attachments have a shorter barrel than would be necessary when using the lens directly on the camera. Since such telephoto lenses are almost exclusively used only with the reflex attachment, this short barrel is a standard fitting, and a special compensating extension tube is available when the lens is mounted directly on the camera.

Photomicrography. The reflex attachment permits direct screen focusing also when used in conjunction with a microscope adaptor for photomicrography. A refinement for this purpose is a clear glass screen in place of the ground glass for fine focusing. The two screens may be interchangeable, and in one model at least they are mounted in a rotating holder for instant changing over. The ground glass screen is used at low magnifications and the clear glass screen at higher magnifications or when the grain of the ground glass becomes disturbing. The viewing magnifier of the reflex housing is first focused on a set of cross-wires engraved on the clear screen, to permit accurate observation of the aerial image.

Reflex Attachments for Fixed-lens Cameras. Designs have also been patented for reflex attachments to be used in front of a camera lens, e.g. where the camera lens is not interchangeable. The purpose of such an arrangement is to permit working with alternative focal lengths provided by afocal attachments in the front of the housing. The reflex attachment must in this case also incorporate in the finder position an optical system corresponding to that of the camera lens. The focusing screen is placed behind this optical unit. The screen then shows the image in the same way as it would appear on the film in the camera. L.A.M.

REFLEX CAMERA

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Type of camera incorporating a ground glass screen on top of the body which receives an image via a 45° mirror. It has been popular since the beginning of the century. Like the miniature camera, the stereoscopic camera, and the field camera, the reflex camera has its own circle of devotees to whom it is the ideal instrument. There have been two major modifications of this original pattern, so that there are now two distinct types: the single lens reflex (the original type) which includes the modern miniature reflex, and the twin-lens reflex. Each of these has developed along its own lines and possesses special advantages not shared by the others.

SINGLE LENS REFLEX

In the single lens reflex, the image is formed by the taking lens on a ground glass screen on top of the camera. The subject can be viewed and focused right up to the instant of exposure. The image on the screen is seen upright, free from parallax error and in the actual size it will appear on the negative, although laterally everything is reversed from left to right.

Large Size Reflexes. Most of the original large single-lens reflex cameras were of the rigid box form. The film or plate is housed at the back of the box, with usually a focal plane shutter immediately in front of the negative. The front of the box forms the lens panel.

Between the lens and the film is a movable mirror which can either lie flat against the top of the box, or swing down to lie at an angle of 45°. When the mirror is lowered it reflects the rays of light that come through the lens, on to a sheet of ground glass set in the top of the box. When the mirror is raised, it covers the underneath of the ground glass screen and the light from the lens falls on the surface of the plate or film in the back of the camera. The position of the mirror is so arranged that when an image is focused on the screen with the mirror lowered, the same image falls into focus on the plate or film when the mirror is raised out of the way.

Pressure on a lever on the outside of the camera raises the mirror. At first the light falls only on the blind of the focal plane shutter, but as the mirror reaches the limit of its travel it presses against a stop which releases the shutter and makes the exposure.

Shutter. Nearly all reflex cameras have self-capping focal plane shutters. These shutters generally give instantaneous speeds down to 1/10 second with Time and Bulb settings. Some of the smaller models—in particular, the miniature reflexes—have shutters that give a range of slow speeds, and have a built-in delayed action release for self portraiture.

One great advantage of the reflex camera is that it will take any lens whose focal length can be accommodated within the dimensions of the camera. This is because the image is focused visually and not by scale. So it can be used with long or moderately short focus lenses, the correct camera extension being given by sunk mounts to bring the lens nearer to the plate and extension tubes to take it farther away.

A reflex camera is naturally used most for subjects which move about and do not allow any time for slow methods of focusing. For this reason reflex cameras are fitted with fast lenses—generally with an aperture of *f* 4·5 and never less than *f* 6·3. The lens is often sunk into the front panel and on old types is covered by a hinged flap. This acts as a sunshade when it is raised to uncover the lens.

Focusing System. In the standard form of reflex camera the lens panel is joined to the body by a short bellows and can be racked out for focusing by turning a knob on the side of the camera. The image appears full size and right-way-up on the focusing screen, and it can be arranged and sharply focused right up to the instant of exposure.

One great disadvantage of reflex focusing shows itself when the lens has to be stopped down. At such times the image on the screen is very difficult to see and often impossible to focus. To get over this difficulty the screen is always fitted with a deep collapsible hood to shield it from the light. Often the hood is extended to reach right up to the eyes of the user.

Formats. Up to about 1930, the most popular format for reflex cameras was undoubtedly the quarter plate size (3¼ × 4¼ ins.). A few were larger than this, but the general trend was towards a less cumbersome size. The first move in the direction of smaller reflexes was the 2¼ × 3¼ ins. roll film camera. This had the disadvantage that the user had either to be satisfied with the normal horizontal format or indulge in acrobatic contortions to hold the camera on its side when he wanted to take vertical pictures. One way of avoiding this was the fitting of a revolving back. The arrival of the 2¼ × 2¼ ins. format solved this problem more easily and reduced the reflex camera to reasonable proportions.

Today, most roll film reflex cameras are made to take a 2¼ ins. square picture. There are also an appreciable number of miniature reflexes that use 35 mm. film.

Focusing Magnifier. The difficulty of focusing the much smaller image was overcome by a built-in focusing magnifier or by substituting a picture-size plano-convex lens for the focusing screen. The lower flat surface of the viewing lens was ground and the image focused on it was automatically magnified.

Eye-level Operation. The bulkier types of reflex are only designed for operation at waist-level with the observer looking down into the

CC-0. Agamnath Digital Preservation Foundation, Chandigarh

screen. For this purpose the camera is generally equipped with a sling so that it can be hung from the user's neck. By mounting it on a tripod and substituting a focusing screen for the plate holder, of course, this type of reflex can be operated and focused like an ordinary stand camera. But the reflex focusing can only be used at or near waist level.

The smaller types of reflex—i.e., those of 2¼ ins. square and smaller formats—are light enough to be held at eye level, and cameras of this class always incorporate some kind of eye-level viewfinder. This may be no more than an open frame finder which folds into the screen hood when not in use. For fast-moving subjects this finder has the advantage that the subject is viewed the right way round and is not dimmed when the lens is stopped down. But it has the disadvantage of dispensing with the reflex screen except for preliminary focusing.

There is another type of eye-level finder which may be fitted instead of or in addition to the open frame type. This consists of a mirror in the screen hood which can be set at 45° to the reflex screen. By holding the camera at eye-level and looking at the mirror, the user sees a reflection of the image on the focusing screen so he can compose and focus right up to the instant of exposure.

The system has the disadvantages associated with the normal reflex focusing screen but in this case the image appears upside down—definitely a further handicap. None of these disadvantages is present in the miniature single lens reflex cameras specially designed for eye-level operation.

Rollfilm Reflexes. The first rollfilm reflex cameras were little more than scaled-down versions of the larger types. Later they were equipped with more accurate shutters and a degree of automatic diaphragm control.

In appearance, current rollfilm single-lens reflexes follow three main patterns, all based on the more or less square box housing the mirror and optical system. The first pattern has the film chambers arranged to each side of this box, thus providing a convenient way of gripping the camera. The film there runs from side to side, and the transport and shutter (if focal plane) controls are ranged on top of the body. The second pattern has the film running vertically between chambers above and below the mirror box. There are thus no protrusions at the side, the camera is slightly more compact, and shutter and transport controls are mounted in the sides of the body. The third arrangement houses the film and transport elements in a separate magazine which attaches to the rear of the camera. This makes the camera body still more compact, and provides interchangeability of film magazines.

Basically the viewing and focusing arrangement is a waist-level screen with folding hood. Frequently this is removable and can be replaced by an eye-level mirror or pentaprism unit. Special focusing attachments with extra powerful magnifiers, etc., are often available.

Most rollfilm single-lens reflex models have a focal plane shutter; some use a diaphragm shutter built into the interchangeable lens.

Miniature Reflexes. The earliest 35 mm. reflex cameras were more or less scaled-down versions of the first design pattern mentioned above for rollfilm reflexes. This shape—with the film chamber and transport systems to each side of the reflex housing—is still the almost exclusive design pattern for 35 mm. single-lens reflex cameras.

The first models of this kind also featured only waist-level ground glass screen focusing. Present day 35 mm. reflexes usually have either an interchangeable finder system to permit waist-level or eye-level focusing, or a permanently built-in eye-level pentaprism unit.

The distinguishing principle of this system is that the image is viewed and focused at eye level through an eye piece which is an integral part of the construction. The eye-piece is a magnifier which gives an enlarged picture of the image formed by the lens.

The ground-glass screen image is reflected by a double mirror system so that it appears upright, though the two mirrors by themselves still show it reversed left-to-right. Most modern eye-level reflexes use a pentaprism with three reflecting surfaces which turn the image upright as well as right-way-round. As the prism is in one piece, it is easily made with a high degree of accuracy, and the reflections do not get out of alignment. Frequently the lower surface of the pentaprism itself acts as the ground-glass screen.

The image is not always formed on a ground glass screen. All or part of the picture may be focused as an aerial image with the aid of a high-power magnifier. This is useful in photomicrography and other specialized applications.

The focusing screen frequently is not ground glass at all, but plastic with a microscopic embossed regular grained texture. This scatters less light than the ground glass, leading to brighter images and greater visual sharpness. The focusing screen may also incorporate a Fresnel field lens (frequently embossed into the same plastic plate) which ensures even visual brightness of the whole image. To increase the brilliance of the screen still further, the greater part of it outside a central area may be clear (without a focusing surface) altogether. Then the centre portion carries either a matted focusing surface or a split-image wedge acting as a rangefinder and surrounded by a focusing screen ring. Within the area of the wedge the unsharp image is split and the two halves displaced relative to each other, as in a split-image rangefinder. When these images line up accurately, the lens is sharply focused on that part of the subject.

An elaboration of this principle is the use of reticular or other patterns in the central area of

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

MINIATURE REFLEX CAMERA. The built-in pentaprism system of this 35 mm. model presents an upright and right-way-round image. The pentaprism is however interchangeable against a waist-level finder which shows the image—reversed left-to-right—on a screen which is viewed from above through a magnifier. The screen is usually partly clear, partly ground glass or grained plastic, and incorporates a pair of crossed wedges acting as a split-field rangefinder. On this camera the screen is also interchangeable, permitting the use of a clear screen, a fully ground screen, etc. Most miniature reflexes have interchangeable lenses and may feature either a diaphragm or a focal plane shutter. Usually also the lens aperture is fully open for accurate focusing and viewing, and closes down automatically to a pre-set value on releasing the shutter. Top left: General view of camera with waist-level finder against a 1-in. scale grid. Top right: Top view with waist-level finder. Centre left: Section through optical system of camera. Centre right: Front view of camera with eye-level pentaprism finder. Bottom right: Interchangeable pentaprism and waist-level finder units and interchangeable screen unit. Simpler 35 mm. reflex cameras have a fixed eye-level pentaprism unit, a more restricted range of interchangeable lenses (or none at all) but frequently a built-in exposure meter.

the focusing screen. These break up the image when it is not sharply focused (visible especially by the jagged borders of what ought to be straight lines). When the image is sharply focused in the plane of the screen it abruptly becomes smooth and continuous, while the reticular pattern disappears.

CC-0. Arvind Gupta. Digital Preservation Foundation, Chandigarh

While the finder screen of a single-lens reflex shows the image without any parallax error, the view on the screen does not necessarily correspond as exactly to the image on the film, as camera advertisements tend to claim. The positioning of the mirror and the framing of the screen may introduce both centring and alignment errors (picture centre not corresponding to screen centre and tilted screen image). Further, most 35 mm. single lens reflexes show slightly less on the screen than they record on the film. This is intended as a safety margin with colour transparencies which are mounted in slide frames with a slightly smaller image opening than the size of the film frame.

A number of miniature reflex models have coupled or automatic exposure meter systems, with shutter or diaphragm automation. The exposure meter is mostly mounted on the camera front (frequently in the front of the pentaprism housing). Several models exist with the meter cell inside the camera—either built into the mirror or at some position in the finder system where it receives a representative sample of the light that makes up the image. Unless the meter cell measures the light in a plane equivalent to the image plane, such measurements may be subject to inconsistent errors when lenses of different focal length are used.

Mirror Systems. The conventional arrangement is for the mirror to be hinged along its top edge, so as to swing between two fixed positions: up against the underside of the focusing screen and down on to a fixed mechanical stop during viewing and focusing. This mirror movement requires a certain amount of space, and so the lens of a single-lens reflex must have a sufficient back focus to clear the mirror movement.

Various systems have been tried to reduce the clearance required. One of the earliest consists of supporting the mirror along its horizontal centre axis, and swinging it back and up rather than hinging it at the top. More modern designs involve systems where the mirror drops down into the bottom of the camera housing, or folds up along its middle. In both these cases a separate means of obscuring the underside of the focusing screen (e.g. by a roller blind shutter) are required. Alternatively—especially with eye-level reflex models—an auxiliary shutter may close the finder eyepiece.

Another variation, used in certain 18 × 24 mm. miniature reflexes, is a sideways mirror movement. Since the 18 × 24 mm. image is upright in the camera, this movement along the long side of the negative takes up less space. The viewing image is then redirected by a more complicated system of reflectors. Equally, it is possible to replace the mirror movement by a sliding prism which moves out of the light path before the exposure.

Two other unusual designs that have been used involve directing the light downwards on to a focusing surface in the bottom of the camera through a semi-reflecting mirror; this surface is then observed by a special optical system in the top of the camera. Some miniature reflex cameras even dispense with a movable mirror altogether, and instead incorporate a beam splitter in the optical system of the lens. This directs part of the light into the finder system, and has the advantage that there are no moving parts between the rear of the lens and the film.

In both the last-named systems only a part of the light reaches the finder, and would on a normal focusing screen yield a very dim image. For that reason optical split-image focusing arrangements which do not present a visually unsharp image at all may be used; since these do not involve the loss of light due to a diffusing focusing screen, the image is sufficiently bright for visual observation. .

In many reflex cameras the mirror is moved out of the way by a spring which is released immediately before the shutter runs down. The mirror there has to be retensioned before every exposure (and in fact before the image can be observed again on the screen). On most modern roll film and miniature reflexes this retensioning movement is coupled with the film transport and shutter tensioning. A spring-loaded mirror movement may sometimes cause some camera shake owing to the "kick" of the mirror as it slams out of the way. High-class designs often balance the mirror movement in such a way as to reduce the momentum of the mirror on impact as far as possible.

Many current miniature (and also some roll film) reflexes feature an instant-return mirror. The mirror there flips back immediately after the exposure, so that the screen image is visible again within a fraction of a second. That almost eliminates the sometimes disturbing image blackout.

The mirror may also be swung out of the way by the mere pressure on the camera release rather than by a spring. That virtually eliminates any "kick", and the mirror returns again into its viewing position once the pressure on the button is released after the exposure. However in this case the travel of the release, and the mechanical pressure required on it, are greater; also if the release is pressed slowly the screen image may disappear a second or two before the actual exposure.

On cameras with a focal plane shutter the protection of the film against light during viewing and focusing raises no special problems: the shutter covers the film at all times except dur-

TWIN-LENS REFLEX CAMERA. Most twin-lens reflexes have a pair of matched viewing and taking lenses mounted on a common panel. Both lenses move together in focusing so that when an image formed by the viewing lens is sharp on the screen, the corresponding image produced by the taking lens on the film will also be sharp. Lenses are not usually interchangeable, but afocal attachments may be available for wide-angle and telephoto pictures. Most twin-lens reflexes take 12 exposures 2¼ × 2¼ inches on standard size 120 roll film; alternative smaller picture formats may be available. On the most advanced models loading as well as counting of the exposures is automatic. ing the actual exposure. With a diaphragm shutter the design requirements become more complex, since the shutter must be open for viewing and focusing, but still let no light through to the film. This is achieved by a more involved shutter cycle and by the provision of a special capping plate or capping shutter which closes the film aperture in the back of the camera. The shutter cycle provides a possibility of continuous opening (for viewing and focusing) and normal opening and closing to control the exposure. During viewing the shutter is open (and the lens diaphragm fully open as well—see below), but the capping plate or shutter closed. On pressing the release button to make the exposure, the shutter closes, the lens diaphragm closes down to a preselected aperture, the mirror and capping plate (which is also hinged) swing out of the way, and the shutter opens and closes again for the actual exposure. The capping shutter may also be a roller blind type immediately in front of the film, and open once the mirror has swung up, just before the main camera shutter opens.

The mechanical movements to get the camera ready for the next exposure are then usually coupled with the film transport mechanism. Winding the transport closes the capping shutter or plate, brings down and tensions the mirror movement, and tensions and opens the shutter (and usually also the lens diaphragm) for viewing and focusing. Although the release cycle is fairly complicated, its various phases are automatically interlinked so that the delay between firing and opening of the shutter for the exposure is as little as 1/50 second with miniature reflexes.

Lenses for Single-lens Reflex Cameras. Camera models with a focal plane shutter permit almost unlimited interchangeability of the lens. The only restriction is that the back focus (distance from the rear of the lens to the image plane) must be sufficient to clear the mirror movement. This presents little difficulty with normal to long focus lenses; wide-angle lenses usually have to be of a special design (so-called inverted telephoto or retrofocus types) which have a back focus greater than the nominal focal length. With wide-angle lenses the screen image may also show some vignetting, since the mirror is usually proportioned to cover just the cone of light rays from the standard lens. The vignetting often improves or even disappears at small lens apertures. The film however always shows the full field of the lens.

Roll film reflexes with diaphragm shutter and interchangeable lenses may have a separate shutter built into each lens. Miniature reflexes usually have the lens mounted interchangeably in front of the diaphragm shutter (which limits the usable range of focal lengths) or may use convertible lens systems where the rear unit of the lens is built into the shutter and only the front half is interchangeable to provide alternative focal lengths.

To keep the lens at full aperture for focusing, yet to permit instant stopping down for the exposure, the lenses usually have a pre-selector iris system. The aperture required is preselected without stopping down the lens. Pressing the shutter release then automatically closes the stop down immediately before moving the mirror out of the way and making the exposure. Where the lens is interchangeable and has its own iris diaphragm, this movement may be controlled by an internal link between the camera and the lens or by suitably disposed twin releases. Long focus lenses frequently have simpler pre-set diaphragm systems.

Scope. The single lens reflex is at its best in child and animal photography: because children and animals will not stay still and are difficult to keep in focus with an ordinary camera; the camera usually has to work close up, when parallax can cause difficulties and there is very little depth of field to play with.

Single lens reflex cameras are also much used by naturalist photographers for close-up pictures of botanical subjects in the field.

TWIN LENS REFLEX CAMERA

In a twin lens reflex camera two lenses are mounted one above the other; the upper lens is used for viewing the subject and the lower for taking the photograph.

There is a mirror fixed at 45° behind the upper lens. Light passing through this lens is reflected upwards by the mirror on to a horizontal ground glass focusing screen set in the top of the box.

A partition shuts off the mirror chamber from the camera proper below. Light passing through the lower lens falls on the surface of the sensitive material—generally roll film—in the back.

The focal lengths of upper and lower lenses are accurately matched and both lenses are mounted on a common panel. This panel can be racked out by a knob on the side of the camera. As the knob is turned to bring the visible image into focus on the screen, the image formed by the lower lens is automatically focused on the surface of the film.

So a twin lens reflex allows the subject to be arranged and sharply focused up to and at the actual instant of exposure. The image on the screen is full size and right way up, but it is reversed from right to left.

Construction. The body of the camera is usually a rigid alloy die-casting with a removable back for film loading. Most models take roll film. In some types the film back can be replaced by one which takes a focusing screen and plates or 35 mm. film.

The lens panel is connected to the body by a light-trapped sleeve that takes the place of the bellows in the conventional camera.

A collapsible hood is normally fitted to shield the focusing screen from extraneous light. This folds down and protects the screen

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

SINGLE-LENS ROLL FILM REFLEX CAMERA. Most cameras of this type are individual designs; typically they take 12 exposures 2¼ × 2¼ ins. on standard size 120 film. The shutter may be a between-lens or a focal-plane type, lenses (and frequently the finder system) are interchangeable and refinements may include interchangeable magazines, plate backs, etc. Top left: *General view of camera against a 1-in. scale grid.* Top right: *Top view.* Centre left: *Side view.* Centre right: *Optical path during viewing and during exposure (with the mirror swung out of the way).* Bottom Left: *General view of an alternative (and older) design against a 1-in. scale grid.* Bottom centre and right: *Top and front views (the latter without lens) of alternative design.*

when not in use. There is also usually a magnifying lens hinged to the hood. This lens can be swung over the focusing screen to give an enlarged picture of the image (or at least the centre of the field) for critical focusing.

With some models, the hood, when erected, can be converted into a frame type viewfinder.

The hood may also have a built-in hinged mirror which, when swung down, permits observation of the screen at eye level (but upside down) through a viewing eyepiece in the back of the hood.

On some modern twin-lens roll film reflexes the whole hood is removable and can be replaced by an eye-level pentaprism viewing unit.

Parallax Error Correction. Because of the vertical separation between its taking and viewing lenses the twin lens reflex suffers from parallax error. The error is negligible at distances beyond about seven feet, but for distances less than this, and particularly for close-ups, most manufacturers provide some form of correction. The correction is automatic in some cameras; in others it calls for a separate adjustment at the time of taking. Where there is no form of correction the user must make his own allowance.

Lenses. The taking lens usually has an aperture of $f3{\cdot}5$ or larger, and the viewing lens, not having to be so highly corrected, has a still bigger aperture—often as much as $f1{\cdot}9$—to give a bright picture on the screen.

Supplementary lenses can be used with a twin lens reflex so long as the viewing lens is fitted with a supplementary lens identical with the one on the taking lens. Most of the better cameras include a range of matched pairs of supplementary lenses among their accessories. When close-up lenses are used the parallax error must be allowed for.

Interchangeable lenses are comparatively rare, since this involves making the whole front panel with the matched viewing and taking lenses and the camera shutter a removable unit. Cameras where this is possible have an extended focusing movement (usually with bellows) to accommodate a reasonable focusing extension for the longest focal length available (usually about 180 mm.). Since the taking lens is removed together with its shutter, there must also be a secondary shutter to protect the film from light during lens changing.

An alternative system is the use of afocal attachments which fit in pairs in front of the viewing and taking lenses and convert the latter into wide-angle or telephoto units. The range of focal lengths possible in this way is limited.

The standard focal length for a $2\frac{1}{4} \times 2\frac{1}{4}$ inch twin-lens reflex is about 75 to 80 mm. Special models also exist with a permanently built-in wide angle-lens (around 55 to 60 mm.) or long-focus lens (135 mm. or more). These are generally used for special professional purposes.

Shutter. Most twin lens cameras have a between-lens shutter, and the usual iris diaphragm on the taking lens—the viewing lens is of course open at full aperture all the time. The better cameras are often designed so that the shutter and the diaphragm settings can be read from above with the camera in the working position. Older twin lens roll film reflexes exist with a focal plane shutter.

Focusing. The brilliant image is seen in full picture size on the screen and it is brought into sharp focus by turning the focusing knob on the side of the camera.

The system has one disadvantage; as the viewing lens works at full aperture, it gives no indication of the depth of field covered by the taking lens. Because of this, twin lens cameras usually carry a depth of field table engraved on a metal plate attached to the back of the body or a depth of field scale engraved around the focusing knob.

Refinements. On the better cameras film transport and shutter cocking are interlocked and sometimes operated by the same lever or handle. One or two manufacturers have produced folding models to reduce the bulk of this type of camera. A number of twin-lens reflexes have built-in (sometimes coupled) exposure meters.

Adapters are made to permit the camera to be used for stereoscopy, photomicrography, copying, and similar specialized subjects. Shutters are generally synchronized for flash photography. Other adapters equip the camera for taking plates and 35 mm. cine film.

Formats. The most popular picture size is $2\frac{1}{4} \times 2\frac{1}{4}$ ins. (6 × 6 cm.); a few models use $1\frac{5}{8} \times 1\frac{5}{8}$ ins. (4 × 4 cm.) or even 24 × 36 mm. Several models provide alternative picture sizes from 24 × 36 mm. up to $2\frac{1}{4} \times 2\frac{1}{4}$ ins. on one size of roll film. Special models, mostly for studio portraiture, also exist in formats up to about 4 × 5 inches. These usually take sheet film or plates.

Scope. Twin lens reflex cameras are almost universal in their uses, with a particular bias towards genre, where their ability to focus moving, unposed figures and arrange the subject accurately in the picture space excels even the camera with coupled rangefinder focusing. At the same time, the sheer ease of focusing prompts their use for a lot of landscape and pictorial still-life that would normally call for the field camera. Twin lens reflexes are for this reason popular for illustrating travel articles and compiling picture series sequences.

Limitations. The twin lens reflex, like every other type of camera, has its characteristic limitations. Firstly, there are very few interchangeable lens cameras of this type, as the focusing movement is insufficient to cover wide angle and long focus lenses and also because both viewing and taking lenses would have to be changed.

In addition, the usual waist-level viewpoint tends to make the sitter's chin and lower jaw in portraits more prominent, and the foreground excessive in landscapes.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

At the same time, the fact that the viewing and taking lenses are so far apart gives the camera a parallax error that no form of compensation can completely counteract.

Further, the twin lens reflex is both heavy and bulky to carry around because it consists practically of two cameras. It is difficult to make it fold up with the extra complication of the reflex mirror mechanism. There have been successful folding twin-lens reflex cameras, but all modern models are rigid.

In addition it is not possible to equip it with many of the camera movements that are desirable for architectural and other work where it may be necessary to correct perspective distortion and provide special depth-of-field control.

Nevertheless, the twin lens reflex is a popular camera among working photographers and keen amateurs. F.P. & L.A.M.

REFLEX COPYING. Method of contact copying documents, drawings, and other line originals by exposure through the back of the sensitive material. This is placed in contact with the matter to be copied. The dark parts reflect little or no light, while the light background reflects most of the light. This produces on the document paper a reversed negative and the latter yields positive copies by repeating the process. Reflex copying is the only method of copying opaque originals without a camera, and documents with writing on both sides.

See also: *Document copying.*

REFLEX HOUSING. Attachment for fitting between the camera body and lens (usually of a miniature camera) to permit the image formed by the lens to be viewed and focused before exposure.

See also: *Reflex attachment.*

REFLEX PRINTER. Special type of contact printer equipped for making reflex prints up to 8 × 10 ins. or larger. In principle it is no different from normal printing boxes; it is larger than most because it is generally designed for making reflex copies of typescript and drawings.

See also: *Document photography.*

REFRACTION. Change in the direction of a ray of light passing from one transparent medium into another of a different density. Refraction takes place because the velocity of light varies according to the density of the medium it is passing through. The action of both lenses and prisms depends on refraction.

See also: *Refractive index.*

REFRACTIVE INDEX. A ray of light which passes from one transparent medium into another of a different kind is bent either towards or away from the normal—i.e., a line at right angles to the common surface at the point where the ray enters.

The angle between the ray and the normal in the first medium is called the angle of incidence, and the angle it makes with it in the second medium (after being bent) is called the angle of refraction.

No matter what the angle of incidence, its sine always bears a constant ratio to that of the angle of refraction. This ratio is the refractive index for the two substances. It is given by:

$$\frac{\text{sine of angle of incidence}}{\text{sine of angle of refraction}}$$

When the refractive index of a single substance is quoted, it refers to the ratio when the first substance is a vacuum.

So the refractive index of a substance is a measure of its power to bend rays of light. The greater the bending, the higher the refractive index—e.g. for air, the index is 1·00029, and for glass anything from 1·5 to 1·8.

The refractive index also varies according to the wavelength of the light: blue rays are

REFRACTIVE INDEX AND ABBE NUMBER OF GLASSES

Glass Type	*Refractive Index*	*Abbe Number*
Hard Crown	1·518	60·3
Borosilicate Crown	1·509	64·4
Medium Barium Crown	1·576	57·4
Dense Barium Crown	1·613	60·0
Light Flint	1·583	41·8
Dense Flint	1·621	36·1
Extra Dense Flint	1·652	33·6
Double Extra Dense Flint	1·802	25·5

REFRACTIVE INDEX. A ray of light is bent on passing from one transparent medium to another. i, angle of incidence. r, angle of refraction. The refractive index is (sine i)/(sine r).

bent more than red. This causes dispersion of the colours; the extent of this is expressed in Abbe numbers.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The ratio of the velocity of the light waves in vacuum to the velocity in any particular material is also a measure of the refractive index of the material:

$$\text{Refractive index} = \frac{\text{Velocity in vacuum}}{\text{Velocity in transparent material}}$$

See also: *Optical glass.*

REGENERATION OF FIXING BATHS. In use a fixing bath undergoes the following changes:

(1) The concentration of free thiosulphate ions decreases through liquid brought in from previous baths, through loss of fixer carried out of the baths by the material being fixed, and partly owing to the formation of sodium argentothiosulphate.

(2) The concentration of silver increases.

(3) The acidity may decrease as the alkaline developer is carried over into the bath, unless an efficient acid stop bath is used.

(4) The concentration of iodide increases (especially in fixing baths used for negatives) owing to the presence of silver iodide in most negative emulsions.

All these changes interfere with the normal action of the fixing bath and thus lead to loss of activity and eventual exhaustion.

The best course for the amateur or small-scale professional photographer is to discard the fixing bath when it is exhausted. For commercial processing laboratories and other large-scale establishments using large quantities of fixing solution it is often sufficiently economical to regenerate the free thiosulphate, or at least to recover the silver accumulated during fixing in the spent solutions.

In regenerating a fixing bath, all the above-mentioned factors have to be taken into account. Thus it is not enough to add more hypo to make up for the amount used up if nothing is done about the other points, especially the increase in silver. The concentration of iodide is only of importance in negative fixing baths; the iodide converts silver bromide in the unfixed emulsion into silver iodide which takes much longer to dissolve in the hypo. This is also the main reason (apart from possible stains due to backing dyes) why negative fixing baths should not be used for prints.

Electrolytic Regeneration. Electrolysis of the fixing bath removes the silver and at the same time liberates free thiosulphate from the argentothiosulphate ions formed at the time of fixation. It is thus the most complete method of regeneration, but requires comparatively costly apparatus and is economical only for reasonably large-scale use.

Various commercial units are available for the purpose, and some firms even hire them out to processing laboratories in return for part of the value of the silver recovered from the waste fixer.

In electrolysis, the process must not be carried to completion, because silver sulphide may be precipitated as a result of secondary reactions if the silver concentration falls very low, or if the current density in the solution is very high. Generally a current density of about 0·15 amperes per square decimetre can be used for every gram per litre of silver in the bath. Most practical installations use large stainless steel or silver cathodes with a surface area of several square metres. The anode is carbon.

During electrolysis the solution must be well agitated. When the silver concentration falls below 0·5 gram per litre, the bath can be returned to use.

Some silver recovery units work continuously and are simply inserted in the fixing bath during use. They can remain there for several months without further attention beyond a periodic check on the pH of the solution. This system is only practical with large tanks.

Silver Recovery by Precipitation. The silver in a fixing bath can be precipitated by various methods. This does not necessarily regenerate the thiosulphate, but may decompose it and accumulate other by-products in the bath which make it unfit for further fixing. In some cases, however, provided the precipitation is not carried to completion, the fixing bath can be used again. This applies to precipitation by sulphide in acid solution, and by certain proprietary reagents.

With all precipitation methods the silver content of the bath should be determined first in order to decide on the amount of reagent needed for precipitation (especially if precipitation is to be incomplete). This can be done by various analytical methods—e.g., precipitation of a sample to completion, visual comparison of a colloidal silver sulphide solution prepared from the bath with a standard colloidal solution, or testing with indicator papers.

Precipitation by Sulphide. This is the cheapest method, but must take place out of doors and well away from any sensitized materials, as it generates hydrogen sulphide gas.

The exhausted solution is collected in a large barrel with outlets in the bottom and about one-quarter to one-third of the way up. After estimation of the silver content, the requisite amount of 20 per cent sodium sulphide solution is added, the solution well stirred, and left to stand for at least 24 hours. The supernatant liquid can then be drawn off at the upper outlet, and (provided the silver is not completely precipitated) brought up to strength with hypo and acid.

For complete precipitation the bath should first be made alkaline. It then requires less

sulphide, but is not suitable for re-use.

The silver sulphide sludge is run off by the bottom outlet of the barrel from time to time, and dried.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Precipitation by Base Metals. For this method the collected volume of exhausted fixer is treated with granulated zinc or zinc dust which precipitates metallic silver. A barrel may be used to accumulate a sludge containing the silver and the general arrangement of equipment is similar to that used in precipitation by sulphide. Other metals—e.g., iron (as steel wool) or copper turnings—can be used.

Other Precipitation Methods. The silver can be precipitated from the fixer with ferrous hydroxide or with sodium hydrosulphite. The latter produces a specially pure deposit of silver, but is comparatively expensive. In the ferrous hydroxide method the solution must be made alkaline before precipitation.

Removal of Iodide. The accumulation of iodide from negative emulsions also limits the life of a fixing bath. It can be removed by adding 5 per cent thallous sulphate solution, which precipitates the iodide as thallous iodide, an orange yellow substance. Some of the bromide will also be precipitated as thallous bromide which is pale yellow. The removal of iodide is reasonably complete when only thallous bromide is precipitated.

The removal of bromide should not be carried to completion, or free thallous sulphate will remain in the bath, and interfere with the fixing action.

Restoration of Thiosulphate Content. After removal of silver by electrolysis, sulphide or hydrosulphite, the fixing bath will need the addition of sodium thiosulphate to bring it up to standard strength. The thiosulphate concentration is best determined either by titration against iodine, or by measuring the specific gravity of the bath.

Restoration of Acidity. The acid neutralized by developer carried over into the bath should be replaced if the acidity drops below the safe level—i.e., if the pH rises above 6·5. The bath may be tested by means of a suitable indicator and re-acidified by sodium bisulphite or sodium or potassium metabisulphite. Hardening fixers containing sulphite and acetic acid can be re-acidified by adding dilute acetic acid. The bath must not become too acid (pH below about 4·5), as that would decompose the thiosulphate. L.A.M.

REGISTERING IMAGES

When making assembly colour prints (e.g., by combining separate, single colour images) some convenient method of accurately registering the images is desirable.

The very nature of some photographs may make it difficult to achieve registration easily, and in photomechanical colour work automatic registration is required.

Photomechanical printing. In sheet-fed printing machines the successive colour printings are registered by the "three-point lay" method. One side of the sheet lies against two points ("lays") fairly wide apart and an adjacent side against a third point. So long as the same sides of the sheet are used every time, it will lie in precisely the same position against the lays, even if the sheet is not exactly square in shape.

In making printing plates in the graphic arts, and in pure colour photography, two register marks are usually used, preferably at the centre of the top and bottom of the subject or at either side. Two points are enough for accurate visual registration although they are not enough for automatic or rapid hand laying of sheets of paper or other material.

Register marks may consist of circles, triangles, segments of a circle, thick and thin lines, etc., but most printers prefer a thin straight line, with three or four lines crossing it at right angles. Originally the main purpose of the crossing lines was for colour proofing, for it was usual to punch a very small hole into the printing plate at one of the intersections of each register line. When one colour had been printed on the paper, a fine needle was passed through the proof from the back in the corresponding positions and the needle points were used to register the proof when printing the next colour. Several intersections were desirable because if there were a number of impressions on each sheet a single hole might become enlarged and give inaccurate registration.

The holes are rarely used today but the marks are, because there is always the risk of a blemish on the intersection of one pair of lines and it is useful to be able to use another.

It is possible to use detail of the subject for registering the successive images in pure colour photography and graphic arts printing processes, but most printers prefer register marks at the margin of the image. It is advisable to place register marks at the edges of any studio set-up even if it is being shot on integral tripack colour film because the marks will be useful if the photograph is subsequently reproduced.

Carbro. Carbro prints are always registered by hand. When the three carbro colour prints are ready on their temporary plastic (usually Perspex) supports, one colour is transferred on to soluble temporary support paper. This is wetted and lightly squeegeed into contact with the next colour image. In this state it can be moved into precise register by hand and squeegeed tightly down for the second transfer. Register marks help but there is sometimes distortion in the images; the register should be

checked elsewhere as well as at the register marks.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Dye Transfer. The system from which dye transfer originated was registered in much the same way as carbro. After one dye image had been transferred to the mordanted paper it was covered with a very thin sheet of plastic, laid just to the edge of the image. The next dyed relief was then laid in position and the thin plastic was then slid out from between the two and the second dye image squeegeed down for transfer.

Dye transfer images are registered by the three-point lay system. The three reliefs are first registered by hand and then guillotined along two adjacent sides so that the images will always be in register with respect to the trimmed edges. The special rubber transfer blanket has three raised studs on its surface which provide the lays for registering the squared off sides of the reliefs. The first image is transferred to a sheet of mordanted paper, laid in position on the transfer blanket; the relief is then removed and replaced with the next relief, from which the dye image is transferred into accurate register with the first image. The process is repeated for the third image and perhaps a fourth (black image).

Colour-masking. The three-point lay method is often used in other colour techniques—e.g., of colour-masking, both for graphic arts and for pure photographic colour print making. Process cameras are often fitted with lays consisting of two slightly curved metal strips on which the lower edge of the photographic plate rests, and a third at one side. These strips, being curved, give a point contact and in practice are more efficient than pins. Three-point lays are also fitted in the "screen gear", which holds the process crossline screen, and often at the copy-board end of the camera, particularly in the transparency holder. This system ensures that there are three positions where the subject and images from it may be removed and replaced in accurate register.

The three-point lay system is also used on enlarger easels when making colour separation images by projection from colour transparencies. There are ready made proprietary devices, but the need can also be served by three suitably positioned nails in a board.

Register in Monochrome Printing. In some monochrome printing methods it is necessary to make two or more exposures in register upon bromide paper or on a plate or film; for example, in certain tone separation methods, where the highlight tones of the picture are printed from one negative and the shadow tones from another, because the two halves of the subject tone range can often be recorded better on two different negatives. It is rarely possible to include register marks in the original scene, but it is always possible to introduce the marks into the negatives afterwards.

When the negatives are dry, register marks are scratched at either side, or top and bottom, of the densest negative (the one exposed for the shadow detail) and the position of those marks is reduced out of the other (highlight detail) negative, after which it is re-washed and dried. A contact print is made on a blue-sensitive (colour blind) plate from the negative containing the register marks. A little water is then put on an unexposed ordinary quarter-plate in the darkroom and, after two or three minutes, while the emulsion absorbs the water and swells, the plate is warmed until the emulsion dissolves and some of it can be lifted off on the tip of the finger and transferred to the highlight detail negative in the clear spaces which have been reduced out. (Many modern pre-hardened emulsions do not dissolve easily; dye transfer relief film is ideal for the purpose.)

The applied emulsion is then dried, still in the darkroom, preferably with a fan or a hair dryer, and the register marks can then be printed-in accurately from the positive. The latter is quite easily hand-registered with the negative by laying them together over a safe-light and checking that they obliterate each other, when they are taped together and contact printed. Of course, there will be no image elsewhere because the emulsion was only put in the register mark spaces. After the usual fixing, washing and drying both negatives show the register marks clearly on black.

Other tone separation processes such as may be used in the making of photograms, colour derivations or in posterizing, which start with one negative or one print, lend themselves much more readily to the introduction of register marks; these can be scratched into the initial negative or positive.

Printing into Register. Printing several images with register marks into register on one sheet of bromide paper or other material is comparatively easy. After test exposures to determine the printing times, one negative is exposed, the register marks only developed with a small brush or a piece of cotton wool and stop bathed with 2 per cent acetic acid. After that the other negatives can be exposed upon the same sheet with the register marks as a guide.

Combining a line drawing with a photograph, or double-printing two different negatives into one print can be done by similar means.

The Blue Key Method. A less convenient method for pure photography purposes, but one which is sometimes convenient for certain graphic arts work, is the use of a "blue key". A very weak and soft contact positive is made from one of the negatives to be double-printed (or vice versa from a positive) and it is then toned blue in a suitable toner (e.g., ferro-prussiate, or dye toners). After bleaching out any remaining metallic silver with Farmer's reducer, a clear blue, non-printing image is left. The blue image should be very weak indeed. It is then taped securely into the enlarger so that

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

each negative in turn can be registered against the blue image and exposed. The bromide paper is left in place throughout, and covered while the second, and any other negatives, are placed in position.

Punch and Pin Register. Perhaps the most common method of registration uses location holes and pins on the films and film holders respectively. This is useful for all cases where transparencies have to be registered with masks, or where an image must be projected in exactly the same location on several different films. Punch registration is less reliable with papers, since these are liable to expand unevenly during processing. (Films do, too; but to a much smaller degree.)

The elements of the pin register system are a punch which punches the holes in one side of the film, and register pins fitted in the negative carrier, contact printing frame or the enlarger easel. The two holes punched are usually of slightly different size, one hole being longer than the other. The pins are however the same size, so that one hole serves as accurate lateral location, and the other for alignment. This extra size of one hole prevents buckling of the film if it has slightly shrunk or stretched during processing. For the smaller hole fits exactly on on to its pin; there is no play.

Various manufacturers in the graphic arts field offer punch register systems; most of them have the holes at standard distances apart. Sometimes there are several distances, according to the size of film being used. In any case it is essential to stick to one system throughout.

The register pins themselves may be built into contact printing frames, or into the negative carrier of an enlarger. For use on the enlarger easel, some models have built-in register pins (and a corresponding punch mounted on the easel).

The pins may be partly retractable, for use with vacuum easels. At least one manufacturer offers register pin bars; these can be fitted on any enlarging easel with the aid of double-sided adhesive tape.

REGISTER PIN SYSTEM. A register bar carrying two standard spaced pins is placed on or built into the enlarger baseboard or the film carrier in a process camera. The negative or colour transparency and masking film are perforated with holes corresponding to the pins. This ensures that the images on the films placed over the bars are always registered in the same way.

Needless to say, the bar must remain in position on the easel during the whole of a sequence of operations.

In making masks by contact printing, the register pins in a special printing frame are used. Both the transparency and the masking film are punched and placed over the register pins of the frame for the exposure. If there is not enough space along the edge of the transparency for the punch holes, a piece of spare film may be taped along one edge for the purpose. The transparency and its mask are—after processing of the latter—placed in register on the pins in the negative carrier of the enlarger. If the separation negatives are also made by contact printing, the transparency, mask and separation film are put together in the printing frame.

If enlarged colour separations are made by projection, the masking film and the separation films are placed in turn on the register pins on the enlarger easel. Alternatively, the mask is made first by enlarging, and placed on top of the separation film for the colour separations. Again the register pins ensure exact superimposition of the processed mask image with the projected image of the transparency (provided that the latter has not been moved in the enlarger).

The punch register method can also be used for monochrome printing, where two or more exposures are made in succession on one bromide paper or film. In this case however it is usually better to make enlarged separation negatives (for example for tone separation processes) and register these visually. The two or more negatives are then taped together, trimmed flush along one edge and punched together. Finally the negatives are contact printed on to the positive material on the enlarger baseboard, the register pins once more serving to keep each negative in register with the positive material. The latter can in this case even be paper, since it is not moved between the exposures and remains on the register pins all the time.

Pin register systems are useful in all cases where images are combined by contact printing, or where two images (for example negative or transparency plus mask) have to be superimposed accurately in a negative carrier. Also it is suitable for all occasions where one image is printed successively on different sheets of printing material (as in masking by projection as described above) where the original is not moved between successive exposures. For projection printing where the negative is moved or different negatives are to be superimposed, visual registration methods with register marks are more suitable.

Pin registration would there require not only a negative carrier with register pins, but also a method of inserting the negative carrier into the enlarger in exactly the same position every time.

F.H.S.

Book: ***Colour Prints*, by J. H. Coote (London).**

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

REGNAULT, HENRY VICTOR, 1810–78. French scientist, professor at the Collège de France. President of the Société Française de Photographie from 1855–68. Proposed (simultaneously with Liebig) pyrogallic acid as developer (1851). Worked on the carbon process.

Described in 1856 an actinometerusing silver chloride paper.

REHALOGENIZATION. Conversion of a silver image back into one of silver halide—e.g., in bleaching for intensification and various toning processes. Generally achieved by treating the image in a solution containing an oxidizing agent (permanganate, bichromate, ferricyanide, etc.) and a halide (potassium chloride or bromide).

See also: *Redevelopment*

REJLANDER, OSCAR GUSTAV, 1813–75. Swedish painter. Worked in England from 1853 on as portrait and genre photographer. A notable exponent of combination printing. His most famous "art photograph" was *The Two Ways of Life*, 1857, made from over 30 negatives. Composed nude and other studies for artists to paint from. Provided a series of photographs of fleeting facial expressions and gestures for Charles Darwin's *Expressions of the Emotions in Man and Animals* (London, 1872).

RELATIVE HUMIDITY. Ratio of the amount of moisture in the air at any temperature to the amount required at that temperature to saturate the air. The relative humidity (RH) of the atmosphere appreciably influences the keeping quality of photographic materials.

See also: *Keeping qualities of materials.*

RELEASE (SHUTTER). Any control or device that releases the shutter mechanism to make an exposure. May take the form of a lever on the shutter itself, or a button on the camera, mechanically linked to the shutter.

See also: *Shutter release.*

RELIEF IMAGE. Three-dimensional image obtained by removing exposed or unexposed areas from the light-sensitive layer, so that the image positions are raised above the surface of the support (e.g., a film base). Used in certain matrix processes such as Dye Transfer. A photomechanical letterpress plate also has a relief image.

See also: *Dye Transfer; Matrix.*

REMBRANDT LIGHTING. Dramatic lighting favoured by the Dutch painter Rembrandt (1606–69). Its effect is to spotlight significant parts of the subject, leaving the remainder in heavy but luminous shadows.

REMOTE CONTROL

Means for operation of equipment at a distance, especially when set up in a position where it is not easily accessible. Remote control systems may be used for still, cine and television cameras as well as for still and cine projectors.

There are various reasons for wanting to operate a camera from a point removed from the actual instrument: self-portraits, pictures of birds or animals from a close-up position while they are being observed from a distance, photographs of inaccessible subjects, etc. In projection, remote control systems enable the operator to sit among the audience or to work his projector while giving a lecture.

In camera operation it may be sufficient to release the shutter only at a distance, visiting the camera before each exposure to reset the shutter and wind on the film. Or a system may have to carry out the whole operation on its own to take one exposure after another without revisiting the camera. Remote control units may also be required to fire flashes during an exposure, or to adjust the focal length and distance setting (and even the exposure) of a cine and television camera. All these requirements have to be met in different ways so that anything more elaborate than a single remote shutter release usually has to be specially made for the job.

Remote Still Camera Releases. There is a certain amount of amateur interest in a remote shutter release for self-portraiture and nature photography. So a number of controls of this type can be bought ready made. There are three kinds: cable, pneumatic and electric.

Long cable releases are suitable for working at camera distances up to about six feet. Beyond that the lost motion caused by spring in the inner cable and its casing makes the release inefficient and other methods have to be used.

The pneumatic release works by transmitting air pressure from a rubber bulb along a narrow plastic tube to a small piston in a closed cylinder. The piston is coupled to a short cable release screwed into the normal socket on a camera shutter. On pressing the rubber bulb the air pressure pushes the piston down the cylinder and operates the cable release. This type of release is reliable and easy to use—the bulb can even lie on the floor and be pressed with the foot—and is effective over distances up to 100 feet. For such long range several plastic tubes can be linked together. The release also works without shock, so that there is no risk of camera shake or damage to the shutter.

An electric release generally involves the use of a solenoid-operated cable release connected to a battery and switch at the end of a remote

CC-0. Vasishtha Tripathi Collection. Digitized by Siddhanta eGangotri Gyaan Kosha

control cable. The battery may be at either the camera or the control switch end. However, there is a limit to the distance at which this control arrangement will work. If there is too great a length of cable in the circuit, its resistance may prevent the solenoid from drawing enough current from the battery to operate the release. So for long distances it is necessary to locate the battery at the camera end to keep the connecting lead short, and switch it on by a relay connected to the remote control lead. When the remote control switch is pressed, only a few milliamps flow in the control wires connecting it to the relay. This is enough to energize the relay, close the switch in the solenoid circuit and operate the shutter release.

A solenoid used in this way would apply the pressure suddenly and is liable to shake the camera. So it is always linked to a dashpot or gear train or a brake of some sort to transform the jerk into a steady progressive push.

Once the release button has been pressed, the current continues to flow in the solenoid until the shutter actually releases.

Fully Cycling Systems. If the camera has a built-in spring or electric motor, working a remote release in the ways described above also actuates the motor which re-tensions the shutter and winds the film. The camera is then immediately ready for a further exposure.

Cameras not equipped in this way can be remotely controlled by coupling a motor drive to the film transport and adding the necessary electrical and mechanical parts to make it perform a complete cycle. Outfits of this kind are available for specific camera models (usually 35 mm. types, as well as at least one twin-lens reflex).

Completely automatic operation is possible by linking the remote control to a timing device or a system where the subject trips the release. Set-ups of this kind are used for automatic instrument recording, and also in nature photography in conjunction with camera traps. In the latter case an animal may set off the camera by means of a trip wire or by contacts hidden underneath a camouflaged board.

Essential in such systems is, also, a camera of sufficient film capacity to take a reasonably large number of exposures without attention. Cameras for this purpose can often be fitted with special large-capacity magazines. For the same reason only an electric motor drive is practical for automatic operation, owing to the limited capacity of spring motors.

Radio Control. Where the operating distance is very great or where it is inconvenient to run control wires, the shutter can be released by radio. The radio link consists of a transmitter worked by the operator, and a receiver at the camera end. As a rule the transmitter sends out a simple switching pulse when the release button is pressed. The receiver picks up the pulse and closes a pair of contacts. These may simply energize the shutter release solenoid or a motor linked to the shutter release, or they may trip the complete cycle of events involved in releasing the shutter and getting the camera ready for the next exposure.

Flash. Strictly speaking all shutter-synchronized flash guns work by remote control, being fired by an impulse provided by closing the shutter contacts. Normally this involves a lead from the camera to the flash gun. Such a lead can be quite long and several flashes can be connected to take the current from a common battery or charged capacitor.

Where extension leads are in the way, the most convenient way of firing flashes by remote control is by a slave unit. This is a capacitor circuit controlled by a photo cell. One flash is connected direct to the camera, and when this is fired the light triggers off the slave unit and fires the extension bulbs with a negligible time lag. Such slave units are suitable for flash bulbs or electronic flash.

An even more elegant way of firing flashes again involves radio control. Here the transmitter is connected to the shutter contacts of the camera. When the contacts close as the shutter is released, the transmitter sends out a switching pulse. A receiver picks up the pulse, closes the firing circuit of the flash unit and thus fires the flash. Any number of receivers, and hence any number of flashes, can be operated from the single camera transmitter. The range of such a set-up is several hundred yards.

When complete remote-controlled camera set-ups are linked to a flash gun, the flash is of course also fired by the remote release. An electronic flash is usually necessary with a self-restoring system to permit remote-controlled exposure series; with a flash bulb the latter has to be changed after every shot by re-visiting the camera.

Cine Cameras. A spring driven or electric cine camera can be released at a distance by any of the devices available for still cameras (pneumatic release, solenoid, etc.). As a cine camera is in any case self-recycling, no further attention is necessary except for periodic rewinding of the motor in the case of a spring-driven camera.

Cameras with an electric drive often have a socket to take a plug and extension lead with which the camera can be set going from a distance. Sometimes the battery pack with its stop-start switch is detachable and takes a long extension lead between it and the camera. The camera can then be mounted on a tripod and controlled with the switch on the battery pack at the other end of the lead.

Some spring-driven cine cameras can have an electric motor drive attached to a special shaft for complete electric remote operation. Such a remote control is also suitable for use with the single-frame exposure control, for instance for time lapse cinematography. In this case the camera is released automatically by a timing device at pre-set intervals. Usually this arrangement is also coupled with lights which switch on

whenever an exposure has to be made. Further elaborations may include automatically controlled screens which obscure the subject from prevailing daylight (for example growing plants) to make exposures at intervals of 1 second to several hours for greatly speeded up films of growth phenomena.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Other functions of the camera, such as the focusing adjustment, zooming (in the case of a zoom lens), aperture control and even the camera mounting may be controlled by relay operated motors in much the same way as with a television camera (see below).

Television Cameras. Television systems are frequently used for observation under conditions where it is impossible or unsafe for a human operator to work the camera (for example observation of events connected with strong radioactivity). So remote-control systems for television cameras are often particularly advanced. Mostly these involve several motors and relay switches. Thus the lens may carry motor drives to change the focal length, to adjust the distance setting or to vary the aperture. A switch at the end of a remote control cable can set each motor in action in either direction—to stop down or open up the lens aperture, zoom to wide angle or long focus settings, etc. In addition built-in motors can provide pan and tilt movements.

Since the control of a number of such functions involves a considerable number of controls wires, various simplified systems are in use. One of these works on the basis of a telephone dial selector; here dialling a number chooses the appropriate camera function, and a single switch then sets the required motor in operation in either direction. If necessary, a number of television cameras can be controlled in this way.

Similar remote control systems also exist for ordinary cine cameras to regulate all functions from a distance. Even still cameras can be controlled by television circuits of this kind. In one case remote-operated motors adjust the lens focus and focal length and swing or tilt the camera. A television camera tube, mounted to receive the image through the viewfinder, shows the operator what the camera is taking in.

Still Projectors. Motorized magazine slide projectors nearly always have provision for remote control. Here the remote unit is simply plugged into the projector and the operator can sit in the midst of the audience and press buttons to change slides, advance the magazine either forwards or backwards, and to operate a motor which focuses the lens. Certain non-motorized slide projectors also permit remote operation by means of a Bowden-type cable which transmits a mechanical impulse to the slide changing mechanism.

Two cable-less remote control arrangements for projectors use ultrasonic signals and radio impulses. In the first case a mechanical or electric whistle emits an inaudible signal (above 20,000 cycles per second) which is picked up by a sensitive microphone attached to the projector. There the amplified signal can close contacts to operate the slide transport. A second separate whistle frequency may also serve for remote focusing.

Radio-controlled slide projectors operate the changing contacts in response to a wireless signal sent out from a battery-powered miniature transmitter and picked up by a receiver attached to the projector.

Impulses recorded on magnetic tape can serve for completely automatic projector control. This involves a tape coupler attached to or built into the tape recorder, and linked with the slide changing contacts of the projector. As the tape with its signal passes over the pick-up head of the tape coupler, the signal impulse closes a relay which starts the slide changing cycle. This system is used for changing slides automatically in a lecture recorded on the same tape.

Cine Projectors. The functions most likely to need remote control are switching the lamp on and off and starting and stopping the projector motor. Reverse running may be sometimes included, as well as single frame projection. The cooling fan normally needs switching on separately; this also avoids the risk of switching on the lamp only by remote control.

The most straightforward remote control system carries wires for each function along a common cable, with appropriate switches at a remote unit at the end. In one system the remote control switch consists of a cube partly filled with mercury and carrying inside the terminals from the various control wires. On turning the cube in different directions, the mercury makes contact across different terminals, so initiating the various functions. Each side of the cube is marked with the control operations that take place when that side is on top.

In motion picture projectors the operations connected with a performance—house lights, interval music, curtains, etc.—may also be coupled to the projector controls. The most advanced systems operate everything by a programming unit which may even take care of the automatic change-over from one projector to another. L.A.M. & F.P.

RENWICK, FRANK FORSTER, 1877–1943. English chemist. Worked from 1898 till 1922, and again as Director of Research from 1925 till his death, with the Britannia Works Company (1898) Ltd. (later Ilford Ltd.). Recently this firm have named a new laboratory after him. From 1922 till 1925 he worked with DuPont at Parlin, N.J., on emulsion manufacture. Specialized in sensitometry, light scatter, photographic chemistry and physics.

CC-0. Kamnigam Digital Preservation Foundation, Chandigarh

During the first World War he developed plates for aerial photography. His name is also connected with the introduction of the Multigrade paper and the Kryptoscreen. He was a President of the Royal Photographic Society from 1927–9. Helped to found the British Photographic Research Association in 1918, the Scientific and Technical Group of the R.P.S. in 1919 and the Photographic Alliance in 1930. Received the Progress Medal of the Royal Photographic Society in 1921.

REPAIRS TO CAMERAS. Whether a photographer should attempt to attend to any fault in his apparatus must depend on his mechanical knowledge in general, his possession of or access to suitable tools and his ability to use them efficiently, as much as on a full knowledge of the equipment and its construction. Even simple repairs are often more difficult than they look because special keys are required to loosen fixtures. Further, not knowing whether a particular screw has a right or left-hand thread may mean damaging the thread and doing more harm than good.

It is generally cheaper, quicker and more reliable to leave repairs to expert mechanics. Many of the larger photographic dealers have their own workshops, staffed by mechanics with specialized experience, who can find the cause of a fault quickly and remedy it. Besides these dealers' repair departments there are photographic repair firms who specialize in repairing photographic apparatus. Most manufacturers' agents maintain mechanics who repair their own products, and only send major work to the factory for attention. This part of a manufacturer's organization also handles repairs within the guarantee period of the instrument.

Today, worn or faulty parts are generally not repaired, but replaced by new original parts. The cost of labour is so high that the expense of, say, repairing an escapement by hand would be out of proportion compared with replacement by a mass-produced, complete item from the factory.

This explains why repairs to obsolete cameras, for which no spare parts are available, are so costly. In these cases no original parts are available to the repairer and he has to make them individually, sometimes at a high cost in time.

It is, however, quite astonishing to find, particularly in countries which have in the past been cut off for years from the country of origin of the camera, the high degree of skill with which workshops have been able to make up gears, screws, levers, etc., to bring instruments anything up to forty years old into perfect working condition.

Common Faults. A survey of some 5,000 repairs to a great variety of cameras shows that about 9 per cent needed no attention at all. The trouble was simply lack of knowledge on the part of the person handling the instrument, particularly in the case of users of the so-called fully automatic (electric eye) cameras. The reasons include refusal to read the instruction manual or a "Camera Guide", misreading a distance scale calibrated in metres for feet, etc., and just plain ignorance of the elementary facts of photography.

Most faults on between lens shutters can be traced to dust, dirt or sand which has found its way into the mechanism, possibly over a period of years. This may slow down the shutter speeds, or block escapement and built-in delayed release action. Gears should generally have a trace of suitable lubricant, but over-lubrication may cause the oil to reach the shutter blades, eventually causing these to stick and seize up.

Inaccuracies in focal plane shutters can frequently be traced to very dry springs or gears. In folding cameras, leaking bellows are high on the list of repairs. The trouble here is mostly caused by gritty particles like sand which have been allowed to remain in the camera and have worked their way through the bellows.

Almost 80 per cent of all folding cameras checked for varying types of complaint have been found with the lens out of parallel to the film plane. This, of course, impairs the over-all definition.

Rangefinders are liable to become inaccurate through shock, a fall or excessive variation in temperature. Viewfinders which show a field different from that of the negative may have become bent or distorted, but it is not unusual, particularly in the lower price range, to find that they have never been accurate, even when new.

Consistently incorrectly exposed results with an electric eye camera indicate a faulty photo-electric meter or shutter. Alternatively, if the meter, lens aperture, and shutter speeds all err in the same direction, the total effect may add up to one, or even two stops over or under exposure. The fault can only be satisfactorily pinpointed with electronic test equipment. The remedy would lie in re-calibration of the meter and/or re-setting of shutter speeds.

Lack of definition can be corrected in many cases simply by resetting an inaccurate distance scale, straightening a distorted camera body or film pressure plate which has lost its spring pressure, and squaring up the lens and film plane. In single lens reflex cameras, out of focus pictures may be the result of inaccurate positioning of a mirror or someone may have replaced the original mirror by one of different thickness or even with a piece of ordinary back-silvered looking glass instead of a surface silvered mirror. Similar complaints in twin lens reflex cameras may be also due to the viewing and taking lenses being out of coincidence.

Scratched negatives, particularly in miniature photography, come fairly high on the list. The

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

cause may be film cassettes with foreign matter, grit, dirt on the light trap through which the film emerges, or a film pressure plate which is not perfectly smooth. (It should be remembered that scratching of the film is caused chiefly when it is kept in a roll. Unrolling, even a few times, is bound to produce some scratching. The remedy is to cut the film immediately after processing into strips of best six frames, which should then be kept flat in a negative wallet.)

Mysterious patches of light in the picture may be traced to internal reflections in the camera. Even a black surface struck by a ray of light will reflect, particularly if it is not a dead matt. Such reflections often reach the sensitized material. To overcome this difficulty, many cameras with large interior surfaces—e.g., twin lens reflexes—are now produced with anti-reflection baffles inside.

Lenses. Repairs to lenses are rarely called for and are only needed if the lenses have been tampered with. The most frequent fault occurs with owners of front cell focusing lenses who remove the lens stop so that they can focus on a subject closer than the normal near limit. In the process the front cell is often fully unscrewed and on re-inserting it the definition is often found to be impaired. This is due to the fact that the large majority of lens threads are of the multi-start type. Without suitable optical and mechanical aids, it is possible to spend days trying to find the correct start for re-insertion.

Another frequent trouble is scratched lens surfaces. Whilst a very few light surface scratches have no noticeable effect on the performance of the lens, a large number will produce light scatter and reduce the definition. As long as they are surface scratches—e.g., of the type caused by incorrect cleaning methods—the lens can be fully restored by repolishing. The problem, however, becomes unsolvable when there are deeper scratches and digs in the lens, or if it is chipped. To remove these by polishing would upset the performance of the lens system and mar the definition. With such lenses the safest thing to do is to fill in the scratch with dead black paint so that it does not create stray reflections. If the coating of a bloomed lens is scratched, this coating can be removed and a new one applied without any ill-effects. W.D.E.

REPEATING BACK. Special form of plate holder by means of which a plate can be used to take a number of smaller-sized negatives—e.g., for taking four quarter plate negatives on a whole plate, or two 2½ x 3½ ins. negatives on a quarter plate. The holder is constructed to take a special dark slide with a cut-out aperture that can be inserted so that it uncovers each section of the plate in turn. This slide is replaced by the normal slide when the holder is out of the camera.

The term also describes the special holder used in one method of making three-colour separation negatives. In effect it holds three plates, side by side, each plate being brought into position in turn by sliding the holder along a grooved track on the camera back. This allows three quick exposures to be made without changing plateholders and withdrawing dark slide covers. The cover over the three plates is arranged so that it always covers the two not in use, leaving the third uncovered in the camera.

Such repeating backs may have the tricolour filters fitted immediately in front of the plates, so that no manual changing of filters is necessary when taking a set of successive separation negatives.

Sometimes there is a clockwork motor, geared to drive the holder across the camera back and also operate the shutter, so that the three exposures can be made in as little as a second.

REPLENISHER. Chemical that can be added to some types of developer to make good the exhaustion of the active constituents that takes place in the course of development. The practice is common in professional and trade processing where the trouble of draining off developing tanks and making up large volumes of fresh developer is a job to be postponed as long as possible; it is scarcely justified in the case of the amateur who uses only small quantities at a time. In colour processing accurate exhaustion tests (e.g., by processing pre-exposed control strips) are necessary to keep the activity of the working developer constant.

See also: *Developers.*

REPRODUCTION FEES. A reproduction fee is paid by an editor, advertiser or other commercial user for permission to reproduce a copyright photograph. The term also includes television "flashing" of a photograph, the right to exhibit, display or project, and use as a greetings card, calendar or picture postcard.

Editorial Use. An editor who uses a picture for its news value or general interest to his readers pays according to a scale of charges for non-exclusive work, or fixes his own figure in the case of exclusive and valuable pictures.

Non-exclusive pictures, offered to several journals at the same time, are paid for by space rates increasing in proportion to the reproduced size of the picture.

Exclusive pictures, usually of special interest to a certain market, fetch much more. A local paper is seldom, if ever, interested in buying exclusive rights; but national papers are always on the look-out for material of popular interest that is not available to competitors, and pay high fees for exclusive use.

Rights Offered. A photograph of high news value or other outstanding merit should not be

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

submitted without informing the editor or user exactly what rights are offered and on what terms. In particular, when offering a picture for reproduction as a calendar, view card or greeting card, the extent of the licence should be clearly stated. The precise use should be taken into account and, in the case of calendars, the year of use.

Commissioned Work. There is no scale of charges for commissioned work. The copyright is vested in the person—e.g., the editor—who assigns the work. He therefore pays a fee for the work done, not a reproduction fee. Fees may be based on the amount of time taken to complete the commission, but they also take into account the cost of materials and incidental expenses, or the incidental expenses may be billed separately by agreement.

Commissioned work may also be billed according to the amount of space finally used. This is satisfactory if a set of pictures is used over several pages, but not if a quarter-page is allotted to a job that has cost the photographer much time and effort. All magazines, especially, have standard page rates. The leading British weeklies pay a black-and-white rate of about £25–£30 per page.

Other Uses. Fees paid for calendar use depend on the quality of the calendar and its circulation. A calendar intended for sale by a big commercial distributor will obviously fetch more than one to be given away by an engineering firm to its clients. Correct pricing of a picture for calendar use demands experience, and it is sometimes better to leave this to an agent who has specialized knowledge. Payment for calendar pictures is sometimes made in the form of a royalty based on the quantity sold.

Payment for picture postcards and greeting cards is also sometimes made in the form of a royalty based on the quantity sold and the price of the card.

If a photograph is exhibited to the public in any place, the copyright holder is entitled to a fee. In the same way, photographs or negatives to be used wholly or in part as material for lantern slides, film strips, or epidiascope prints, or for advertising, cigarette cards, confectionery lines, jig-saw puzzles, etc., are also subject to reproduction fees.

Minimum Fees. In the United Kingdom leading press groups have adopted certain minimum scales of reproduction fees. Some editors or commercial users pay more. Others follow scales of their own which may be lower. Proportionately higher fees may be asked in the case of pictures of exceptional merit, or whenever the photographer knows that the buyer normally pays a higher rate.

Colour photographs fetch considerably more than black-and-white pictures and there is a moderately good market for first class material, although in the United Kingdom it is difficult to sell 35 mm. transparencies; 4 × 5 ins. material is the ideal minimum size for colour work.

The governing fact is that photographs bought for publication are subject to the elementary economic laws of supply and demand. Because the supply greatly exceeds the demand the level of payment is, on the whole, at the discretion of the consumer—except in cases in which the material offered or its author is particularly sought after. If photographs are submitted without the photographer explicitly demanding a specific fee, publishers will assume that their own standard rate of payment will be acceptable. But it is by no means common and not always politic to stipulate a fee.

Reproduction fees are paid after publication and as a rule on the last day of the month in which it has taken place. Fees for pictures illustrating an article are assessed with the article and paid as one sum.

The not very reasonable attitude of some publishers to refuse reproduction fees to amateurs is becoming rare. There has never been justification for this in any but strictly non-commercial media of publication. R.S.

Book: *How to Take Photographs that Editors will Buy*, by R. Spillman (London).

REPRODUCTION QUALITY. For satisfactory photomechanical reproduction, a print should be pure black-and-white (neither toned nor tinted), of full tone, and on glossy paper, preferably glazed.

A negative can reproduce correctly tone for tone a fairly long range of subject brightnesses. A bromide print, however, can deal faithfully only with a tone range which is often much shorter than that of the negative. In particular the tones at the light and dark ends of the scale tend to become compressed. Thus if the print is very contrasty, its scale is much too short to accommodate many of the negative tones satisfactorily, and either highlight or shadow tones (often both) get lost.

In a good bromide print for reproduction the whitest tone must not be pure white, nor must the darkest tone disappear into complete darkness. All the tones must be visible and distinct from each other.

Criteria of Quality. When a photograph is to be reproduced in print, a copy negative must first be made. This is used to produce the printing plate. The best test of a photograph for reproduction is therefore whether it will make a perfect copy negative and print. Thus a bright and too contrasty print will, during reproduction, lose its highlight and shadow gradations, while a softer print will give much better results. In fact, prints for reproduction should be soft rather than contrasty.

On the other hand, the tone range of a photographic print is extended (quite apart from the contrast grade of the printing paper) if the darkest possible tone the paper can give is as black as possible, and the paper base as

white as possible. This is also important for good reproduction. Therefore a sepia toned print (where the darkest tone is considerably lighter than black) is quite unsuitable. Similarly matt or rough surfaces, when they are as black as possible, appear only as dark grey when compared with a good black tone on a glossy and glazed surface. Shadow gradations which are indistinguishable on a matt surface, can be clearly seen on a glossy one.

For the same reason a tinted paper base will be much darker than a pure white one, again reducing the over-all tone range.

If a toned effect is wanted, the photo-engraver still prefers to work from a black-and-white print, though an example of the toned effect can be supplied separately so that the engraver can modify his methods if necessary, and to help the printer to choose the right coloured printing ink.

Processes. There are three principal methods of reproducing photographs in the printing press, each having its special field of application depending on such factors as the quality of the paper to be printed on, the number of copies to be printed and the standard of reproduction demanded. In each, the method of transferring the ink to the paper is basically different. Although broadly speaking the type of photographic print described above is equally suitable for all three processes, there are points of difference which may profitably be considered when turning out a print specially for reproduction by one particular method.

Typographic Method. The first is the typographic method, where the printing surface consists of raised dots of varying size. These dots carry the ink. They are all equally dark, dark tones and light tones in the finished reproduction being created by what is really an optical illusion. Where the dots are large (and the clear spaces between them correspondingly small) the area seen as a whole looks darker than where the dots are small with larger empty spaces between them.

The typographic or letterpress method can cope with almost any type of subject. It is ideal for crisp subjects; letterpress blocks give good and clean definition. But light subjects and unsharp and diffused prints are difficult to record by this method.

Lithography. The second printing method is lithography. Here again dots are used, but they are on a flat surface, and not raised as in the case of a letterpress printing plate. With this method much softer and more delicate prints are reproduced well, particularly light subjects. Dark subjects are, however, not so well rendered, as the maximum black obtainable is not very deep.

Photogravure. The third printing method is photogravure. Here the tones of the picture are actually formed by the amount of ink deposited on the paper and not by the size of dots into which the picture is broken up. It will produce particularly deep shadow tones, and is therefore ideal for strong and heavy types of subject. It is less efficient for light and delicate subjects, as there may be some loss of tone in the highlights. F.H.S.

Book: *Photographs and the Printer*, by F. H. Smith (London).

REPROGRAPHY. General term applied to photographic techniques of reproducing flat originals (documents, photographs, printed matter, pictures, etc.). Its scope covers copying as well as graphic arts processes.

See also: *Document copying; Photo-mechanical reproduction.*

REPTILES. Reptiles are best photographed in captivity. Trying to locate them in their natural surroundings is a hazardous business and practical experience has proved that unless pictures of a rare specimen are required—and that makes the job even more difficult—it is much simpler and quicker to obtain what will pass for natural photographs by working in a zoo.

Zoos offer very suitable conditions and the collections there cover a great number of species most of which may be photographed in complete safety. Many of the subjects are small, and fascinating pictures may be obtained by close-ups.

Temperature. A frequent source of spoiled pictures is the difference in temperature between the exterior of a reptile house and the interior. The best of the collection are nearly always from tropical climates, and consequently the temperature inside is kept high. This may result in a steamed up lens, not only on the external surface, but on the internal one as well. All condensation must be clear before making the exposure. Fifteen minutes is usually sufficient for the moisture to evaporate as the lens warms up to the temperature of the house.

Lighting. The normal illumination in such places may be adequate for photography, and the fact that the majority of the specimens on most occasions are slow movers provides a great chance to capture shots of many venomous creatures. On the whole, better results will be obtained with the aid of flash. (Permission to use flash should always be sought, as some species may react violently.) The glass panel, which provides safety, sometimes produces reflections; the use of a polarizing filter might help in some instances, although the difficulty can be easily overcome by placing the camera lens very close to the glass of the cage.

Equipment. The following is an ideal set of equipment for reptile photography: a camera capable of quick action both in film winding, focusing and shutter operation—an automatic twin lens reflex covers these requirements ideally—a supplementary lens for close-ups,

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

CC-0. Agamirably Split Into Digital Preservation Foundation, Chandigarh

plus a battery-operated electronic flash of at least 200 joules capacity, preferably split into two flash heads of 100 joules each. The use of two flash heads eliminates the harshness and dense shadows produced by the use of one lamp only, but nevertheless, very good results can be obtained with one lamp.

The Subject. In photographing reptiles, the variety of size is so great that hard and fast rules are out of the question; the subject may be a crocodile, a frog, a snake (such as the Royal Python of some 30 feet in length) or a Pigmy Iguana of a mere few inches. In tackling venomous species—e.g., our native vipers and adders—in the field, where there is no protecting glass, the most important piece of equipment is a pair of stout leg boots. Poisonous snakes are not really dangerous unless provoked by an adversary, but prevention in this case is very much easier than cure.

Field Photographs. Photographing reptiles in their natural surroundings calls first for an intimate knowledge of the subject and then for plenty of patience. Without knowing all about the habits and haunts of the reptile the photographer will not know where to look, and having found a suitable subject he will probably scare it away at once unless he knows how to stalk it.

Whether the reptile is poisonous or not, it must be stalked carefully, from the down-wind side, with the camera at the ready. The exposure should be made from the greatest distance that will give an image of reasonable size. Where possible a long focus or telephoto lens should be used to avoid disturbing the subject.

One of the greatest difficulties in photographing reptiles in their natural surroundings is that the colouring of the subject is often the same as that of the background. Even when the skin carries a bold pattern it becomes lost in the contrasty shadows cast by the bright sunshine sought by most creatures of the species.

One way of making the subject stand out is to photograph it against the light or in the strong low-angle illumination of early or late sunshine in clear weather. Another way is to transfer the creature to a less confusing background—e.g., a patch of sand. This is only possible with a limited number of sluggish snakes—it is out of the question with lizards.

There is no point in going to the trouble of taking pictures of reptiles in the field if the same pictures could be taken more easily in the Reptile House at the Zoo. In other words the subject should, if possible, be photographed doing something characteristic which it would not be able or likely to do in captivity. Behaviour, courtship, and even combat with others of its species are all interesting.

Photographs of the reptile hunting, attacking, and devouring its prey may be difficult to organize, but for that very reason are rare and worth seeking. Pictures of this type are sometimes obtainable by the use of a tethered bait in an open place that the reptile is known to haunt. All field photographs of reptiles should be accompanied by particulars of the date, time of day, temperature and place where taken. This information greatly adds to the value of the photographs as records, even if the subject is being pursued primarily for its pictorial qualities.

RE-SCREENING. Photography of a half-tone image (e.g. a printed reproduction) through a half-tone screen to produce a new half-tone printing plate or block. This usually requires special precautions to avoid moiré interference patterns between the two screen images.

See also: *Half-tone screen reproduction.*

RESEARCH IN PHOTOGRAPHY. During the nineteenth century photography developed from a crude, slow and impermanent method of making chemical silhouettes, using lace, fern leaves and so on, as stencils, to the point where permanent, minutely-detailed records of nature could be obtained by snapshot exposures in cameras, and reproduced as prints on paper. These developments, largely the efforts of individual amateur workers, were achieved empirically, and the basic question, "How is photography possible at all?", remained unanswered.

When it was discovered that, by using gelatin as a medium, the photographic material could be stored—and hence sold—the industry, as distinct from the art, of photography became possible, and research into every aspect of the photographic process became essential for its further progress.

At first such researches were one-man efforts by scientists working with limited facilities. The typical photographic manufacturer at that time was a small concern producing a limited number of products usually devised by its founder. During the first quarter of the twentieth century the more research-minded of these firms grew and in some cases amalgamated to form the big manufacturing organizations of today.

Accordingly, although photography still offers scope—if only in the devising of new applications—to the individual scientist and the amateur research worker, most of the research directed to the production of new or improved photograhic materials and equipment is today necessarily carried out either in the research laboratories of the big photographic and optical manufacturers, or by scientists subsidized by these firms while working in university laboratories, e.g. at Bristol and Liège. In addition, research on specialized aspects of photography is carried out in Government Departments and such institutions as the Institut D'Optique (Paris), National Bureau of Standards (Washington), the National Physical Laboratory (London), the Physikalisch-Technische Bun-

desanstalt (Berlin), the Eidgenössiche Technische Hoch-Schule (Zürich), and the Graphische Versuchs-und Lehranstalt (Vienna).

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The work in a typical photographic research laboratory is of three general types: on photographic theory, on materials and processes, and on various projects not directly concerned with photography.

Theory. This covers the physical chemistry of gelatin, the physics and chemistry of the silver halides, the nature of the change which takes place when silver halide is exposed to light, the nature of the development process, the theory of tone reproduction and the effects of the structure of the image and the characteristics of lenses on the resolving power and sharpness of the photographic image.

The use of photographic emulsions to record the sounds and colours as well as the shapes of nature was a consequence of the development of the theory underlying these techniques.

Under the heading "psycho-physics" photography and more particularly, colour and stereo photography, have stimulated many interesting researches on the effective presentation of pictures and on the mental and physical aspects of vision itself.

Materials and Processes. Many hundreds of different forms of photographic emulsion are now available. Whereas the earliest types were capable of recording ultra-violet and blue light only, emulsions are now made for recording the whole or any part of the visible spectrum, infra-red and X-radiation. They range in appearance from thin water-clear layers capable of legibly recording the contents of the Bible in an area less than a square inch, to thick opaque layers used to record atomic disintegrations. There is scarcely an industry or a science for which some special form of photographic material has not been specially devised.

Despite the advances made in theoretical studies, the technique of emulsion making is still in part an art in which practice is in advance of the chemical and physical conditions which control the results. The same may be said of the manufacture of gelatin, the medium in which the light-sensitive halides are suspended. The manufacturer of photographic emulsions has to be far more careful in the choice of gelatins than does the manufacturer of table jellies! It is easier to make advances in the applications of photography than in emulsion manufacture itself. Long before there were emulsions fit for the task, for example, the many ways in which colour photography could be achieved, had been fully realized.

Research, however, does not stop when a new form of photographic material has been devised. In addition to the design of conventional cameras and their accessories, such applications as document copying, photofinishing, aerial survey or photomechanical reproduction must also have the equipment devised to use the material, and the research laboratory plays its part in the field studies and statistical investigations necessary to get this into suitable commercial form.

General Research. The physicists, chemists, engineers and mathematicians in a typical photographic research laboratory necessarily uncover in the course of their work fascinating by-paths which are of no apparent importance to photography as such. The large laboratories typical of the photographic industry are always generous with such information they bring to light in this way as their communications to scientific publications frequently bear witness. Occasionally when scientists have explored these by-paths the results have been commercially rewarding. Some methods of manufacturing artificial silk, soluble surgical dressings, coagulating rubber latex—all these and many more benefits derive from the exploration of by-paths opened up during photographic research.

Publication of Results. Much of the successful research carried out by photographic manufacturers is naturally published in the form of patent specifications. Papers on the theory of the photographic process and most of its applications are published as communications to the appropriate scientific journals. The *Journal of Photographic Science* (Great Britain), *Photographic Science and Engineering* (U.S.A.), *Journal of the Society of Motion Picture and Television Engineers* (U.S.A.), *Zhurnal Nauchnoi i Prikladnoi Fotografii i Kinomatografii* (U.S.S.R.), *Uspekhi Nauchnoi Fotografii* (U.S.S.R.), *Tekhnika Kino i Televidenya* (U.S.S.R.), *Zeitschrift für Wissenschaftliche Photographie, Photophysik und Photochemie* (E. Germany), *Journal of the Society of Scientific Photography of Japan*, *Photographische Korrespondenz* (W. Germany), *Sciences et Industries Photographiques* (France), are the principal journals published throughout the world devoted exclusively to photographic subjects. In addition, *Photographic Abstracts* (London), *Abstracts of Photographic Science and Engineering Literature* (New York), and *Referativnyi Zhurnal Fotokinotekhnika* (Moscow) provide a wide coverage of photographic literature.

In the period 1889–1965, over 50 International Congresses and Conferences on the science of photography have been held in different countries, and the proceedings of these congresses provide convenient periodical cross-sections of progress, more particularly in the theory of photography.

In 1950 the first of three volumes of *Progress in Photography* was published as an attempt at reviewing international progress both in theory and in its many applications. After 1959 the quarterly *Perspective* and the volumes of the Focal Library took over the task of providing up-to-date world-wide progress reviews. D.A.S.

RESIDUES. Residual processing solutions—e.g., fixing baths—which have removed soluble silver salts from negatives or prints and been treated to recover the silver.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

See also: *Regeneration of fixing baths; Silver reclamation.*

RESIST. Image or pattern in the form of a protective layer on a metal or other surface to prevent or control access of chemical solutions (for example etching baths) or physical action (for example sand blasting) on that surface. As a result the reversed pattern of the resist image is etched or otherwise ingrained into the surface. The resist may be applied in various ways to the surface to be treated, including by photography—in which case we are dealing with a photo resist—and is removed from the surface after treatment.

Photo-resists are used in the graphic arts for the production of printing-formes of every description, such as letterpress, line and half-tone blocks, planographic printing plates, gravure plates and cylinders, silk-screen, etc. This classical application dates back more than a century. For several decades photo-resists have also become of major and rapidly increasing importance for engineering and electronic purposes. Examples are "chemical" milling, the production of small two-dimensional metal parts and strain-gauges; furthermore the production of printed circuits and quite recently the production of minute electronic devices, such as transistors and that of micro-miniature circuits. Yet other applications are glass etching (graticules) and etchings in plastics.

Principle. The photo-resist is a solution of a light-sensitive material which is spread as a thin layer on the surface of a substrate (i.e. metal, glass, plastics, semi-conductors, etc.). The layer is usually dried and is then exposed. The exposed areas are rendered insoluble, leaving the unexposed areas soluble in suitable solvents. Alternatively, the reverse takes place, i.e. the exposed areas become soluble whereas the non-exposed areas remain unaffected by the solvent.

In either case a resist stencil is obtained on the surface of the substrate after exposure of the layer under a mask, i.e. usually under a photographic negative. According to the nature of the resist the stencil is either a negative or a positive replica of the pattern of the mask.

The resist stencil thus left on the substrate protects it imagewise against chemical or physical treatment such as etching, electroplating, dying, evaporation and only the areas laid bare by the solvent are affected.

Chemically, photo-resists are solutions of natural or man-made colloids, resins, lacquers or polymers in water or in organic solvents which after drying leave a *coherent* layer on the substrate. The aqueous solutions of colloids, such as gelatin, gum arabic, albumin, polyvinylalcohol, etc. are in themselves not light-sensitive. They become sensitive to light by incorporation of a sensitizer in the solution, usually by that of an alkali bichromate or a diazo compound. The solutions of resins, lacquers or polymers in organic solvents may be light-sensitive in their own right (e.g. natural bitumen or polyvinyl-cinnamate) or they might be rendered sensitive by bichromates, diazo-compounds or azides (examples are shellac solutions, called cold top enamel, and certain rubber derivatives).

Photo-resists in Aqueous Solution. The layers from water-soluble colloids or polymers are usually developed in water or by concentrated salt solutions (e.g. solutions of calcium chloride). Although the exposed areas are strongly tanned by the exposure, the resists still allow aqueous solutions, such as acid solutions or electro-plating baths, to penetrate unless subjected to an appropriate after-treatment. This process, known as burning-in usually consists in heating the resist to a temperature somewhat below the point of charring, i.e. to about 600°F. However, in recent years aqueous solutions of polyvinyl-alcohol in conjuhction with bichromate have become very popular and after development of their layers in water are treated with certain strongly absorbed dyes, such as log-wood dye. Preferably after immersion in a solution of a bichromate or in chromic acid, they are then so strongly tanned that the stencils become impenetrable after burning-in at a much lower temperature.

Owing to the rapidly increasing use of photomechanical procedures for the production of stencils on substrates which are adversely affected by heat (e.g. laminated plastics) or which are very delicate (e.g. thin silicon or germanium wafers) the burning-in process required for water soluble photo-resists renders the latter somewhat obsolete.

Photo-resists in Organic Solvents. Modern photo-resists are therefore almost exclusively based on resins or polymers in organic solvents. These leave on the substrate a resist stencil which is highly resistant to etching or electro-plating solutions without any after-treatment.

The classical representative of this group is the light-sensitive natural bitumen, first used by Nièpce. A thin coating of bitumen becomes somewhat less soluble in organic solvents after exposure to light. However, very long exposure times are required and even then the discrimination between exposed and non-exposed areas is rather low. The bitumen process is therefore obsolete. Recent attempts for a revival do not seem to have met with success.

A group of photo-resists based on either alcoholic shellac solutions or on partly polymerized phenol-formaldehyde and similar resins attained considerable practicability and are used to this day. Exposure of the layers renders the exposed areas insoluble in dilute

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

alkali solution or in alcohol. However, these layers are rather sensitive to temperature and moisture conditions and the chemical resistance of the stencils obtained is relatively poor. They cannot therefore compete with the very stable and reliable photo-resists of modern design.

There are numerous representatives of this group, many of them patented, and the research in this field is very actively pursued. Many, but by no means all, of them are fundamentally based on its first representative, the polyvinyl-cinnamate ester. In itself the resist is not very sensitive to light but its sensitivity is greatly enhanced by addition of certain dyes or other organic compounds to its solutions. Some photo-resists of this description are sufficiently sensitive for allowing camera exposures.

The members of this group are sensitive in their own right. Those of another group are non-sensitive and need sensitization by addition of suitable sensitizers which must be soluble in organic solvents. So certain derivatives of rubber can be sensitized by azides (of high molecular weight). Systems of this description are widely used.

The great advantage of photo-resists in organic solvents is that the coated layers are to all intents and purposes immune against temperature and moisture conditions and that as a coated layer they remain light-sensitive and developable for a long time. In this respect they are very different from bichromated colloid layers which deteriorate within a few days or even hours owing to spontaneous hardening, the so-called dark reaction.

Furthermore, the developed stencils are highly resistant to chemical and physical treatment without the need for any burning-in.

Nevertheless, this type of resists still suffers from two short-comings of lesser importance: firstly, development in organic solvents usually leaves the surface of the substrate in a rather hydrophobic, i.e. water-repellent, state. Consequently the attack of etching solutions is initially not always as uniform as one would wish for. Similarly, image-wise electro-plating requires a perfectly hydrophilic, i.e. water-accepting, surface in order to assure perfect adhesion of the plated metal to the substrate; but it is not always easy to transform the originally hydrophobic, into a satisfactory hydrophylic surface.

Secondly, the very reason that the stencils are almost impenetrable by aqueous solutions and practically insoluble in organic solutions makes it somewhat difficult to remove the stencils without mechanical aids from the surface of delicate substrates after they have served their purpose.

Positive-Positive Resists All photo-resists so far considered yield a positive stencil when exposed under a negative and vice versa. For a long time systems have been known which work in reverse, i.e. they give a positive pattern when exposed under a positive. These systems, such as the ferri-ferro gum system were originally based on water soluble colloids and they have acquired considerable practical significance, though for visual image rather than for stencil formation.

Some resists on the market are coated from solutions of polymers in organic solvents. The coated layer is highly water-, acid-, and to a certain extent alkali-resistant. By exposure the layer is converted in to a state where it is soluble in weak alkali solutions which are in fact used as developer. In this way the exposed areas are removed while the unexposed areas remain on the substrate and form the photo-stencil. Thus a positive stencil is obtained by exposure under a positive mask.

Two-layer Processes These are, strictly speaking, not photo-resists. Here a lacquer or resin layer which is not light-sensitive is coated on the substrate. This first layer is then overcoated by a second photo-resist layer, for instance, by a bichromated polyvinyl alcohol layer. After exposure and development of the top layer the photo-stencil obtained is used for imagewise removal of the bottom layer under the areas laid bare in the top layer. Removal is usually accomplished by means of a viscous solvent for the lacquer or the resin.

Future Development Research and development concerned with photo-resists aims at specimens of highest sensitivity to light combined with high resolution and a maximum of discrimination between exposed and non-exposed areas towards developers. With the present trend of the electronic industry to miniaturization, stencils are required which give safe protection against powerful acids (such as hydrofluoric acid and its mixtures with nitric acid) and against alkaline plating solutions and which are at the same time extremely thin, as only thin layers give the required resolution and edge definition. Furthermore the resist layer ought to adhere firmly to the surface of the substrate, as adhesion is a major factor in successful etching or electroplating. E.E.L.

RESOLVING POWER. Ability of an optical or a photographic system to reproduce fine detail. In photography, the image resolution on the final picture depends on the resolving power of the sensitive emulsion, and on that of the lens. The two are not related but the effective resolution is a function of both.

The resolving power in either case is generally specified in terms of the greatest number of lines per millimetre which can be distinctly recorded on the emulsion or separated visually in the image.

The over-all resolving power of the system is always less than the resolving power of either

of its components (i.e., lens and emulsion). For reasonably accurate photographic measurements of lens resolution the sensitive material must therefore have a much greater resolving power than the lens; this will reduce the error due to interaction between the image blur of lens and emulsion. Similarly, resolution tests of sensitive materials must be carried out with as perfect a lens as possible and under conditions where it will yield the highest resolution.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Resolving power is by itself only an imperfect measure of sharpness, since other factors also enter into it. A more comprehensive physical measure is acutance.

Emulsions. With films and plates the resolving power depends on the graininess and the contrast of the emulsion, as well as on secondary factors such as thickness, colour of the exposing light, etc. Coarse grained materials naturally tend to resolve less detail than fine-grained ones, but not every fine grain film necessarily has a high resolving power. Double-coated films, as used for amateur snapshooting to ensure great exposure latitude, show very low resolving power owing to the spreading of the image through irradiation and other effects.

Measurement of emulsion resolution must be made under carefully controlled conditions of exposure and development (both of which affect the resolving power) and with a standard test object. This used to be a black-and-white high-contrast line chart. The resolution figure obtained was not, however, always indicative of how the material would behave with medium and low contrast subjects. It is therefore becoming usual to make resolution tests also with charts of reduced contrast.

Lenses. With a lens, the resolving power is a measure of the ability of a lens to form distinct images of fine, close lines. It is stated as the maximum number of lines separated by spaces of line width that the lens can reproduce as separate images. A lens is said to be able to resolve so many lines to the inch or millimetre.

The resolving power of a lens is a maximum on the axis and decreases for off-axis image-points because of the off-axis aberrations. So resolving power must be stated as being measured on the axis or at some specified point off-axis.

Imperfect correction of the coma and astigmatism of a lens produces an image patch of a point-object that is longer in one direction than in another, so the value of the resolving power varies according to the direction of the lines forming the image. For this reason the resolving power is usually specified for lines running radially from the axis, and at right-angles to it, giving radial and transverse resolving powers for any point in the field.

The decrease of resolution for off-axis image-points and the effect of the emulsion on resolution are shown very well by the following example, which is a test on a 100 mm. *f*4·5 anastigmat lens at *f*6·3 when used with commercial medium- and coarse-grain panchromatic films. The table gives the resolving power in lines per millimetre for axial and 25° off-axis image-points.

RESOLVING POWER TEST

	Medium-Grain	*Coarse-Grain*
Resolution on axis	42 lines/mm.	28 lines/mm.
Resolution at 25° off-axis	20 lines/mm.	15 lines/mm.

These results show that the resolution is better on the axis than away from it, and that medium-grain film gives better resolution than coarse.

Effect of Aperture. The effect of certain lens aberrations is reduced at smaller apertures (higher *f*-numbers), so the resolving power improves with stopping down. At small apertures diffraction effects are however liable to lead to a deterioration of image quality.

The best detail resolution of a lens is therefore obtained at a compromise aperture, small enough to lead to good lens correction and large enough to avoid deterioration due to a diffraction.

With some lenses stopping down can reduce the resolving power even before the effect of diffraction becomes noticeable, because the optimum definition may be a matter of balancing the image resolution of the central and of the marginal areas of the lens.

The resolving power depends also on the contrast of the test image used to measure it. The obtainable resolution is always higher with a high contrast image than with a low contrast one. The variation of resolving power with contrast is often expressed in the form of a contrast transfer function curve which gives a more complete indication of lens performance in terms of detail recorded than a single resolving power figure. D.P.C.

RESTRAINER. Chemical added to inhibit the fog formation in certain developers where the developer acts both on the exposed and unexposed silver salts in the emulsion. At the same time the restrainer reduces both the development speed (increases the development time) and also the emulsion speed of the sensitive material. Generally, highly active and strongly alkaline developers need a restrainer most, while low energy fine grain developers often do not include a restrainer at all. The amount of restrainer added also depends on the sensitive material. Films and plates can stand more heavily restrained developers than papers.

Potassium bromide is the most frequently used restrainer. Its restraining action depends both on its concentration and on the other ingredients present, especially the developing agent. Generally, contrasty developers are

most affected by potassium bromide. Paper developers with high potassium bromide content give warm black or often unpleasant greenish tones.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Sodium bromide can also be used in much the same way. Seven parts of potassium bromide are equivalent to about six parts of anhydrous sodium bromide or eight parts of the hydrated salt.

Ammonium bromide must not be used as restrainer unless specially called for in the formula. An alkaline developer containing ammonium bromide would liberate ammonia and thus be rather uncertain in its activity.

Very rarely, sodium chloride or potassium iodide are used as restrainers.

Anti-fogging agents are also restrainers, and are often more efficient in keeping down fog due to deterioration of the emulsion, oxidation of the developer, and other chemical effects. They do not, however, restrain the activity of the developer to the same extent as potassium bromide.

See also: *Developers.*

RETICULATION. Distortion of the emulsion layer of the negative caused generally by the use of a cold developer followed by a warm fixing bath. The emulsion wrinkles into a regular pattern for which there is no cure. The same thing may occur if a concentrated developer is followed by a plain rinse (especially in colour processing). The primary cause of reticulation—present in the above cases—is excessive swelling of the gelatine.

Reticulation can be avoided by always developing at a lower temperature than 75° F. (24° C.) and keeping all solutions within 3° F. (2° C.) of the same temperature. In colour processing in warm weather, a rinse of 5 per cent magnesium sulphate (instead of plain water) is advisable after the first development to avoid excessive swelling of the emulsion.

Reticulation is sometimes produced deliberately for the special texture it gives to the picture. This breaks up large areas of even tone, and can thus improve the pictorial effect of broad open views. In that it resembles the effect of a texture screen but once the negative is reticulated it cannot be made normal again.

There are two methods of intentional reticulation: the negative is developed at a temperature of 105–115° F. (40–45° C.). This automatically produces reticulation. Negatives that have already been developed and fixed (in an acid hardening fixer) may be bathed in a 10 per cent solution of sodium carbonate at 120–125° F. (49–50° C.). As soon as the gelatin feels wrinkled when touched gently, it is washed in cold water.

Slight accidental reticulation can sometimes be cured if the negative is bathed in alcohol (diluted with 1 part in 5 of water in the case of films) and then treated with an alum hardener.

Reticulation of the gelatin anti-curl backing occurs sometimes on films; in fact the anti-curl backing is more prone to reticulation than the actual emulsion in some cases. Fortunately this fault does not usually show in the final print.

RETICULE (RETICLE). American term for graticule, a sighting or measuring aid consisting of a fine line pattern superimposed on the image visible in certain optical instruments.

See also: *Graticule.*

RETOUCHING

Any work carried out on a negative or print by hand with a brush, pencil, knife, etc., is known as retouching. The purpose of retouching is: to remove or disguise blemishes in the negative or print; to do the same thing for the sitter—e.g., to remove wrinkles; to add something to the photograph—e.g., clouds—to make it a better picture; or to work up the tones of a photograph for photomechanical reproduction.

NEGATIVES

Plates, roll and flat films present no great difficulties in retouching, although it is always better to retouch the print if convenient, since a spoilt negative cannot be replaced like a print. 35 mm. and other miniature negatives are best left alone altogether, retouching being carried out either on the print, or by making an enlarged negative and carrying out the work on that.

The plate to be retouched is mounted in a frame on a retouching desk and illuminated from behind. Films to be retouched are held down by the edges on a clear glass plate in the same type of desk.

Those who can manage to use a watchmaker's glass will find it a great advantage in carrying out very fine detail. A 4 ins. glass is about right for most people.

Dark Marks. Small negative areas—e.g., halation rings—can be reduced physically by removing part of the gelatin layer, and with it part of the silver image.

This form of local reduction is carried out by rubbing the negative surface with a fine metal polish paste, or a mixture of finely powdered pumice, vaseline, and a little paraffin wax, or with Baskett's reducer.

Physical reducers are applied on a pad of cotton wool over fairly large areas, or on a suitable stump for small areas that require more local control.

From time to time the paste is washed off

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

ABRASIVE REDUCTION. Clears larger, less well-defined, areas. 1. Rub stump with reducing paste applied to it over surface until area to be treated is sufficiently reduced. 2. Remove all powder by wiping with cotton wool.

KNIFING. Lightens small areas or fine details. 1. Scrape area in close parallel strokes. 2. Overlay with second set of strokes at an angle to first to hide texture of work.

with alcohol or carbon tetrachloride, to check the progress of the reduction.

With experience, small dark areas can also be reduced by chemical means. The negative is first soaked in water charged with a little wetting agent. Then, using a pad of cotton wool, a weak solution of Farmer's reducer is applied to the area. A supply of fresh water and cotton wool, or better still a dish of clean water, should be kept handy in case any reducer goes in the wrong place: provided that the reducer is not too strong, should this happen a quick rinse in water will prevent any reduction occurring. No attempt should be made at reducing the dark area on the first application of reducer: the reducer should be weak enough to require repeated applications before showing any effect; in this way, patchy, uneven reduction is avoided. When the density has been reduced sufficiently, the negative must be well washed before drying.

Small spots or flaws are more easily removed by chemical reduction. The technique should be the same as for larger areas, except that a brush instead of cotton wool is used to apply the reducer.

Another way of removing small blemishes is by physical reduction with a retouching knife; this is a specially shaped knife, usually with interchangeable blades. The type of blade used depends on whether negatives or prints are to be retouched, but, although this is not critical, once a blade is used for one type of work, it should not be used for any other.

The blemishes are thinned by carefully scraping the gelatin layer with the point of the knife, which must be kept very sharp. The technique is simple, but the beginner should practise on an old negative. The point of the knife barely touches the surface of the negative and each stroke scrapes away only a minute shred of gelatin. Small areas are lightened by scraping first in one direction, and then at an angle until the density of the spot treated is gradually reduced to that of the surrounding image.

It is important to have the knife razor-sharp, as an unsharp edge calls for relatively heavy pressure which digs it into the gelatin and removes too much at once. When knifing is lightly and skilfully carried out the results are practically invisible.

It is even possible for actual areas of tone to be scraped away with a retouching knife. In this way dense areas can be lightened and even have modelling introduced. But the technique is extremely difficult and should only be attempted after extensive experience on waste or unimportant negatives.

Spotting. Small transparent spots and pinholes in the negative are best removed by spotting with dye or water colour.

CHEMICAL REDUCTION. Useful for removing dark spots. 1. Soak negative (or print) in water with wetting agent added. 2. Touch out the spot with brush charged with Farmer's reducer.

SPOTTING. Darkens small spots or areas on negatives and prints. 1. Stipple larger areas with water colour made up to suitable strength. 2. Fill in small spots in dense areas with single application of strong water colour or indian ink.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

DYE SPOTTING. *Accurately matches small or larger spots. 1. Apply dilute dye to area. 2. Repeat application until surrounding density is matched.*

BLOCKING OUT. *Produces completely white backgrounds. 1. Paint band round subject outline on negative with black retouching dye. 2. Fill in rest of area with opaque pigment.*

A fine sable brush with a perfect point is filled with diluted grey retouching dye or water colour pigment, turned to a point on a piece of paper, and applied to the spot. The brush is used fairly dry; a wet "loaded" brush applies the colour in heavy, uncontrollable blobs.

There are distinct differences between pigments and dyes used for spotting:

(1) The dye is a solution which stains the gelatin, while the water colour is a suspension of solid pigment.

(2) The dye sinks into the gelatin, while the pigment settles and dries in a layer on top.

(3) The dye is applied by repeatedly touching the spot with dilute solution until the correct density has been built up. The pigment is applied by touching the spot once only. The strength of the pigment must therefore match the tone of the surrounding area, as repeated application would smudge the pigment already there.

(4) If too much pigment is applied, it is easily wiped off with a piece of moist cotton wool but dye can only be removed by soaking the negative in water for some time.

(5) Dye retouching is grainless, while the pigment application is grainy and may become visible on enlarging.

(6) With dye, large spots are filled in by applying repeated washes of dilute solution. With pigment, larger areas can only be covered by applying many small spots side by side—stippling the solid pigment on to the negative with the point of the brush.

(7) Dye is absorbed by the gelatin emulsion, so it can only be used where the gelatin layer is intact. But pigment, particularly if it is mixed with a little gum, will stick directly to the film or glass support, and so can be used to fill in actual holes or scratches in the emulsion.

Blocking Out. It is often necessary to remove the background of the negative completely—particularly in photographs used for catalogue illustrations, advertising, and composite pictures. This is done by blocking out the image of the subject.

To start with, a band about ⅛ in. wide is painted around the outline of the subject with black retouching dye or opaque medium sold specially or this purpose. When using dye, a number of fairly weak washes are applied until the band is opaque; this technique gives a soft edge that is much less obvious than that of a layer of pigment put on in a single application.

The area outside the band may then be filled in with opaque pigment painted on the back of the negative, or covered with black paper.

It is often useful to be able to hold back particular areas of the print—e.g., an obtrusive background—without blocking them out completely. This can be done by covering the corresponding area on the negative with a wash of dilute black or red (neo-coccine) dye. The parts treated will then print paler than the rest and become less assertive. This treatment is a remedy for areas of under-exposed shadow that create excessively dark areas on the print. When applying the dye, it is better to use it in very weak washes and build up the depth gradually.

Retouching foils. A more modern method of area tone control uses retouching foils. These are thin cellulose sheets carrying a red or purple dye layer. This layer is bleached out by a special solution supplied with the foil. In use, the foil is placed in contact with the negative (preferably taped together) and the required areas bleached out—over a light box—by applying the bleacher with a brush. In this way fairly intricate outlines can be followed accurately, and desired areas held back (by not bleaching them out) during printing. The negative is of course printed in register with this foil mask. The foil is available in different densities, and two foils can be superimposed with different portions bleached out to provide varying degrees of control.

Portraits. On portrait negatives it is sometimes desirable to remove minor facial blemishes and flaws, or to soften outlines and wrinkles.

Dark marks on the print appear as light areas on the negative and can thus be "touched out" by covering them with pencil. (Light marks on the print which appear as dark marks on the negative are either knifed out on the

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

PENCIL RETOUCHING. Removes facial blemishes, etc., on portrait negatives. 1. After treating surface with retouching medium, pencil in light areas. 2. Best hold for pencil.

negative or spotted out on the print.)

As pencil will not take on gelatin, the surface is first rubbed over with a matt varnish. This can be bought or can be made up—e.g., from the following formula:

Gum dammar	2 parts
Canada balsam	1 part
Turpentine	80 parts

Method. A little of this applied to the negative with a piece of flannel, well rubbed in and allowed to dry, will provide a "tooth" for the pencil.

Retouching pencils are made in several degrees of hardness. A hard lead is best for small amounts of darkening and a softer one for adding more density.

During retouching the pencil point is rubbed with a circular motion over the spots requiring treatment. Some workers use short straight strokes, but this style tends to show up more on enlarging.

The density that can be added by pencil retouching is limited. After a few applications over the same place, the pencil point tends to polish the surface so that it will not take any more pencil work. Soft pencils give more blackening than hard ones, but even they refuse to build up density beyond a certain point.

The pressure of the pencil point must be light, or it will polish the surface smooth much sooner. Excessive pressure may push the matt varnish layer aside completely, especially if it has not been given enough time to dry.

The retouching can be removed—together with the varnish layer—by rubbing over the print surface with a plug of cotton wool soaked in petrol or turpentine.

Pencil retouching requires a good knowledge of facial anatomy if the effect is to look natural and blend with the original negative image. Retouching aimed at giving roundness to the face is only permissible where the face muscles could themselves have given roundness; it must produce face shadows only where these could arise naturally from the skin and bone structure.

Retouching Machines. For commercial purposes, where large numbers of negatives have to be retouched, machines for speeding up the operation have been produced. Not only are these fast in use, but they also make it easy for unskilled retouchers to achieve perfect results with a minimum of practice.

The negative is loaded into a carrier which is illuminated from underneath. When the machine is switched on, this carrier oscillates at a very high frequency. Because the actual movement is so slight and fast, the negative appears to be stationary. However, when touched with a pencil, a smooth mark is made which, because of the oscillations, is even and without any sharp edges. In other words, instead of the retoucher moving the pencil, the machine moves the negative. By slowly drawing the pencil across the negative, it is claimed that whole areas of tone can be built up in this way.

PRINTS

Prints to be retouched are laid face up on a flat table or desk in good light.

Most of the spots that have to be touched out on prints could be prevented by greater care at some earlier stage of making the print or negative. It always takes more trouble to touch a spot out than to prevent it.

Spots on the print are either lighter or darker than the surrounding surface. If they are lighter they can be made less noticeable by darkening them on the print. If darker, they can be touched out on the negative or reduced on the print.

Light Spots. There are three ways of darkening out a light spot on the print and they may be used in combination: by filling in the light spots with opaque pigment; by colouring the spots over with suitable dye; by spotting with a soft pencil.

Pigment Retouching. Spotting prints with pigment is a simple operation. The necessary skill can be easily acquired with a little preliminary practice on a waste print.

The expert retoucher uses good quality sable brushes with long tapering points (if the point is bent over by pressing it against a hard surface it should spring out straight as soon as the pressure is released). A Number 0 brush is suitable for normal spotting; Size 2 is used for filling in larger areas.

Good quality artists' water colours are the most suitable pigments. Cheap colours often change after exposure to air and light. Payne's grey and indian ink give the right tints for matching the grey and black tones of bromide prints. Warm tone (chlorobromide) prints may call for a slight addition of burnt umber. Burnt umber is also suitable for sepia toned prints, and if the print is a cold sepia the tone can be matched by adding a little indian ink.

These pigments are suitable for retouching matt or rough surface prints. When a glossy print is spotted with ordinary water colour, the

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

dull brush work stands out on the shiny surface. To counteract this, a very small quantity of liquid gum is added to the water used for mixing the colour, or as a quick dodge, mix a little colour on the back of gummed paper. An alternative method is to cover the pigment with a spot of negative retouching medium.

A small quantity of Payne's grey is squeezed out upon a palette or sheet of clean glass and a small quantity of indian ink is added. A drop or two of water is mixed into the colours with a brush. The colour and depth are checked on a piece of white paper, or on the margin of the print.

It is usually more convenient to start by matching the colour to the deepest shadow so that the pigment can later be diluted with extra water for working on the lighter areas.

If the brush has been used to mix the pigment, it must be well washed, and most of the mixture removed with blotting paper. It is then rolled into the pigment so that it attains a long tapering point and the surplus pigment is wiped off the point on a sheet of clean paper. The brush is then applied lightly and the spot should disappear almost at a touch.

If the defect is too large for it to be treated with a single touch several successive applications are given, each being allowed to dry before the next is applied. The brush is used almost dry and the colour is applied sparingly. No attempt is made to "paint out" large defects; they are covered with a light stipple or a number of small dots of colour.

After the darkest tones have been spotted the pigment is diluted slightly and used to touch out the blemishes on areas that are not quite as dark, and so on up to the highest lights where the faintest trace of very dilute pigment on the brush is sufficient.

When a batch of prints is being dealt with, the darkest tones on all the prints are spotted before going on to the lighter tones.

Light lines on the print are gradually covered by a number of delicate touches or "dots" with the brush.

Those who do not wish to use water colour can purchase print spotting preparations manufactured for the purpose.

This form of retouching, since it is carried out with solid colour, is always visible as a raised mark on the print. For this reason it is unsuitable for glossy surfaces but generally satisfactory on matt or rough papers. (There is, however, nothing against using pigments for retouching glossy prints intended for reproduction.)

Dye Retouching. During recent years another way of finishing prints and modifying tone values has come into popular use: dye retouching.

Dyes are superior to pigments for retouching because they penetrate the emulsion and are quite invisible even upon a glossy surface paper.

Dye retouching can be used to take out white spots, lines, scratches and similar defects. It can also be used to alter the tones of a print; if a shadow lacks depth it can be given a thin wash of dye to deepen its tone, or highlights like patches of sky seen through trees, windows in interior subjects, or a prominent highlight in a portrait can be washed over to make them less assertive.

The aim is to match the colour as well as the depth of the image. As supplied, the black dyes match the colour of the normal bromide print. For warm-toned images or prints made on chlorobromide paper the black dye is mixed with a suitable amount of brown.

The dye is diluted with water and mixed on a porcelain palette or in an odd saucer. After mixing, it must be kept well stirred or the colours may be patchy when they dry. A little dye is taken on the brush and tested on white paper or the edge of the print. If it is too dark, more water is added until it comes to the right depth of tone. The darkest tones are dealt with first and then the dye is progressively diluted to spot correspondingly lighter tones.

The commonest fault is to take too much dye up on the brush. This forms a blob and dries too dark. If too much colour is applied it can be sometimes wiped off with wet cotton wool, but it is generally more satisfactory to soak the prints in cold water to remove the dye, and then make a fresh start.

Glossy prints are first soaked in water for a few minutes. The print is then placed upon a smooth surface, and spotting carried out on the wet print. When the print is dry the spotting will be quite invisible and after re-soaking the print can be glazed as usual. Another way of making spotting invisible on a glazed print is to add a trace of gum to the dye solution.

Pencil Retouching. When light marks on the print are quite small and the adjacent tones not too dark, a pencil may be used for spotting them. Although not so satisfactory as dye retouching, the technique is easier to master and often much more speedy to use.

A pencil with a soft lead is sharpened to a good point. The area to be filled is then lightly stroked with the pencil so as to leave very small, light dashes. The pencil should not be pressed hard against the surface. In this way, by repeatedly covering the area lightly, the tone is built up to match the adjacent tones. If a mistake is made, it can be easily removed by rubbing with a clean piece of bread, or lightened or softened with the finger tip.

Very small spots are filled by the same method—never by pressing the point of the pencil in the spot; always stroke the spot, however small. With practice, it is quite easy to make a stroke in even the smallest of spots, and a surprising speed can be attained.

When the pencil retouching has been completed, the surface of the print must either be sprayed with a fixative or steamed over a boiling kettle; this is essential to prevent the

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

RETOUCHING TOOLS. A, *magnifying glass.* B, *paper stump.* C, *felt stump; both stumps used for applying graphite powder or abrasive reducer to negative.* D, *retouching knife taking interchangeable blades (available with various cutting edges).* E, *retouching knife with fixed blade.* F, *retouching pencil in holder.* G, *dye brush.* H, *spotting brush.*

retouching from coming off. Special fixative—as used by artists—can be sprayed on with a tubular spray which is usually sold with the fixative. If steam is used instead, the print must be held close to the spout of a boiling kettle until the gelatin surface becomes tacky.

Dark Spots. Dye retouching will only cover up light spots on dark areas (because there is no such thing as a white dye). Dark spots on light areas of the print can be avoided by touching out the corresponding clear spots on the negative with dye pigment or pencil. But there are objections to working on the negative because once a negative is spoiled there is no second chance; while miniature negatives are very difficult to retouch successfully.

It is safer, and generally easier, to convert the dark blemish on the print to a white patch by chemical retouching or knifing and then touch it out with dye or pigment.

Chemical Retouching. Chemical retouching is the process of bleaching out dark areas on the print. The process is not confined to the removal of black spots; areas of dark tone can be lightened and highlights made brighter.

The commonest reducer is called Farmer's reducer, formed by mixing potassium ferricyanide and hypo in water. The following is perhaps the easiest method for spotting prints.

The tip of the spotting brush is moistened and applied first to a crystal of ferricyanide and then to the black spot on the print. All the black spots are treated in this way and the print is put into a plain hypo fixing bath.

All black spots on the white parts of the print will disappear in a few seconds; elsewhere they will change to white spots on a darker ground and in that condition they can be easily dealt with by pigment or dye spotting.

The print is removed from the hypo bath, well washed, and dried before any further work is done on it.

If the print contains an area where the tone is too dark, it may be lightened by the same method, but in this case the action must be stopped when it has gone far enough. The action may be controlled by using a mixture of the following solutions:

Stock solution A		
Hypo	4 ounces	100 grams
Water	40 ounces	1,000 c.cm.
Stock solution B		
Potassium ferricyanide	4 ounces	100 grams
Water	40 ounces	1,000 c.cm.

About 100 minims (5 c.cm.) of B are added to 1 ounce (25 c.cm.) of A immediately before use. The mixed solution will not keep; for use it should be pale lemon yellow and should be discarded as soon as its colour disappears or changes to blue green.

The solution is painted over the dark areas of the wet print and as soon as the reducing action has gone far enough, the print is washed vigorously in clean water. To be on the safe side the action should be stopped while the tone is still a little too dark as it goes on reducing for the first second or two in the washing water.

This method of local reduction can be used to give more sparkle to highlights, to add clouds to blank skies, or to improve the tones in a portrait. It can also be used to remove unwanted objects like telegraph poles, printed notices, and advertisements that mar a landscape picture. In this case the unwanted object is completely bleached out and the white area is retouched by successive applications of black or grey dye or pigment to match the surrounding tones.

Knifing. Very small, dark spots can be quickly removed with a retouching knife, using the same technique as for negatives. However, extra care must be taken to leave a smooth surface on the print; some paper surfaces, such as glossy, show up knifing very badly unless the knife is used carefully.

As with chemical retouching, it is better to knife the spot until it is quite clear and then dye it to match the surrounding area.

Reinforcement. Various methods may be used to reinforce the tones in a print by manual application of graphite or pigment. The most popular system uses pigment in an oil medium, and is known as oil reinforcement. This is a special technique, and as such barely comes within the scope of normal retouching.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Transparencies. While miniature colour transparencies are too small for retouching of detail, the transparency as a whole may need some overall colour correction to modify colour casts.

Apart from chemical methods of after treatment this can be done by binding up sheets of pale tinted cellophane or plastic with the transparency, or by tinting the whole film. That involves immersing the transparency in a suitable dye bath until the required modification of the colour is obtained.

Larger transparencies permit some retouching with dyes. Suitable dyes for this purpose are similar to those used for tinting and colouring black-and-white prints. Knife retouching and scraping are not possible on transparencies, since this would remove the three layers unevenly.

Colour Prints. Colour print retouching is also possible with water-soluble dyes of the same kind as employed for colouring prints. It is best to use several applications of the dilute dye to build up or modify a colour tone. The more dye is added, the darker the treated detail becomes. Owing to the presence of three emulsion layers, removal of dark spots and other blemishes is impossible also from a colour print. Such faults are best retouched on the colour negative, leaving lighter areas if necessary on the print, which can then be filled in afterwards.

Colour Negatives. As negative colour tones are made up of three dyes, retouching of colour negatives equally needs three colours.

The most suitable medium is a set of coloured retouching pencils in yellow, magenta and cyan plus a dark brown or black pencil to lighten shadow detail where necessary.

Judging the right colour effect needs some experience, not only because of the reversal of the colours but also because the mask tint of some colour negative materials is superimposed on the colours of the image.

Spots and blemishes on colour negatives often have a predominant colour themselves. For instance spots may be greenish, bluish or reddish and need filling in by applying the pencil or pencils of the complimentary colours. The brown or black pencil can then be used to equalize density differences.

It often helps the retoucher to have a black-and-white guide print made from the negative on a panchromatic bromide paper.

One way of assessing the effect of the individual retouching colours separately is to use coloured viewing filters. The effect of the yellow pencil retouching is checked through a blue filter (which greatly subdues the confusing effect of the magenta and cyan dye images). Similarly a green viewing filter can be used to check the retouching work with the magenta pencil on its own, and a red filter for the cyan corrections. The density of retouched spots should equal or smoothly blend with their surroundings when viewed through each filter in turn.

Before the start of the pencil work the film surface requires an application of retouching medium.

For slight corrections this can be on the emulsion side; where a great deal of retouching is necessary both sides can be treated and worked over with the pencils. During the work the negative should be in a retouching desk, lit from underneath either by daylight or by daylight blue tungsten bulbs. It is best to have a rather higher intensity of illumination than for black-and-white negatives, to permit easier judgement of the colour adjustments.

R.M.F.

RETOUCHING DESK. Table or stand to support and illuminate negatives during retouching. It consists of a base supporting a hinged frame which is adjustable to different angles to suit the needs of the worker. In the centre of the frame there is a recessed opening to take the negative. The opening may be fitted with a nest of adapters to hold negatives of different sizes. There may be an adjustable flap over the frame to screen off stray light. The desk is used in a window, over a sheet of white paper which acts as a reflector and illuminates the back of the negative. Instead of daylight, many operators prefer to use the diffused light from a low-powered electric lamp with the rest of the room in semi-darkness.

A retouching desk should be of rigid construction and of fairly large size. It must be capable of supporting the negative as well as the pressure of the operator's hands resting upon it. It should be possible to adjust the angle. The desk should be set upon a rigid table.

In some studios the desk consists of a table with the recessed aperture for the negative or nest of adapters actually cut in the top and illuminated from below by diffused electric lighting. Another type of desk that is popular with amateurs is made in the form of a box with a sloping top cut out to take the negative. Inside the box a small electric lamp bulb—not more than 25 watts—behind a sheet of opal glass provides the illumination. It is important for such boxes to be well ventilated to prevent the heat from the lamp from steaming up the back of the negative or even melting the emulsion.

On professional retouching desks the

negative carrier is free to rotate in a circular recess so that the operator can turn it to the easiest position for working on.

For retouching film negatives, the aperture is first fitted with a sheet of glass—opal for preference. The negative is placed in position over the glass and held flat by a masking frame.

Certain mechanized retouching desks support the negative on an electrically-driven vibrating carrier. This simplifies pencil work. The pencil has only to be applied to the areas to be shaded and the vibration of the negative carrier produces the pencil stroke pattern.

On any type of retouching desk the negative carrier and adapters must be a good fit so that light cannot leak around the edges and shine directly into the retoucher's eyes. Very thin negatives that transmit a lot of light and dazzle the retoucher may be roughly masked down with black paper to the actual area being retouched, or the power of the light can be reduced by inserting sheets of paper between the lamp and the negative carrier. R.M.F.

RETROFOCUS SYSTEM. Term frequently applied to lens systems which have a back focal distance appreciably greater than their nominal focal length. Such lenses are used in miniature reflex cameras and in cine cameras as wide-angle lenses, because the back focal distance with a normal lens design is inadequate to accommodate the shutter, reflex mirror or other constructional features of the camera.

Retrofocus lenses are almost invariably of the inverted telephoto type. This construction is predominantly used for wide-angle lenses, but may also be found in lenses of normal focus.

See also: *Wide-angle lens.*

REVERSAL MATERIALS. Most negative materials can be processed by reversal to yield a direct positive. For the best results, however, the negative emulsion should have specific characteristics, and special reversal emulsions are therefore manufactured. Most of the black-and-white materials are narrow gauge amateur cine films, and a few 35 mm. and larger size reversal films are also available for still photography. An appreciable proportion of the colour films marketed for amateur use are designed for reversal processing. In addition, materials using special reversal systems are produced for copying, rapid photography, and similar purposes.

Normal Taking Materials. Reversal films (reversal plates are practically non-existent) for use in the camera have the following characteristics.

(1) A thin emulsion layer. The final image is formed by the silver salts left in the emulsion after the first exposure and development. The total silver halide should not therefore exceed about twice the amount made developable by the normal camera exposure. Otherwise too great camera exposures become necessary to leave only the correct amount of unexposed silver halide, i.e., the effective speed of the emulsion falls, although a perfectly good image is formed by the first exposure.

(2) A continuous and even range of grain sizes from small to large. This is important to permit processing compensation by controlling the second exposure. The silver halide left after dissolving away the negative image is not evenly sensitive everywhere; it is most sensitive where slight first exposure has left comparatively large (and therefore fast) halide grains undeveloped. It is least sensitive where heavy first exposure (corresponding to the highlights of the subject) has left only the smallest (and slowest) halide crystals unaffected. A controlled second exposure, even if not complete, will therefore yield a positive image, corresponding to the negative, on development. The quality of that image will depend on the continuity and range of halide crystal sizes in the emulsion.

(3) Freedom from fog. In the positive image fog degrades the highlights, while in the negative image produced on first development fog reduces the maximum density obtainable in the positive. Reversal films are coated on a clear (non-tinted) base, even in the 35 mm. format.

(4) Reasonably high contrast. The positive image produced on second development has to show adequate brilliance and yield a full range of tones from very thin to nearly black.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Speed of Reversal Materials. The speed criteria on which the usual film speed systems are based do not apply to reversal materials, since the result of the reversal process is a positive and not a negative image. Emulsion speeds, when quoted—even if in a standard system—therefore imply merely that the material is to be exposed like a negative film of the stated speed to yield the best results. Such speed figures are not therefore based on the same sensitometric measurements.

Other Characteristics. Reversal materials are nowadays usually available with panchromatic emulsions, though they could equally well be sensitized only orthochromatically.

As transparencies have to stand up to considerable magnification in projection (especially narrow gauge cine film), most reversal films have fine grain emulsions. The positive image produced by reversal is in any case intrinsically finer in grain than the negative from which it is derived. This is because the latter uses up most of the larger halide grains in the emulsion (see above).

To reduce the risk of halation to a minimum, some reversal films carry an anti-halo layer between the emulsion and the support. The reason for this is that a gelatin layer on the back of the film would very soon get scratched during the normal manipulation of the viewing and projection, while a tinted base would make clear highlights impossible.

Special Taking Materials. Sensitized papers are used as camera material by some street photographers. There the image produced by the camera exposure is partially developed, exposed to daylight, and allowed to develop out fully. The result is a negative with a much stronger positive image superimposed on it, so that the picture appears as a positive. The highlights are of course never white, but the picture is generally acceptable to the average customer of the photographer.

A combination of a sensitized negative paper and a non-sensitive positive paper is employed in the cameras using the Land process. The papers are loaded into the camera in separate rolls, and the negative and positive images developed inside the camera by the transfer diffusion process. The so-called picture rolls or packs are available in a range of speeds up to 3,200 A.S.A. (10,000 A.S.A. for special purposes) in black-and-white and colour, and as transparency material to yield monochrome positive transparencies.

Reversal Materials for Copying. A number of commercial process and photomechanical films and papers are designed to yield equally good results by negative or reversal processing. Special reversal materials also utilize the fog-destruction or the transfer diffusion system.

Several self-positive materials of the fog-destruction type are marketed by leading manufacturers under various trade names. They can be used for contact copying of documents either by transmitted light or by the reflex copying method. Only a single exposure (usually to yellow light) is necessary which destroys the original emulsion fogging in proportion to the density of the original being copied, after which straightforward development and fixation (or stabilization) yields the positive image. In practice the papers may be processed by application of the developer by a brush or similar device while the material is placed on an absorbent porous block, followed by the stabilizer used in the same manner. This permits rapid and certain processing even by unskilled staff in normal office conditions—where this system of copying is frequently used.

Transfer diffusion materials may use two separate supports for the negative and positive images, or carry both emulsions on one support. In the first case the two emulsions are squeegeed together in the processing solution after exposure, and stripped apart when developed; this often takes place in desk-size automatic processing machines for office use. The double emulsion type of material has a tanned positive layer; after exposure and processing the negative layer is dissolved away by warm water. L.A.M.

REVERSAL PROCESS

Reversal is a method of developing an image to produce a positive directly on a plate or film that has been exposed in the camera. It can serve equally for making a direct negative from a negative or a direct positive from a positive transparency.

The stages of making first the negative and then the positive are usually carried out in the same emulsion layer instead of on two different sensitive materials. Most amateur cine films and many types of colour film are processed by reversal. The advantage is that no separate printing material is called for. But only one copy can be made at a time. Any further copies have to be made by the relatively lengthy technique of duplication.

Materials. In principle, any sensitive silver halide emulsion may be processed by reversal, but there are materials which carry an emulsion with suitable characteristics for this particular method of processing.

The right characteristics for a reversal emulsion are an even range of large and small silver halide grains in the emulsion; and ability

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

to give reasonably high contrast. Reversal colour films may utilize dyes of different absorption characteristics from those used in negative colour films which have to be printed on a positive colour material.

Special direct reversal materials are also made for document copying and similar purposes. There the positive image is produced at the same time as the negative image by a process of transfer diffusion. An alternative system uses a pre-fogged emulsion which is exposed in such a way that the fog density is destroyed by the image exposure.

Exposure. Reversal materials have a very limited exposure latitude and therefore require accurate exposure. The reason is that the additional control over density provided by the printing process is very largely absent. Over-exposure uses up too much of the sensitive salts in the emulsion for the negative stage, and does not leave enough for the final positive. Similarly, under-exposure leaves too much silver halide for the positive stage.

Exposures with reversal cine film and colour film should be based on the highlights of the subject rather than the shadows.

BLACK-AND-WHITE REVERSAL

The stages in reversal processing are:

(1) First development to form the normal negative image.

(2) Bleaching to remove the negative image. This leaves behind varying amounts of silver bromide. The amount of silver bromide left behind is inversely proportional to the silver salt used to form the first image. Where the negative image was dense, the bleaching process leaves only a little silver bromide behind; where it was thin it leaves a correspondingly greater amount.

(3) Re-exposure to white light to render the remaining silver bromide developable.

(4) Second development to blacken the residual image, producing the positive.

Results vary greatly; they depend both on the sensitive material and on the developer—particularly the first developer—used.

Not all emulsions will yield good reversal images. Very soft materials are not suitable; in fact a fairly contrasty emulsion is preferable. The special reversal materials on the market are best used with the developers recommended for them.

Duplicate negatives can be made by reversal processing of a number of normal negative materials. Usually the manufacturers publish specific recommendations and formulae. Duplicate transparencies from black-and-white transparencies should be made on clear-based emulsions, otherwise the inherent base tint may give the transparency a general and sometimes disturbing tinge.

The First Image. The character of the final image depends to a great extent on the original

EXPOSURE AND REVERSAL MATERIALS. Left hand column: *Effect of under-exposure.* Centre column: *Correct exposure.* Right hand column: *Effect of over-exposure. In all cases:* 1. *Subject.* 2. *Latent image after camera exposure.* 3. *First development.* 4. *Silver image bleached out.* 5. *Remaining silver halide re-exposed.* 6. *Second development.* 7. *Corresponding image tones. Under-exposure leaves too much silver halide after first development and destroys shadow gradation of subject since the deeper shadows merge into black in the first image. Over-exposure uses up too much silver halide before second development, leaving too little for the final image, and thus destroys highlight detail.*

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

REVERSAL PROCESSING. 1. The exposed film is first developed in a normal negative developer containing a suitable concentration of silver solvent. This produces a negative image. 2. After a thorough wash, a bleacher removes all the silver produced by the first developer, leaving only a positive image of unexposed silver halide. 3. Thorough exposure of the whole film to strong artificial light renders the remaining silver halide developable. All subsequent stages can take place in normal white light (but not daylight unless adequately subdued). 4. Redevelopment in a normal negative developer blackens all the silver halide, and yields the reversed positive image of the original scene on the same film as exposed in the camera.

negative image; a weak first image usually yields a dense, second image; a contrasty and dense first image will yield a contrasty and thin second image.

The best results follow when the silver bromide used up for the first image is about the same as the silver bromide left behind after bleaching. So both the original exposure and the first development are important.

While a certain amount of control is possible in the first development, it is risky because under- or over-development affects the contrast. It is much sounder to standardize the first development so that the original exposure alone controls the density of the negative image. There will thus be very little latitude to spare when making the original exposure.

The Second Image. After bleaching, the simplest procedure is to expose the residual silver bromide fully to white light, and then develop it out completely.

If the original exposure and first development were suitably balanced, no further control is necessary. In that case it does not matter whether the re-exposure takes place before, during, or after, the bleaching process; the white light can in fact be switched on as soon as the film is in the bleacher.

Some control is possible during re-exposure and during the second development, but the latitude is small. A first image that is very thin will not produce a good final picture.

But if the first image is only slightly on the thin side, the re-exposure may be curtailed. The results (tone gradation especially) will now depend upon the stage at which the second exposure is given.

During re-exposure before bleaching, the residual silver bromide is masked by the negative image, while after bleaching the light reaches the whole emulsion evenly. After only partial re-exposure some of the silver bromide will remain undevelopable, and the final image will be less dense.

Automatic Control. In commercial processing of reversal cine film, a photocell, influenced by the amount of light transmitted by the negative image (or alternatively by the residual image) automatically adjusts the strength of the light for the re-exposure. This system is known as automatic exposure compensation. The limits of this method of control are fixed by the shadow detail and the highlight density of the negative image.

If the shadows are so thin that almost all the silver bromide is left in the emulsion after the first development, the shadow gradation in the final image will be negligible, however much the re-exposure is controlled. In other words, the shadows will be solid black.

In such a case a controlled re-exposure through the negative image before bleaching will improve matters. The silver image will itself selectively control the light reaching the shadow areas, and will improve gradation.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

If the highlights of the negative image are so dense that very little silver bromide is left behind in the emulsion, even full re-exposure will not bring out much highlight detail, and it may block up the shadow completely. And the fact that the contrast of the negative image tends to be lower at high density (particularly in the shoulder region of the characteristic curve), makes matters still worse.

A certain amount of control is also possible by shortening the duration of the second development. The result is different from partial re-exposure; control during re-exposure affects the density but not the contrast of the image; control during redevelopment lowers both the density and the contrast.

Thin negative images may be controlled to some extent during redevelopment. Reducing the time in the second developer reduces the final image density, but may give far too little contrast. This method is therefore limited to negative images which are fairly thin and at the same time very contrasty. But such images are usually the result of under-exposure in the first place so they will still lack shadow detail.

An incompletely redeveloped image must be fixed to remove all silver bromide still left.

Formulae and Procedure. The first developer is generally a normal negative developer (e.g., metol-hydroquinone, or para-aminophenol). It is used at 3–4 times its normal strength, with 2–3 parts of potassium thiocyanate or sodium thiosulphate added to every 1,000 parts of working solution.

A suitable formula is:

Metol	35 grains	2 grams
Sodium sulphite, anhydrous	3½ ounces	90 grams
Hydroquinone	140 grains	8 grams
Sodium carbonate, anhydrous	2 ounces	50 grams
Potassium thiocyanate	35 grains	2 grams
Water to make	40 ounces	1,000 c.cm.

The material should be developed for the time recommended for it by the manufacturers.

Development is followed by a 2–3 minute rinse in plain water, after which the negative image is removed in the following bleaching solution (also known as the reversing bath):

Potassium bichromate	88 grains	5 grams
Sulphuric acid, concentrated	96 minims	5 c.cm.
Water to make	40 ounces	1,000 c.cm.

The bleacher is best made up in two stock solutions of 5 per cent bichromate and 5 per cent (by volume) of sulphuric acid. These are then mixed, 1 part of each with 8 parts of water, just before use. The used solution must be thrown away afterwards.

When the negative image has completely disappeared, the material is rinsed again for 3–4 minutes, and the yellow stain removed in the following clearing bath:

Sodium sulphite, anhydrous	1 ounce	25 grams
Sodium hydroxide, 10 per cent	96 minims	5 c.cm.
Water to make	40 ounces	1,000 c.cm.

This solution can be used repeatedly until it takes too long to remove the yellow stain.

After yet another wash of 1–2 minutes the emulsion layer is exposed partially (1–2 minutes), or completely (5–7 minutes), to white light (about 12 ins.—30 cm.—from a 100 watt bulb). The exposed image is then developed in a normal negative or positive developer or in the first developer. To give really high contrast a normal hydroquinone developer may be used.

If the second development is curtailed, the material is fixed to remove the undeveloped silver bromide and then washed and dried.

Direct Blackening. The operations of re-exposure and second development may be bypassed by immersing the film in an ordinary sulphide darkener. This has the same effect as complete re-exposure and re-development, but it gives a dense and contrasty sepia image.

A thiocarbamide darkener (below) works just as well, and has the advantage of being odourless.

Thiocarbamide	44 grains	2·5 grams
Sodium hydroxide	265 grains	15 grams
Water to make	40 ounces	1,000 c.cm.

This solution can be made up at 10 times the above strength, and diluted for use.

The direct darkener is useful if the film is wound on a reel in a developing tank, as there is no longer any need for removing the film. It is not, of course, suitable for redevelopment of colour films.

Direct blackening gives no opportunity for control after bleaching.

An alternative method of blackening the image is to immerse the film in a solution of equal parts 0·1 per cent thiosinamine and 0·1 per cent acetic acid. This fogs the silver bromide chemically, and renders it developable without exposure to light. After this treatment, the film need not be removed from the developing tank, but it must still be redeveloped.

IMAGE-ETCH REVERSAL

An excellent formula for reversing line images, especially when on thin film "process" emulsions, such as "lith", is the following:

Solution A		
Water (125–150° F.)	30 ounces	750 c.cm.
Copper sulphate	4¾ ounces	120 grams
Citric acid	6 ounces	150 grams
Potassium bromide	130 grains	7·5 grams
Water to make	40 ounces	1,000 c.cm.
Solution B		
Hydrogen peroxide (10 vol.)		

Before use mix equal parts of A. and B.

The initial negative image should be fully developed, so that a strong image is seen on the base side. After a short wash, and without fixing, the negative is bathed, in white light, in the above-mentioned image-etch bleach solution which dissolves away the developed silver image together with the gelatine containing it. A gentle wipe with wet cotton wool

removes the last traces of the initial image, and the film is then thoroughly fogged in bright light and re-developed in the first developer.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

SPECIAL METHODS

In addition to normal black-and-white photography, the reversal process has important applications in special processes and is essential in processing certain colour materials.

Colour. Reversal processing of colour materials follows the same general lines as reversal processing of black-and-white materials, except that a colour coupling developer is used for the second development. This develops the positive silver image and at the same time reacts with the colour couplers present in the three sensitive layers of the film, thus producing three-dye images superimposed on the silver images. The final stage is the removal of the silver images, leaving the pure dye images.

Diffusion Transfer. In this process the negative and positive images are developed simultaneously but in different emulsion layers.

The negative emulsion is a silver halide emulsion which is exposed normally. It is developed in contact with a plain gelatin emulsion containing a silver halide solvent and a small quantity of colloidal silver or silver sulphide. During development of the negative image, the silver halide solvent (usually hypo) diffuses from the positive emulsion into the negative. There it dissolves some of the silver halide not used by the negative, and diffuses back into the positive layer where the dissolved silver halide is reduced by the developer and deposited as silver on the silver or silver sulphide nuclei already present. The density of the image produced is proportional to the amount of unused silver halide available in any spot in the negative emulsion. After development the negative and positive emulsions are stripped apart, and washed and dried. Usually the negative requires fixing.

This process is used mainly for copying documents by transmitted or reflected light and special processing machines are available which squeegee the two emulsions together and develop them in close contact.

The Polaroid negative-positive process also uses the same principle for exposures in the camera, there the negative and positive emulsions coated on separate paper supports are loaded into the special camera in rolls. The positive paper carries small pods of jellified processing solutions. Squeegeeing the negative and positive emulsions into intimate contact breaks the pods and spreads the developer jelly evenly between the two layers. After about one minute the negative and positive are stripped apart.

A corresponding process can also yield colour prints. Here the negative material incorporates combinations of developer and dye molecules in special layers which are used to develop the appropriate negative images. The unused dye-developer molecules diffuse into the positive receiving layer and there form a positive colour print corresponding to the negative images developed in the negative film.

Some direct reversal papers using the transfer diffusion system carry both emulsions on one support. The bottom layer is the positive emulsion which is tanned after coating, while the top layer is an untanned silver halide emulsion. After exposure, development, and transfer diffusion the negative image is washed off with warm water which leaves the tanned positive layer unaffected.

Fog Destruction. This is a commercially used method of document copying by contact printing. In this process the material is uniformly fogged during manufacture so as to produce the maximum density required subsequently. When making a direct positive print with such a paper, printing destroys the original fog in proportion to the printing exposure. Development in any rapid working developer then produces the positive image.

The printing exposure generally requires light of a different colour from that used for the fogging exposure, and a yellow filter is therefore employed for printing. The speed of these materials is very low; they can be handled in subdued artificial light. L.A.M.

Books: *Developing*, by C. I. Jacobson (London); *How to Process*, by L. J. Wheeler (London); *Processing Chemistry*, by L. F. A. Mason (London).

REVERSED NEGATIVE. Negative that has been deliberately manipulated to record a mirror image—i.e., one that has been reversed, left to right.

Such a negative is needed in certain photomechanical reproduction processes in which the final print is a reversed picture of the negative.

Image reversal is produced by photographing the original through a right-angled (reversing) prism or mirror or by stripping and turning the film.

REVERSE READING. A reproduction which is a mirror image (i.e. reversal left-to-right) of the original when viewed from the image side.

REVERSING CLUTCH. Device inside a 35 mm. camera to disengage the transport sprocket from the transport mechanism. This permits the film to be rewound into its cassette after exposure. Also known as reversing or rewind button (or lever).

See also: *Film transport.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

REVOLVING BACK. Feature of some plate cameras which permits the plate holder to be rotated in its plane. In this way horizontal, upright, or intermediate shots are possible without moving the camera, thus saving a great deal of time in setting up. Revolving backs are often found on large single-lens reflex plate cameras where it is impractical to hold the camera sideways to change the format from horizontal to upright.

REWIND. Mechanism for returning a film in a camera or projector from the take-up spool or reel to the feed spool.

Still cameras using 35 mm. (or 70 mm. or sub-miniature film) in light-tight cassettes without a backing paper progressively wind the film up on a take-up spool as it gets exposed. Since the film is then unprotected (except where a light-tight take-up cassette is also used) it has to be respooled into the feed cassette before unloading from the camera. Miniature cameras usually have a knob or crank to do this; occasionally even powered rewinds are available.

In a cine camera no rewinding of the exposed film is normally involved. However some cameras have provision for winding the film backwards in order to expose a length a second time—for special effects like dissolves and double exposures.

In cine projectors the rewind system spools the film from the take-up reel at high speed back on to the feed reel, ready for the next show.

High speed rewinds are also featured on tape recorders for the same purpose.

REYNAUD, ÉMILE, 1844–1918. French showman and inventor. Used in 1877 a mirror drum for optical compensation, made in 1889–92 the projection Praxinoscope (a combination of magic lantern and Zoetrope), patented in 1888 perforated flexible strips for the synthesis of motion, and used from 1892 such strips (first drawn, later photographed) in his Théâtre Optique in Paris. After the popularization of the motion picture film he felt frustrated, sold his apparatus for scrap and threw his films into the Seine.

RHEOSTAT. Variable resistance used in electrical circuits to adjust the current flowing in the circuit. In photography rheostats are used principally for controlling the current through over-run and other high intensity filament lamps so that they can be used at a lower level of illumination when focusing the camera and brought up to full brilliance for exposure. This procedure greatly extends the life of such lamps.

It is not advisable to use such dimming resistances for varying the brilliance of lighting for exposure, because the drop in brilliance is always accompanied by a change in colour temperature.

Rheostats are made in the form of coiled lengths of resistance wire connected to the contacts of a rotary or sliding selector switch. The position of the selector arm (and the amount of current flowing in the circuit) is controlled by a knob on the outside of the case. A calibrated scale may be added.

There are two regular methods of varying the resistance in the circuit:

(1) All the resistance is connected in series with the circuit and gradually taken out to increase the current.

(2) Resistance coils are progressively added in parallel to an initial resistance coil connected in series with the circuit. As extra resistances are added, the current through the circuit increases.

Rheostats are also used for controlling the current through arc lamps. The closer the carbons are brought together, the lower the resistance of the arc and the greater the current in the circuit. A variable resistance is one way of keeping the current down to the optimum working value.

RIIS, JACOB, A, 1849–1914. American photoreporter born in Denmark. Settled in America 1870 and became a police-court reporter for the *New York Tribune*. Began in 1887 taking flashlight photographs in New York slums of social conditions responsible for crime. His pictures influenced Theodore Roosevelt to undertake social reform measures, and today the Jacob A. Riis Neighborhood Settlement stands on the site of once notorious tenements.

RIM LIGHTING. Lighting set-up, used particularly in portraiture, where the light source is more or less behind the subject and thus outlines its contour with a brilliant rim of light.

See also: *Lighting the subject.*

RINSE. Brief wash either with clean water or a special rinsing bath given to a sensitive material in the course of processing. Its object is to remove—or neutralize—chemicals from a previous bath adhering to the negative or print; this stops the image from being discoloured in a subsequent bath and ensures that the chemicals cannot contaminate the subsequent bath and impair its action. The principal rinse is given between development and fixing.

See also: *Stop bath.*

RIPENING OF EMULSION. Essential stage in the manufacture of a photographic emulsion in which it is heated in the presence of a silver

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

halide solvent under controlled conditions. The result is that the average size of the grains —and therefore the sensitivity—increases. Also known as Ostwald ripening.

See also: *Sensitized material manufacture.*

RISING FRONT. Lens panel constructed so that it can slide vertically to allow the lens to be raised above—or dropped below—the normal position. It is used principally to prevent the distortion of verticals in photographs of tall buildings.

See also: *Camera movements.*

ROBERTSON, JAMES. Dates unknown. English photographer. Chief engraver to the Imperial Mint at Constantinople and landscape photographer in Mediterranean countries in the 1850s. His photographs taken in the Crimea immediately following the fall of Sebastopol in September 1855 form a sequel to Roger Fenton's photographic coverage of the siege. In association with A. Beato, Robertson documented the scenes of the Indian Mutiny in 1857.

ROBINSON, HENRY PEACH, 1830–1901. English professional photographer from 1857 onward. Leading pictorialist and exhibitor. Made elaborate compositions by photomontage, the best known and earliest being *Fading Away* 1858. Prolific and influential writer on the art of photography. Founder member of the Linked Ring, 1892.

ROCHELLE SALT. Developing agent used in the kallitype process; also used as a sensitizer.

See also: *Sodium potassium tartrate.*

RODCHENKO, ALEKSANDR MIKHAILOVICH, 1891–1956. Russian artist, photographer and photojournalist. Professor at the Higher Technical Art Institute 1921–31, and theatre art director. First to use photomontage in illustrating printed publications. Considerably influenced the development of Soviet photography by creating new forms of pictorial expression.

ROENTGEN, WILHELM CONRAD, 1845–1923. German professor of physics. Discovered the Roentgen or X-rays and thus radiography (1895), which revolutionized physical theories, medical diagnostics and therapy, and the study of crystal structure. Roentgen received the Nobel Prize in 1901. Biography by F. Dessauer (Olten 1945); O. Glasser (London 1933).

ROHR, MORITZ VON, 1868–1940. German lens designer. Outstanding writer on the history of optical and ophthalmological instruments. A bibliography of his 571 books and articles was published in *Forschungen zur Geschichte der Optik*, 1943.

ROLLEIFLEX. Roll film twin-lens reflex camera, introduced in 1928 by Franke & Heidecke of Brunswick, Germany. This camera and its sister model, the Rolleicord, started the wide popularity of twin-lens cameras which appealed especially to amateurs.

At the same time, the full size image on the ground glass screen made the camera specially useful to pictorial workers and to many professional feature photographers.

The present-day Rolleiflex features automatic crank-operated film transport coupled to the shutter tensioning, automatic loading by means of film feeler rollers, an *f* 3·5 or 2·8 lens, and a Synchro-Compur shutter with exposure value scale and X-M flash synchronization.

On the whole, the Rollei cameras are intended to be self-sufficient and were not visualized as part of a camera system of accessories and special equipment. The lens, for instance, is not interchangeable. The camera thus has definite recognized limitations, and is designed to produce the best possible results within its scope.

Nevertheless the makers have produced certain accessories such as supplementary lenses for close-ups, adaptor backs and kits for using plates or 35 mm. film, and even a supplementary rangefinder.

ROLL FILM. One of the most popular types of negative material, particularly for amateur photography. A roll film consists of a length of celluloid, coated with a sensitive emulsion on one side and a layer of plain gelatin on the other to reduce its tendency to curl.

The film is attached to an opaque paper backing and wound on to a wooden or metal spool. The backing paper is longer than the film and the surplus length wraps around the spool to protect the film from the action of light before and after exposure in the camera. Numbers on the back of the backing paper show through a window in the camera, indicating the position of the successive frames of the film.

The earliest roll film was made in 1875 by L. Warnerke who coated a gelatin emulsion on a paper support and subsequently stripped off the developed negative for printing.

In 1889 the Eastman (later Kodak) Company made the first roll film having a celluloid support with an opaque backing paper to permit daylight loading into the camera and in 1903 they improved it by adding the anti-curl backing layer of gelatin.

See also: *Film transport; Negative materials; Sensitized materials history; Sensitized materials manufacture; Sizes and packings; Spools; Supports for emulsions.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

ROLL FILM ADAPTOR. Attachment for the back of a plate camera to enable it to take photographs on roll films. It consists of a shallow box with cylindrical chambers for the film at each end with a film aperture between, which is kept covered by a dark slide between exposures.

The adaptor can thus be removed from the camera without exposing the film to the light; it is fitted with the usual film transport knob and number window.

ROLL HEAD PRINTER. Mechanized photographic printing equipment in use in photo finishing laboratories for high print outputs. The main characteristic of the printer is that the paper is loaded in a continuous roll of a standard size (e.g. 3½ or 5 inches wide) and fed through the exposure stage of the printing unit. The latter may be a contact printer or (more usually) an automatic enlarger with a limited range of magnifications. All prints are made the same width, the magnification of the enlarger being changed only for different negative formats. Exposures are frequently controlled electronically. After the whole paper roll is exposed, it is processed in a continuous paper processor where it passes through all treatment stages including drying (on a glazing drum) before the pictures are cut off from the roll.

See also: *Contact printer; Wholesale photo finishing.*

ROSCOE, SIR HENRY ENFIELD, 1833–1915. English chemist. Collaborator of Robert Bunsen. Together they carried out investigations on the chemical action of light which resulted in the enunciation of the Bunsen-Roscoe Law (1854/9), on photometry, actinometry and spectrum analysis. Also produced exposure tables based on the position of the sun, and advocated the use of magnesium light (1859). Autobiography: 1906.

ROSS, ANDREW, 1798–1859. English optician; established firm of optical instrument makers in London, 1830. Designed the first photographic lens in Britain for Fox Talbot, 1839, and the first British portrait lens, a double combination similar to Petzval's, for Henry Collen, 1841. Ross mentioned to Talbot the accelerating property of gallic acid, of which he had learned from the Rev. J. B. Reade.

ROYAL PHOTOGRAPHIC SOCIETY. Founded in 1853 to promote the general advancement of photographic science and its applications.

Her Majesty Queen Elizabeth II is the gracious Patron of the Society, an association with the Royal Family which has persisted from earliest days.

There are now over 7,000 members of whom about 35 per cent are resident overseas.

The Associateship (A.R.P.S.) and Fellowship (F.R.P.S.) are open to all members who can produce evidence of outstanding ability in any branch of photography.

Groups of the Society have been formed to study specialized aspects of photography, namely, colour, kinematography, medical, photo-journalism, pictorial, scientific and technical. These groups arrange conferences, lectures, demonstrations, exhibitions, visits, print circulations and criticisms, and publish bulletins, including *Photographic Abstracts*, which summarize current photographic literature. A bibliography of literature of medical photography is also maintained.

The Society publishes the *Photographic Journal* and the *Journal of Photographic Science*. These are free to members.

The Society's exhibitions are world-famous and cover all aspects and applications of photography, contributions being received from almost all nations, irrespective of size.

Over a number of years the Society has built up a collection of masterpieces of photography and of historical apparatus and equipment, which are preserved at the Society's premises and in the Science Museum, South Kensington.

The Society's house has a lounge for the use of members and a Library where books can be consulted or borrowed. Postal facilities are also available to members in the British Isles. Social functions include an annual Dinner Dance in London.

A full and comprehensive programme of lectures and meetings is arranged each year, in London and in the provinces, most of these being reproduced or reported in the Society's publications. These include lectures arranged periodically to perpetuate the memory of distinguished workers in photography.

The Society makes awards for distinguished work, the most outstanding being its Progress Medal, which is awarded in recognition of any invention, research, publication or exhibition which has resulted in any important advance in the science, art or practice of photography. This medal has been awarded on fifty occasions, many to recipients of foreign nationality.

RUBBER SOLUTION. Solution of rubber in naptha used in photography as a mountant for prints.

RUDOLPH, PAUL, 1858–1935. German mathematical optician. Collaborated with Abbe and calculated (1889) the characteristics of the first Zeiss anastigmats produced from the new Jena optical glasses in 1890. Rudolph calculated the new Zeiss Tessar lenses (1902) and in 1920 a Double-Plasmat (produced by H. Meyer of Görlitz). He received the Progress Medal of the Royal Photographic Society in 1905.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

RUSSELL, MAJOR CHARLES, 1820–87, English amateur photographer. Invented in 1861 the tannin process (dry collodion plates for negatives preserved with tannin), and in 1862 the alkaline pyrogallol-ammonia developer. Worked also on the composition of developers (recommending potassium bromide as a restrainer) and on reversal development (1862). Described in 1866 a yellow anti-halation backing.

RUSSIA AND THE U.S.S.R.

The development of photography in Russia can be divided into two periods: pre-revolutionary and Soviet.

Early Developments. The diplomat A. P. Bestuzhev-Ryumin (1693–1766), when in Denmark, made the important observation in 1725 that light has an influence on iron salts. But photography proper began in Russia in 1839 with the photogenic drawing process. Yu F. Fritsche (1808–1871), a chemist and botanist, reported on Fox Talbot's method at a meeting of the Academy of Sciences on the 23rd May 1839. In the same year I. Kh. Gamel (1788–1862) made the acquaintance of Fox Talbot in London and sent photographs and a description of his method both in May and June 1839 to the Academy of Sciences.

The same year Gamel sent a camera and photographic equipment based on the designs of J. N. Niépce and J. M. Daguerre to the Academy. In 1840 the Moscow photographer A. F. Grekov (at the same time as the French physicist H. L. Fizeau) worked out a method of silvering copper and brass plates to reduce the mirror-like gloss of daguerreotypes. F. Arago reported on this invention by A. F. Grekov to the French Academy of Sciences on 16th November 1840.

Fox Talbot wrote to the Academy of Sciences on the 14th December 1841 enclosing several photographs made by his calotype process. In the proceedings of the Physico-Mathematical Section of the Academy of Sciences of the 7th January 1842, thanks are expressed to Talbot for his communication. Daguerreotype workshops were opened in Petersburg—Davin'on and Fokon'e, Shenfel'd, A. I. Den'er, L. S. Plakhov, Veninger, S. L. Levitskiĭ and others.

I. K. Gamel subsequently received over 160 documents on the history of the invention of photography from Isidore Niépce—letters of Nicéphore Niépce, Daguerre, Isidore Niépce and others. They are in the archives of the Academy, and were published in 1949, under the title *Dokumenti po Istorii Izobreteniya Fotografii* (*Documents on the history of the invention of photography*), edited by T. P. Kravets, corresponding member of the A.N. S.S.S.R. (U.S.S.R. Academy of Sciences).

The wet collodion process developed rapidly in Russia, thanks to the discovery of pyroxylin in 1852 by General K. K. Mann, a Russian chemist, who was in charge of the Glavnaya Laboratoriya Departmenta Vrachebnikh Zagotovlenii (Main Laboratory of the Department of Medical Supplies).

L. V. Warnerke (real name Vladislav Malakhovskiĭ, 1837–1900) was a Polish inventor who lived and worked in Russia up to the end of the 1870s, after which he worked in England and made a sensitive negative material in both his laboratories in Petersburg and London. Dry silver bromide gelatin layers appeared in Russia at the end of the 1870s. In 1878 a paper and plates with dry silver bromide gelatin layers were prepared in Warnerke's laboratory.

In 1881 Boldyrev (born 1850—date of death unknown), a Petersburg photographer, coated a transparent and flexible non-flam film base, first with collodion, and later with a dry gelatin emulsion. In 1882 he successfully demonstrated it at the All-Russian Industrial Exhibition in Moscow, but owing to lack of money was unable to achieve industrial production of his invention.

In pre-revolutionary Russia a number of original cameras and various parts of them were also invented. Of particular interest are: a camera to take spools, paper and film, designed in 1875 by L. V. Warnerke in England and a portable camera, designed in 1879 by D. P. Yezuchevsky (1835–98) and intended for expeditions. This latter camera won a prize in 1882 at the geographical exhibition in Venice, and in the same year it was demonstrated at the Industrial Exhibition in Moscow.

Stereophotography originated in Russia in the 1850s. Aleksandrovsky, in 1854 invented a stereophotographic camera which was capable of producing two photographic images simultaneously for viewing in a stereoscope. He obtained a Russian patent on the 14th December, 1854. D. P. Ezuchevsky invented a stereoscopic camera in 1875 and spent many years perfecting it. The claim for the invention of this stereoscopic camera was lodged in January 1900 after his death and Russian patent No. 5713 dated 14th September 1901 was obtained for his widow by A. Ezuchevskaya.

In 1882 S. A. Yurkovsky, a Vitebsk photographer, invented the first instantaneous roller blind shutter on which many present-day shutters are still based. He published two articles in the journal *Fotograf* giving detailed descriptions of these shutters.

In 1889 K. K. Brandel, a photographer at the Warsaw University, received Russian licence No. 11513 for a hand-operated revolving camera for taking photographs on negative paper.

In 1891 V. A. Dyubyuk (1842–1892), a Moscow photographer, invented a chrono-

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

photographic camera for obtaining a continuous sequence of photographs of galloping and racing horses. He demonstrated his photographs at a photographic exhibition in Moscow in 1892, and in the same year in Paris. They were shown on a continuously moving film using a special apparatus.

Colour photography began in Russia in the middle of the 1890s. I. Yanovsky, a photographer in Warsaw, published a description of his Chromograph for three-colour photography in March 1895 in the Journal *Fotograf—Lyubitel* (*The Amateur Photographer*). Z. Kozlovsky, a photographer in Kiev, invented a three-colour photographic camera in 1897 and received Russian patent No. 2661 dated 19th October 1899, on his application dated 1897. S. O. Maksimovich (1876–1942), Petersburg, invented a subtractive-additive method of three colour cinematography in 1909. (German patent No. 229007 of 22nd December 1909.) In 1912 he used a double-sided beam-splitting prism.

In 1899 I. L. Polyakov (born 1877—date of death not established), a student at a Moscow technical college, invented a selenium photometer for the automatic control of exposure and received Russian (No. 10116) and German (No. 117559) patents. I. L. Polyakov's photometer was the first to use two photo-elements connected in opposition, a system widely used nowadays. This patent is the first to mention the use of a photo-element for determining exposure.

In 1902 A. A. Popovitsky, a Petersburg photographer, invented a camera with spherical mirrors instead of a lens which he patented in 1904 in Russia, France and Germany.

Engineer R. Y. Tille designed a multi-lens "Panoramagraph" camera in 1898, for three-dimensional photography from aerial balloons.

During the 1904–5 Russo-Japanese War a long-focus camera designed by the Russian officer S. A. Ulyanin (born 1871; date of death not established) was used.

P. P. Sokolov, afterwards lecturer in the Moscow college of Higher Technology, published in December 1908 in the Journal *Vestnik Fotografii* (*Photographic Herald*) his invention of stereophotography using a lenticular light-sensitive material. In 1911 he published a book entitled *Avtostereoskopiya i Integral'naya Fotografiya* (*Autostereoscopy and Integral Photography*) by Professor Lipmann.

In 1911 the Russian officer V. F. Potte (1866–1918) invented the prototype of a semi-automatic aerial film camera, which was extensively used in the Air Force.

The photographer E. E. Gorin (1881–1951) lodged an application on 27th October 1916 for his invention of electrophotographic apparatus.

Early Photographic Industry. The first photographic manufacturer in Russia was A. N. Sukhachyov of Petersburg who produced paper from 1862 onwards. He was followed in 1877 by Starkov and in 1880 by L. V. Warnerke (who also with A. E. Felish made bromo-gelatin plates). In 1882 N. K. Klyachko of Moscow began the manufacture of cameras and accessories.

Other factories producing bromo-gelatin films were built in 1896—K. I. Freilandt's Vsya Rossiya, Captain Zankovsky's Pobeda and Joseph Pokorny's Iris (first in Libava and later in Moscow).

The first Russian optical firm—FOS—started in Warsaw in 1899, producing anastigmat lenses from optical glass obtained from abroad.

Very few photographic cameras were made in Russia before the revolution. According to the Customs' records, the total number of cameras which were imported into Tsarist Russia during the 25 years prior to World War I was about 500,000. In the year preceding the first World War about 16,000 cameras for amateur and professional use were imported into Russia.

After the Revolution the existing factories and workshops were transferred to the Fotokomiteti v Moskve i Petrograde (Photo-Committees of Moscow and Petrogard) in 1918 and on 27th August, 1919, V. I. Lenin signed a decree of the Soviet Narodnikh Kommisarov (Council of People's Commissars) transferring the photographic industry to the Narodny Komissariat Prosvescheniya (People's Commissariat for Education).

Organizational changes took place in the administration of the photographic industry in 1924. An optico-mechanical industry trust (T.O.M.P.) was formed and in 1926 a photo-cine-chemical trust (F.O.K.K.T.) was set up under the Higher Council for national economy, for the Russkaya Sovietskaya Federativnaya Sotsialisticheskaya Respublika (R.S.F.S.R.—Russian Soviet Federative Socialist Republic). This latter trust marked the beginning of the development in the U.S.S.R. of the photo-chemical and optico-mechanical industry.

Production of Materials. The chemico-photographic trust started large scale production of photographic papers in 1927. The mass-production of black-and-white cinema film stock began in 1931, of multi-layer colour negative and positive photographic materials in 1948. The U.S.S.R. is now second only to the U.S.A. in film production output having risen six times since 1940. Photographic film and paper factories are today distributed in a number of towns in the U.S.S.R. and supply the requirements of the cinema, of industry and of amateurs. The products cover orthochromatic, panchromatic, and infra-red sensitive black-and-white materials for commercial, technical and scientific work, including radiography, spectrography, photomicrography, astronomy, survey and other applications. A wide range of negative materials for special purposes is made, together with cine films of high light

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

sensitivity—up to 350 units GOST (Soviet standard) or 27° DIN.

Colour photography is finding wide application, especially the negative-positive process. Colour films are made for daylight as well as artificial light. There are also films with automatic masking components. Reversal colour film is made mainly for amateur cinematography (narrow gauge film) and application in photography is limited. Paper for colour prints in two grades of contrast and the necessary chemicals for treatment are also on the market.

Photographic papers for black-and-white photography are produced with silver bromide, chloro-bromide, and chloride emulsions in different surfaces and base tints. They are available for amateur use and for technical purposes (document and reflex printing papers, oscillograph and other recording papers, materials for photo-telegraphy, and so on).

The progress in sensitive materials in the Soviet Union may be illustrated by the increasing film speeds available:

GROWTH IN THE LIGHT-SENSITIVITY OF ONE TYPE OF SOVIET FILM

Year of Manufacture	*Spectral Properties*	*GOST Speed*
1928–1929	Orthochromatic	80
1936–1937	Panchromatic	240
1941	Panchromatic	1,000
1945	Panchromatic	1,500
1947	Panchromatic	2,500
1948	Panchromatic	4,000

From 1950 onwards, photographic plates coated with thick layers of emulsion have been prepared for research in nuclear physics and cosmic rays. In 1959 the Yu. Yanonis paper factory in Kaunass began production of electrophotographic papers.

Photographic chemicals are available separately, for mixing to individual requirements, or in sets.

Production of Equipment. Photographic lens manufacture developed in Russia in 1890. The physicist Professor A. L. Gershun (1868–1915) was the founder of the optical machine-tool industry. Academician D.S. Rozhdestvensky (1876–1940) made considerable contributions to the Russian optical and precision mechanical industry. In 1915 I. V. Grebenschikov (1887–1953), academician since 1932, and N. N. Kachalov organized the production of optical glass, the import of which was restricted owing to the First World War.

Two large optical glass factories have been built to supply the motion picture and photographic industries in the U.S.S.R. Their production programme covers a comprehensive range of advanced photographic and optical equipment.

The first mass-produced Soviet cameras using photographic plates were made in 1929 by the co-operative artel Fototrud. They were folding plate cameras of 9 × 12 cm. format fitted with imported lenses and shutters.

In the middle of 1930 T.O.M.P. produced the first models of the Fotokor amateur camera with an *f* 4·5 anastigmat. They went into mass production at the end of 1931 and by 1941 the yearly output reached 200,000. At the beginning of 1934 the Dzerzhinsky labour colony in Kharkov began to produce the FED miniature camera for 35 mm. film. This first appeared on the market in 1935 and modified variations are still being manufactured.

During world war 1941–1945 the production of amateur cameras was stopped in U.S.S.R. It was restarted in 1945, when the optic-mechanical factories began to make new models of cameras and interchangeable optical systems for them.

The number of factories producing cameras grew with the years and their output and variety increased considerably, more than sixty models of different types and classes having been produced. The present-day range covers precision miniature cameras with built-in photo-electric exposure meters, reflex cameras of different types, stereo-cameras, simple cameras for beginners, commercial equipment for copying, process work, printing and cartography, aerial cameras, phototheodolites, medical cameras, precision cine film cameras, and others.

The first experimental Soviet lenses were designed between 1925 and 1928. The production of the Ortogoz anastigmat lens for the Fotokor camera began at the end of 1929. An improved lens—the Industar—followed, and was available in focal lengths from 3·5 to 120 cm., with various maximum apertures. In the post-war period production started of high speed Jupiter lenses (up to *f* 1·5) for miniature cameras. They included normal, wide angle and tele-lenses, with coated elements for increased light transmission.

The coating of lenses was achieved in 1934 by academician I. V. Grebenshchikov. For instance, the Industar—4 lens had a light loss of 37·5 per cent before coating and of only 16 per cent after coating. In 1946, Academicians I. V. Grebenshchikov, A. G. Vlasov and N. V. Suikovskaya published a book entitled *Prosvetlenie Optiki* (*Methods of coating lenses*).

The following figures give some idea of camera production in the U.S.S.R.: there were 355,000 cameras produced in 1940, 1,022,000 in 1955, 1,472,000 in 1958, 1,616,000 in 1959 and 1,764,000 in 1960. The total yearly output of photographic equipment now exceeds 1,700,000 pieces, and continues to rise.

Connected with the change to semi-automatic and full automatic cameras with exposure control, mass production of diaphragm shutters and special objectives started. The making of semi-automatic and automatic single lens reflex cameras began in 1964.

At the same time, output of lenses which satisfy the demands of professional and amateur photographers alike continues to grow. In

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

focal length these range from 20 mm. (for range finder cameras) to 4,000 mm. (for single lens reflex cameras); one is being manufactured with a 37 to 80 mm. variable focal length.

On sale is an adequate quantity of enlargers for all negative sizes. Light filters, auxiliary lenses and many supplementary devices are also available, as well as lighting equipment, including twelve speedlight models.

Some factories are producing photomicrographic equipment, apparatus for the sensitometric testing of photographic materials and for spectral and X-ray analysis, electron microscopes, equipment for micro-filming and other scientific and technical purposes.

Scientific Research. Work on the science of photography began in Russia in the middle of the 1870s. Questions relating to photographic chemistry and optical sensitization were elucidated by K. A. Timiryazev (1843–1920), a botanist and physiologist, afterwards academician, in many of his works: *ob Usvoenii Sveta Rosteniem* (*The Assimiliation of Light by a Plant*) (1875), *Zavisimost' Fotokhimicheskikh Yavlenii of Amplitudy Svetovoi Volny* (*The Relation between Photochemical Phenomena and the Amplitude of the Light Wave*) (1884), *Fotokhimicheskoe Deistvie Krainikh Luchei Vidimogo Spektra* (*The Photochemical Action of the Rays at the Extreme Ends of the Visible Spectrum*) (1893), *Fotografiya pripody c fotografiya v prirode* (*The Photography of Nature, and Photography in Nature*) (1895): and in his Croonian lecture to the Royal Society in London, on the cosmic role of plants (1903).

The electrochemical theory of development of the photographic image originated in 1877. V. V. Lermantov (1945–1919) in his work entitled *O fotograficheskom protsesse* (*The Photographic Process*) (1877), on the basis of his experimental results, put forward the suggestion that during the development of a photographic negative, silver was precipitated electrochemically from the developer onto the silver particles of the latent image. It was the result of the work of a local galvanic element formed by a silver particle which was soluble in the silver salt and in the developer solution.

Russian scientists have made their contribution to the development of dry silver bromide gelatin materials. V. I. Sreznevsky (1849–1937), one of the founders of the photographic section of the Russian Technical Society, and director of its laboratory in the 1880s, was largely responsible for the introduction of dry gelatin materials into Russia.

In 1880 L. V. Warnerke (V. Malakhovsky) designed a sensitometer, the first of its kind in the world, for the quantitative measurement of light sensitivity. It consisted of a glass plate with twenty-five square areas of gradually increasing density. A phosphorescing plate of calcium sulphide, activated by burning a 2·5 cm. length of magnesium ribbon, was used as the standard light source. Exposure was made 60 seconds after igniting the magnesium, and also lasted for 60 seconds.

A. L. Gershun worked on lenses and on the photography of the equatorial solar corona.

N. A. Shilov (1872–1930) explained in his book *K Teorii Fotograficheskogo Proyavitelya* (*Theory of the Photographic Developer*) (1915) the preservative part played by sodium sulphite.

S. W. Maximovich (1876–1942) obtained Russian and German patents in 1909 (No. 229007) for his three-colour method of photography and cinematography.

The work of Soviet scientists was carried on within the framework of a single state plan with constant exchange of information. In the chemical field they devoted themselves to the study of the theory and technology of the production of sensitive materials, the photochemistry of the photographic layer and the problems of the latent image, the processing of sensitive materials, trade and bulk processing methods, etc.

Emulsion Chemistry. The first task in building new factories for sensitive materials in the U.S.S.R. was to work out suitable production methods. In 1929–33 K. V. Chibisov and his colleagues studied the relationship between the conditions of formation of sensitive emulsions and their sensitometric characteristics. The basic factors in the preparation of ammoniacal and non-ammoniacal emulsions were determined as a result of this work.

Developing the theory of emulsion production, K. V. Chibisov and A. A. Mikhailova established the physico-chemical principles of the first and second ripening stages. K. V. Chibisov, together with A. A. Titov and A. A. Mikhailova, investigated the silver-gelatin complex formed during ripening and proved that the sensitivity specks consisted of metallic silver and not of silver sulphide, as had been hitherto presumed.

Worthy of note in latent image research was the work of A. L. Rabinovitch (1893–1942) and K. S. Bagdasaryan on the mechanism of the action of light on silver halide without gelatin. Certain laws of development were observed in the increase of sensitivity of silver halide during the production of photographic emulsions.

Studying the nature of the latent image, T. P. Kravets (1876–1955) and M. V. Savostyanova and their colleagues proved that under the influence of light colloidal particles of silver, which were the centres of the latent image, were formed inside the crystals of silver bromide.

T. P. Kravet's theory is based on an analogy between the photochemical formation of colour centres in alkali halide and silver halide crystals. He pointed out that the colour of coloured silver halide crystals is of the same nature as that occurring in colloidal mixtures of alkali metals, i.e. it is due to the scattering of light by these

CC-0. Agam Prasad Vidyarthi Preservation Foundation Chandigarh

particles. This theory has been confirmed by the studies of M. V. Savostyanova, R. V. Nikitina and A. S. Toporets. In 1930, M. V. Savestyanova, afterwards professor of physico-mathematical sciences, published her study on the nature of the colour centres in rock salt. She made an estimation of the absorption coefficients and scattering produced by different coloured crystals of rock salt with the aim of verifying the colloidal nature of the latter, and established that the position and width of the absorption curve depends on the diameter of the particles. She also demonstrated that the colouration of coloured rock salt is due to its colloidal nature.

The electrical conductivity of the latent photographic image in silver bromide layers was studied by E. A. Kirillov, professor in the Odessa State University, and his students from 1925 onwards. Their studies have established that the spectral distribution of absorption and of the photo-effect change in like manner when a halide compound is used (silver chloride, bromide, iodide) the maximum of the spectral distribution of the photo-effect occurring in the near ultra-violet region.

In 1926 the physicist Ya. I. Frenkel (1894–1952) put forward a quantitative theory of the ionic electro-conductivity of crystals. This was based on the movements of "interstitial" ions and the "hole" which they leave behind them. This "defects" theory is a prerequisite for the theory of the formation of sensitivity centres in an emulsion microcrystal due to "defects" and "dislocations" of the crystalline lattice in the silver halide (cracks, foreign ions, colloidal particles, metal).

K. V. Chibisov (born 1897), corresponding member of the Academy of Sciences of the U.S.S.R. (since 1946), has been investigating the nature of photographic sensitivity since 1928. K. V. Chibisov, A. A. Titov and A. A. Mikhailova from 1946–1948 studied photographic sensitivity by two methods: firstly, through the kinetics of the interaction between silver ions and gelatin in a homogeneous medium, and secondly, through the kinetics of the formation of non-halide silver (metallic silver and silver sulphide) in emulsions prepared in different conditions, and making a parallel observation of the changes in their photographic properties. They came to the conclusion that the formation of the light-sensitive centres is a process of reduction, whereby the kinetics of the changes in the light-sensitivity are not connected with the kinetics of silver sulphide formation but with the formation of metallic silver, since the sulphide compounds are only accelerators of chemical ripening and are not sensitizers. In 1948, Chibisov and Titov stated that the mechanism of latent image formation which was arrived at by Gurney and Mott on the basis of completely general conceptions, agreed most satisfactorily both with the results of an experimental investigation of isolated crystals and with those obtained by a direct investigation of a photographic layer.

Chibisov emphasized that two independent kinds of process, which lead to latent image formation, take place in different regions in the silver halide crystals: the primary process originates inside the monocrystalline sheets, whereas the secondary processes are localized in the structural dislocations in the crystals.

P. D. Dankov established the correspondence between the permanent crystalline lattices in metallic silver and in silver sulphide in diagonal directions.

From 1929 onwards several scientists (V. A. Bekunov, N. V. Makarov, D. I. Virnikov and others) in different research establishments investigated the photographic activity of gelatin and worked out production methods for high activity gelatins as well as establishing a standard of quality for gelatin.

In addition to study on the main questions of emulsion production, intensive work was done on specific technological questions and coating of photographic papers. The processes of emulsion-washing were studied by V. A. Mikhailov (1933) and V. S. Koltsov (1939). Subsequently a number of workers, notably A. A. Titov, worked out various methods for separation of the solid phase from the liquid and thus eliminated washing—the most indeterminate factor in the production of photographic materials—from the industrial process.

The theory advanced by B. V. Deryagin, which established the relationships between the thickness of the emulsion layer, the viscosity of the emulsion introduced, and the speed and temperature of coating, is worthy of note among the work done on the coating of photographic emulsions. This work made it possible to secure the high-quality coating of multi-layer colour photographic materials.

A number of scientists, A. P. Zhdanov, K. S. Bogomolov, N. A. Perfilov and others investigated the preparation of thick layered photographic plates for nuclear physics.

Soviet specialists presented reports at the First and Second International Conferences on nuclear photography in Strasbourg in July, 1957 and in Montreal in 1958. The Third International Conference on nuclear photography was held in Moscow from the 12th–17th July, 1960, in which ninety-five scientists from twenty-two countries took part, and at which Soviet specialists presented thirty-four reports out of a total number of eighty-five. The proceedings of the Third International Conference in Moscow, July, 1960 were published in 1962 under the title *Yadernaya Fotografiya* (*Nuclear Photography*) under the general editoriship of K. S. Bogomolov and N. A. Perfilov.

Various new emulsions which have been developed in recent years in a number of laboratories (for instance those of Bogomolov and Perfilov) represent considerable internationally recognized progress.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Scientific studies have been made in recent years on the new photographic processes electrophotography (xerography) and thermography. Academician A. N. Terenin and E. K. Putseĭko established in 1949 that zinc oxide could be optically sensitized by means of organic dyes. In 1961 I. I. Zhilevich and E. L. Nemirovsky published the book *Elektrofotografiya* (*Electro Photography*). Questions relating to thermography and the use of light-sensitive varnishes and plastics for obtaining images are discussed in the symposium *Sovremennoe Razvitie Fotograficheskikh Protsessov* (*Modern developments in photographic processes*) published in 1960 and edited by Professor N. I. Kirillov.

In the field of optical sensitizers, I. I. Levkoyev, A. I. Kiprianov, N. N. Sveshnikov, and others in the years between 1929 and 1955 prepared a number of extremely effective orthochromatic, panchromatic and infra-red sensitizing dyes. Sensitizers with stable components were also synthesized for multi-layer colour materials. This research provided a basis for the industrial production of the required number of sensitizers.

Alongside applied questions, research was carried out into the physical chemistry of optical sensitization. A. I. Rabinovich and his colleagues (1932–8) studied the adsorption of dyes on silver bromide; Y. I. Bokinin, K. S. Bagdasaryan and others studied the photochemical mechanism of the decomposition of optically sensitized silver halide.

Processing. The development of the motion picture printing industry required considerable research into the photographic processing of film materials. In 1948 N. I. Kirillov put forward a method of continuous flow processing of sensitive emulsions.

At the same time research was in progress on the theory of photographic development and between 1925 and 1928 K. V. Chibisov studied the development process with the aid of photomicrography. A. I. Rabinovich proposed and studied in experimental form the adsorption theory of development, while P. D. Dankov between 1939 and 1949 explained the process of the generation of silver halide as being an electro-chemical reaction. The most important work in this field was done by G. P. Faierman who worked out a general theory of development.

In 1939 D. A. Frank-Kamenetsky stated that the fundamental reaction in development is the electronic oxidation of the developing agent at the surface of a silver centre of development, which, being in contact and equilibrium with silver bromide ions, are dissolved and precipitated practically instantaneously on the surface of the centre. In his opinion, the speed of the resulting process is regulated by the speed of the relatively slow process of diffusion of the developer to the surface of the centre. Kh. S. Bagdasar'yan, in his researches on the kinetics and mechanism of photographic development, proposed a theory of development as a purely electrode process. He considered that the transfer of an electron from a molecule of the developing agent to the surface of the metallic silver is not only the primary, but also the rate-determining step, whereas the secondary reaction, the discharge of silver ions at the silver surface, is very rapid.

The Soviet system of sensitometry GOST—2847—45—2817—50 was worked out theoretically and practically by Professor Yu. N. Gorokhovsky, I. A. Cherny, G. I. Kireev, S. S. Gilev, and F. L. Burmistrov under the direction of T. P. Kravets, corresponding member of the Academy of Sciences of the U.S.S.R. It is a specification for the general sensitometry (determination of the properties of a material in relation to white light) and for the determination of the absolute spectral sensitivity and resolving power of photographic materials.

In 1948 P. V. Kozlov explained the physicochemical basis of ciné film manufacture.

Colour. The production of colour images in a three-layer film by means of colour development was studied experimentally by A. E. Poraĭ-Koshets (1877–1944), a chemist and academician (since 1935). From 1939–1941 G. I. Arbuzov conducted a series of experiments on the formation of colour images in positive multilayer cine film by the silver-dye-bleach process.

Equipment. The main problems of development in the optical and precision engineering fields were computation of photographic lenses, optical apparatus, methods of sound-recording and projection of cinema film, questions of lighting techniques, the design of still and motion picture cameras, cine film processing and printing machinery, and so on.

Of all these problems, lens computation is most directly lined with photography and has been the subject of research by G. G. Slyusarev, A. I. Tudorovsky, D. S. Volosov and M. V. Tsivkin. Original types of wide angle lenses for aerial photographic equipment were calculated by M. P. Rusinov. His Lyar has an angle of 100° and his Russar one of 112°. In 1934 I. V. Grebenshchikov and his colleagues worked out and put into production methods of coating lenses.

A. A. Melnikov designed new types of shutters between 1935 and 1939, while L. P. Riftin and G. Y. Grinevich took the lead in camera design and construction.

Research and Teaching Institutes. At the suggestion of D. S. Rozhdestvensky the Gosudarstvenni Opticheski Institut (G.O.I.—State Optical Institute) was organized in 1918 in Petrograd. A photographic section which aimed to give research service to the photographic industry was established at this institute in 1926.

The Vsesoyuzni Nauchno-issledovatelski Kinofotoinstitut (N.I.K.F.I.—All-Union Scientific Research Institute of Cinematography and

Photography), was set up in Moscow in 1929.

In the same year the Institut Aerofotosyemki (Institute of Aerial Photography) was established in Leningrad. This latter institute was later reorganized into the Tsentralni Nauchno-issledovatelski Institut Geodezii, Aerofotosyemki i Kartografii (Central Scientific Research Institute of Geodesy, Aerial Photography and Cartography) and it is today located in Moscow.

Problems of photography were also studied by the photo-chemical laboratory of the Nauchno-Khimicheski Institut Imeni Karpova (Karpov Chemical Research Institute) and in the research institute of the printing industry.

In addition to the research institutes listed above, problems of photography are studied in the Department of Photography at Moscow University, by the Institut Metrologii i Standartizatsii (Institute of Meteorology and Standards), in the physics departments of the Universities of Leningrad and Odessa, in the department of organic chemistry of the universities of Kharkov and Kiev, by the Kharkovski Khimiko-Tekhnologicheski Institut (Kharkov Institute of Chemical Technology) and others.

A commission for scientific photography and cinematography was formed within the Akademiya Nauk S.S.S.R. in 1948. Its task is the co-ordination of research work, information and contacts between research institutes, factories and individuals working in different branches of photography.

The founder of photographic education in Russia was Professor V. I. Kurdyumov (1853–1904) who organized the first photographic research laboratory in 1901 at the Institut Inzhenerov Putei Soobshcheniya (Institute of Transport Communications Engineers).

The Vysshi Institut Fotografii i Fototekhniki (Higher Institute of Photography and Photographic Technique) was organized in 1918 in Petrograd at the suggestion of Petrograd scientists. This institute was later reorganized and is now the Institut Kino-inzhenerov (Leningrad Institute of Film Engineers). The Gosudarstvennaya Shkola Kinematografii (State School of Cinematography) set up in 1919, later became the Vysshi Gosudarstvenni Institut Kinematografii (Higher State Institute of Cinematography) in Moscow.

A photographic institute, opened in Kiev in 1921 was later reorganized into a film institute.

The teaching of photography and the training of qualified specialists in scientific photography and photographic technique is carried on at Moscow, Kiev, Alma-Ata, Kazan and other universities, at the Moskovski Institut Geodezii, Aerofotosyemki i Kartografii (Moscow Institute of Geodesy, Aerial Photography and Cartography), at the Institut Tonkoi Khimicheskoi Tekhnologii (Institute of Technology of Fine Chemicals) and in other teaching organizations.

CC-0. Agamitra Digital Preservation Foundation, Chandigarh

Scientific Photography. Photography has been used in astronomy since 1874.

Astrophotography and photographic astrometry began in 1874, when the astronomers B. Gessel'berg in the Pulkovsky observatory and V. K. Tserasky in the Moscow observatory obtained photographs which were suitable for making measurements of the transit of Venus across the solar disc. From 1881 to 1888 Gessel'berg systematically photographed sun spots.

Astronomer S. N. Kostinsky (1867–1936) of the Pulkovsky observatory, determined the natural motions of stars from photographs, using a stereoscopic method. From 1896 to 1936 he photographed the satellites of the outer planets. In 1906 he discovered the effect on each other of two neighbouring images on a photographic plate, which is now known as the Kostinsky effect.

Photographic astrospectrography began in Russia in 1879 when B. Gessel'berg started to make a series of spectrographic observations on photographic plates. Academician A. A. Belopol'sky (1854–1934) was one of the founders of photographic astrospectrography. In 1892 he started to photograph the spectra of stars and in 1895 he used photographic plates to determine the velocity of light from the stars by measuring the displacements of the lines in their spectra. He published more than 250 papers on astrospectrography. S. N. Blazhko in 1904 and 1907 obtained photographs of the spectra of meteors.

P. K. Shternberg (1865–1920), an astronomer at the Moscow observatory, obtained 300 photographs of double stars over the years 1902 to 1915.

In 1909 G. A. Tikhov used colour filters to determine the colour of 252 stars in the Pleiades and began to study Mars.

In 1936 A. A. Mikhaĭlov determined the Einstein effect from measurements made on two pairs of plates. In 1951 A. N. Deĭch generalized the photographic observations on double stars in the 61st Cygnus. In 1949 A. B. Severnuĭi and A. B. Gil'varg made quartz interference polarizing filters with transmission bands of 1·8 A in width for studies of the sun, and in 1950 they narrowed the width of the transmission band down to 0·5 A.

Over the period 1949–1952 Academicians G. A. Shaĭn and V. G. Gaze used very narrow-cut red interference filters to photograph the luminous clouds of interstellar hydrogen.

From 1950 onwards, Academician V. G. Tesenkov in collaboration with D. I. Rozhkovsky photographed gaseous nebulae using the red hydrogen line and a D. D. Maksutov type of meniscus telescope.

In 1948 the astronomers A. A. Kalinyak and V. B. Nikonov and the astrophysicist I. I. Krasovsky used an electron-optical infra-red image converter with photographic plates and a suitable colour filter to obtain photographs

of the centres of the galaxies in infra-red rays.

On the 7th October 1959 photographs were taken on board the third Soviet cosmic rocket by means of television apparatus equipped with a photographic camera with two lenses and a small programmed installation for the automatic development and fixing of the photographic film. On a signal from the earth, the first photographs of the other side of the moon, at a distance of 65,200–68,400 kilometres from its centre, were obtained and transmitted in the course of 40 minutes. The book *Pervuie Fotografic Obratnoi Stovonui Lunui* (*The First Photographs of the Other Side of the Moon*) was published in 1959.

In recent years phase-contrast and analogous methods have been widely used in photomicrography. In 1955 the microbiologist, Professor M. A. Peshkov perfected a special method of photomicrography for studying cells in vivo.

Electron-micrography, which enables large organic molecules, ultra-microscopic viruses etc. to be studied, is widely used in physics, chemistry and biology.

Radiography of opaque objects is widely used in medicine and in non-destructive testing.

From the beginning of the 1930s fluorography has been widely used for the early detection of lung tuberculosis in mass observations of single groups of people. M. S. Ovoshchnikov, V. N. Ivanov and A. I. Prokofiev designed a tomofluorograph which combined the principles of tomography and fluorography.

From 1938–1940 L. V. Al'tshuller and V. A. Tsukerman developed a method of "impulse radiography" which enabled radiographs to be taken in several millionths of a second.

Electron diffraction photography which is based on photographing the diffractions of high speed electrons by atoms, molecules and crystalline and amorphous bodies, has been in process of development since the 1930s. P. D. Dankov and his collaborators have been making electron-diffraction investigations of the structures of oxide films on the surface of iron, copper and aluminium since 1938.

D. V. Skobel'tsuin obtained photographs of elementary particles in a Wilson chamber in 1926.

The use of photographic plates coated with thick layers of emulsion for studying nuclear reactions was suggested in 1927 by the Leningrad Professor L. V. Muisovsky. A. P. Zhdanov in 1950, in order to make accurate determinations of the nature of fission nuclei, suggested introducing into the emulsions on photographic plates certain pre-selected chemical elements, for studies of the interaction of the latter with cosmic rays. Autoradiography for the detection of invisible radioactive elements is used in biology and medicine. In 1904 Professor E. S. London was the first to use this method for determining the distribution of natural radioactive elements in an anatomical preparation. A. A. Drobkov described experiments in which he used radioactive phosphorus to obtain autoradiographs of tobacco which had been attacked by a virus disease.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Photographic Societies. The Fifth (photographic) section of the Russkoye Tekhnicheskoye Obshchestvo (Russian Technical Society) in Petersburg was formed in 1878. It published the journal *Fotograf* (*The Photographer*) from 1880–1884, also a bulletin *Sborniki Trudov Vth Otdela* (*Collected Papers of the Vth Section*). This Society organized the 1st Congress of Photography in Russia in 1882 and became the main photographic research centre in Russia. Active members of the photographic section included V. I. Sreznevsky, L. V. Warnerke, K. K. Mann, D. I. Mendeleyev, Wagner, the photographers S. L. Levitsky, A. I. Denier, D. P. Yezuchevsky and others.

The Russkoye Fotograficheskoye Obshchestvo (Russian Photographic Society) was founded in Moscow in 1894 and rapidly became an all-Russian photographic organization. It worked for the development of artistic photography in Russia.

The first conference of Russian photographers took place in Moscow in 1896 and more than twenty photographers took part. A second congress was held in 1908 in Kiev.

The Russian Photographic Society discontinued its activities until 1921 and then resumed them until 1930.

At the present time, photographic correspondents are in alliance with the photographic sections of the republican and regional unions of journalists.

Photographic sections exist to serve newspaper photographers. These sections are attached to the unions of journalists.

Photographic Exhibitions. A photographic section was organized in 1882 at the All-Russian Industrial Exhibition in Moscow. The Fifth (photographic) section of the Russkoye Tekhnicheskoye Obshchestvo organized photographic exhibitions in Petersburg in 1888, 1889, 1891, 1894 and 1898.

In 1889 the photographic section of the Society for the Propogation of Technical Knowledge in Moscow, organized a large photographic exhibition to mark the occasion of the jubilee of the discovery of photography in 1839. There were more than 1500 exhibits by professional and amateur photographers, whilst, in the same year, the photographic section of the Russian Technical Society in Petersburg arranged an exhibition, also dedicated to the jubilee of the discovery of photography.

The first international photographic exhibition was arranged in Moscow in 1902 and in Petersburg in 1903. The Akademiya Khudozhestv (Academy of Arts) organized an exhibition of artistic and technical photography in Leningrad in 1924.

A big exhibition, titled *Desyat' let Sovietskoi Fotografii* (*Ten Years of Soviet Photography*), was held in Moscow in 1927 and in 1937 an All-

Union exhibition of photographic art in the Musei Izobrazitelnikh Iskusstv im. A. S. Pushkina (Pushkin Museum of Fine Arts). Exhibitions of colour photography have been organized annually in Moscow in the post-war period. A number of exhibitions were organized also in Leningrad.

From 1960 onwards All-Union exhibitions of pictorial photography have been organized every year. In 1962, 755 photographs by 394 photographers were exhibited.

Exhibitions of Soviet photography have also been held abroad. In 1931 an exhibition of the work of the photojournalists of the magazine *Ogonek* was held in London and other towns in England and Scotland. In 1934 an exhibition of photojournalism in Warsaw met with great success. From 1935–1938 the work of Soviet experts in photojournalism was represented in forty International photographic exhibitions and photo salons.

In 1936 the International Photographic Exhibition in Prague had a large section devoted to Soviet photographic art. In 1937 an exhibition of Soviet Photographic Art was organized in London and other towns in England. The photographic section of the Union of Soviet Friendship Societies participated in a large number of international exhibitions in many countries. This society organizes thematic and personal exhibitions of Soviet photography abroad and exhibitions of foreign photographic art in Moscow.

Documentary Photography. The year 1859 saw the publication of an album *Fotograficheskiye Vidi Ierusalima i Ego Okresnostei* (*Photographic Views of Jerusalem and its Environs*); between 1870 and 1892 five volumes were published in a series *Amur, Vostochnaya i Zapadnaya Sibir* (*The Amur, Eastern and Western Siberia*). A *Turkestanski Albom* (*Turkestan Album*) was published showing the costumes, crafts, homes and architectural monuments of the peoples of Central Asia in those years. An album titled *Tipi Narodnostei Srednei Azii* (*Nationalities of Central Asia*) was specially prepared for the Third International Congress of Orientalists, held in Petersburg.

M. P. Dmitriev (1858–1948), a photographer in Nizhny Novgorod, was responsible for the development of documentary and news photography at the end of the nineteenth and at the beginning of the twentieth centuries. Over a period of years, beginning in 1888, he amassed the Volga Collection of 1,200 documentary photographs of great artistic merit.

P. A. Otzup (1883–1963) was a photographer in both pre-revolutionary and Soviet eras. He photographed the historical events of October 1917, and in 1918 produced the well-known photographs of V. I. Lenin on the platform, in the Kremlin and reading newspapers in his study.

In the Soviet period, photo-reportage work has reached high levels. Leading people in this field include P. K. Novitsky (1887–1942), who was a news photographer from 1911 and later a film camerman, M. M. Kalashnikov (1906–44), who was killed at the front during the War of 1941–5, and D. G. Debabov (1901–49).

The cosmonaut G. C. Titov during his flight in the cosmic ship "Vostok—2" on the 6th–7th August 1961 produced the first cosmic colour photographs.

Artistic Photography. This type of photography began to develop in Russia between 1850 and 1860 and its progress in the latter half of the nineteenth century is linked with the name of S. L. Levitsky (1819–98), who may be justly considered the founder of Russian professional photography. He acquired a daguerreotype camera from A. F. Grekov in 1839 and opened a daguerreotype workshop in Petersburg in 1850. He was a skilled portrait photographer, and his many portraits of Russian writers include N. V. Gogol and A. I. Gertsen. He won a gold medal at the first international photographic exhibition in Paris, 1851. A. J. Denier, a painter and member of the Russkaya Akademiya Khudozhestv (Russian Academy of Arts) opened a daguerreotype studio in Petersburg in 1853 and many leading writers and artists e.g. the Ukranian poet Tarasa Shevchenko, the Russian poets F. I. Tyutchev and N. A. Nekrasov, and the painter I. N. Kramsky were photographed there. In the years between 1840 and 1860 the Russian painters L. S. Plakhov, I. N. Kramskoi, Mikhai Zichi, A. I. Kuindzhi and others took up photography as an art. L. S. Plakhov opened a daguerreotype studio.

The Russakaya Akademiya Khudozhestv in Petersburg included photography in its art exhibition in 1876, and in 1904 and in 1908 organized special exhibitions of artistic photography.

V. A. Karrik (1827–1887) was one of the early masters of photo-journalism in Russia. Born in Edinburgh, he came to Russia with his parents in early childhood, received his primary education in Petersburg and Kronstadt and, at the age of 16, entered the architectural faculty of the Academy of Arts. In 1858–1859 he studied photography in Edinburgh under MacGregor and in 1859 he and MacGregor came to Russia and opened a photographic establishment. His collection included more than 800 photographs of different localities and types of inhabitants of the Russia of that time.

A. O. Karelin (1837–1906), a photographer in Nizhny Novgorod, is one of the leading figures in pre-revolutionary genre and portrait photography. He won a gold medal at the International Photographic Exhibition held in Edinburgh in 1880. Karelin's realistic photographic compositions were much like the painting of the Peredvizhniki (a group of leading Russian realist painters at the end of the nineteenth century).

S. A. Lobovikov (1870–1946) a photographer in Vyatka, specialized in genre photographs of

CC-0. Jangamwadi Math Collection. Digitized by eGangotri

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

country life in Russia before the revolution. N. P. Andreev (1882–1947) of Sergiev Posad, caught the spirit of the Russian seasons in his photographs.

The most outstanding craftsmen in artistic photography in the Soviet period include Y. P. Yeremin (1881–1948), who has a considerable collection of Crimean and Caucasian landscapes and country houses near Moscow to his credit. I. A. Bokhonov (1891–1952), instructor in pictorial photography in the Vsesoyuzni Gosudarstvenni Institut Kinematografii (All-Union State Institute of Cinematography) taught many leading photographers and film cameramen and was himself an outstanding craftsman in landscape and portrait photography.

M. S. Nappel'baum (1869–1956) was a noted craftsman in portraiture. He took the well-known portraits of V. I. Lenin in 1918.

A. M. Rodchenko (1891–1956), an artist by profession, was one of the outstanding portraitists of the younger generation. There was also V. D. Shakhovskoi (real name Pogrebshchikov), (1899–1963) photographic correspondent of the magazine *Sovetskii Soyuz* (*The Soviet Union*) who produced a series of fine landscapes, photographic portraits and work scenes, including subjects of a documentary and publicity nature.

N. A. Petrov (1876–1940), Professor at the Kievski Politekhnicheskiinstitut (Kiev Polytechnical Instaitute) is also well known as a photographic artist, a historian and teacher.

Magazines. *Fotograf* of 1864–6 was well up to the level of photographic science of its day. In the 1860's and 70's a number of magazines appeared, the most important of them being *Fotograficheski Vestnik* (*Photographic Herald*) in 1867 and 1887–1910, *Fotograficheskoye Obozreniye* (*Photographic Review*) from 1865 to 1879 and 1895–1902. The best Russian photographic magazine in the second half of the nineteenth century was the journal *Fotograf* (*The Photographer*), the organ of the fifth (photographic) section of the Russian Technical Society (1880–4). Others included *Fotograf-Lyubitel* (*The Amateur Photographer*), 1890–1909, *Russkii Fotografichikii Zhurnal* (*The Russian Photographic Journal*), 1895–1898, *Zhurnal Russkogo Fotograficheskogo Obshchestava* (*Journal of the Russian Photographic Society*), *Vestnik Fotografii* (*Photographic Herald*), 1908–1918, and *Fotograficheskie Novosti* (*Photographic News*), 1907–1918.

During the Soviet period there have been published *Sovetskoye Foto* (*Soviet Photo*) from 1926, to 1941 and from 1957, and *Fotograf* from 1926–30, being the organ of the *Vserossiiskoye Obshchestvo Fotografov* (*All Russian Photographic Society*); *Optiko-Mekhanicheskaya Promyshlennost* (*Optico-Mechanical Industry*) from 1931–41, 1946–47 and 1956 onwards, *Fotokhimicheskaya Promyshlennost* (*Photo-Chemical Industry*) from 1932 to 1936, *Fotolyubitel* (*Amateur Photographer*) 1936–1937, and *Kinofotokhimicheskaya Promyshlennost* (*Cine-Photo-Chemical Industry*) from 1935 to 1941, being the organ of the Glavnoye Upravleniya Kinopromyshlennosti Vsesoyuznogo Komiteta po Delam Iskusstvo (Central Board of the Cinema Industry of the All-Union Committee of Art Affairs). A *Zhurnal Nauchnoi i Prikladnoi Fotografii* (*Journal of Scientific and Applied Photography*) began publication in 1956. Collections of material titled *Uspekhi Nauchnoi Fotografii* (*Progress in Scientific Photography*) have been appearing since 1951.

Books on Photography. The latest scientific works on photography are: *Osnovui Teorii Fotograficheskikh Protsessov* (*Fundamentals of the Theory of the Photographic Processes*) by Yu. M. Katushev, V. I. Sheberstov (1954). *Teoriya Fotograficheskikh Protsessov* (*Theory of Photographic processes*) by K. S. Lyalikov (Moscow 1960). *Spektral'nuie Issledovaniya Fotograficheskovo Protsessa* (*Spectroscopic Investigations of the Photographic Process*) by Yu. N. Gorokhovsky (Moscow 1960). *Fotokhimiya Krasitelei i Rodstvennuikh Organicheskikh Soedinenii* (*The Photochemistry of Dyes and Related Organic Compounds*) by A. N. Terenin (Moscow and Leningrad 1947). *Fiziko-khimiya Naneseniya Tonkikh Sloev na Dvizhushchuyusya Podlozhku* (*The Physical Chemistry of the Coating of Thin Layers on to a Moving Support*) by B. V. Deryagin and S. M. Levi (Moscow 1959). *Teoriya Nepreruivnuikh Protsessov Obrabotki Svetochuvstvitel'nuikh Materialov* (*The Theory of the Continuous Processing of Light-Sensitive Materials*) by N. I. Kirillov (Moscow 1948). *Osnovui Protessov Obrabotki Svetochuvstvitel'niukh Materialov* (*Fundamentals of the Methods of Processing Light-Sensitive Materials*) by N. I. Kirillov (1954). *Prosvetlenie Optiki* (*The Coating of Lenses*) by I. V. Grebenshchikov, A. G. Vlasov, N. V. Suïkovskaya (1946). *Metodui Pascheta Slozhnuikh Fotograficheskikh Sistem* (*Methods of Computing Complex Photographic Systems*) by D. S. Volosov (Moscow 1948). *Teoriya i Raschet Svetoopticheskikh Sistem* (*Theory and Calculation of Light-Optical Systems*) by D. S. Volosov and M. V. Tsivkin (Moscow 1960). *Tsvetnoe Proyavlenie Trekhsloinuikh Svetochuvstvitel'nuikh Materialov* (*The Colour Development of Three-Layer Light-Sensitive Materials*) by V. S. Chel'tsov and S. A. Bongardt (1958). *Fotoreproduktsiya Nevidimogo* (*Photographic Reproduction of the Invisible*) by A. I. and G. A. Didebulidze (Tbilici 1948) *Fotograficheskie Metodi Nauchnogo Issledovaniya* (*Photographic Methods of Scientific Research*) by I. V. Sokolov (1953).

Works on the history of photography include: *Dokumentui po Istorii Izobreteniya Fotografii* (*Documents on the History of the Invention of Photography*), edited by T. P. Kravets (1949), *Ocherki po Istorii Fotografii v S.S.S.R.* (*An outline of the History of Photogrhapy in the U.S.S.R.*) by G. M. Boltyansky

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

(1939), *Sovetskaya Khudozhestvennaya Fotografiya* (*Soviet Artistic Photography*) by S. A. Morozov (1960), *Izobretenie Fotograficheskikh Protsessov, Niepsa, Dagerra i Talbota* (*The Photographic Processes Invented by Niepce, Daguerre, and Talbot*) by I. V. Sokolov (1953).

A number of photographic albums have been published: *Sovetskoe Fotoiskusstvo* (*Soviet Photographic Art*) (Moscow 1939), *Fotoiskusstvo S.S.S.R.* (*Photographic Art U.S.S.R.*) (Moscow 1962) *Dni i Lyudi* (*Days and People*) (1962), *Sovetskoe Fotoiskusstvo* (*Soviet Photographic Art*) (1962), *Sowjetische Meisterfotos* (*Soviet Masterpieces of Photography*), edited by M. Bugaeva (published in the German Democratic Republic, 1962).

Popular books on photography are published in editions of 100,000–350,000 copies. The book by V. I. Vrikunin, *25 Vrokov Fotografii* (*25 Lessons in Photography*) was issued in eleven editions; the number of copies of the last edition reached 1,300,000.

The works of outstanding foreign photographic specialists have been published in the Russian language, among them *The Theory of the Photographic Process* by C. E. K. Mees (New York, 1942) was published in 1949; and *Fundamentals of Photographic Theory* by T. H. James and G. C. Higgins (1948), was published in 1954.

Single articles from the foreign photographic periodicals have also been published, for example those written by T. Evans, J. W. Mitchell, et al. I.V.S. & V.A.Y.-G.

RUTHERFURD, LEWIS MORRIS, 1816–92. American physicist. Photographed the Pleiades in 1864 with wet collodion plates, using a specially corrected lens. In the same year he constructed the first telescope, of 11¼ ins. aperture, corrected for photographic rays. He also produced excellent specimens of diffraction gratings.

Also, in collaboration with Seely in New York, produced a photograph of a solar spectrum two metres long.

RUZICKA, JOSEPH, 1870–1961. Czechoslovakian medical doctor. Settled in the U.S.A. Internationally known amateur pictorialist of the period before World War I.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

S

SABATTIER, ARMAND, 1834–1910. French doctor and scientist. Described in 1862 the "pseudo-solarization reversal"; a negative image on a wet collodion plate changed to a positive when daylight fell on the plate during development. This Sabattier effect was exploited for making positives by reversal, a second exposure and development being given after the first exposure and developing.

SABATTIER EFFECT. When a partly developed image is briefly exposed to actinic light, the final developed image becomes reversed. This is because in areas where the negative image had started to form, the emulsion is desensitized by the oxidation products of development. The result is that the extra exposure affects only the shadow areas of the original negative so that the final image is a positive.

This type of reversal is known as the Sabattier effect, after its discoverer.

See also: *Solarization.*

SAFELIGHT. The nature of the working illumination in the darkroom depends on the sensitive material that is being handled. Most of the films, plates, and printing papers normally used in photography are blind (or only slightly sensitive) to certain colours. So it is generally possible to illuminate the darkroom with light of a colour that does not affect the sensitive material in use if it is exposed within reasonable limits of time and distance.

Sensitized Materials. The following safelight screens are recommended for use with the various types of sensitive material. These colours may be accepted as being safe in the absence of any more specific recommendation published by the manufacturer.

Contact printing material—paper, film, lantern plates, document papers, and all very slow, non-colour-sensitive materials: fairly bright yellow.

Enlarging papers—bromide and chlorobromide papers: orange or olive green.

Orthochromatic materials—films and plates: ruby red.

Panchromatic materials—all except the very slowest films and plates: deep green or bluish green.

Very slow panchromatic materials—films and plates: dark green.

X-ray materials—films and paper: light brown or special type of olive green.

Process materials—plates, films, special lantern plates, and all fast non-colour-sensitive materials: dark brown or light red.

Desensitized panchromatic materials—films and plates: bright green.

Colour films and papers—very deep olive green or brown, according to makers' recommendations.

Fast panchromatic materials or colour films are never exposed to the direct safelight for any purpose other than inspection during development, and even then never for more than a second or two. Inspection should not take place until it is thought that development is nearing completion.

Screens. Safelight screens are made of dyed fabric, coloured celluloid or plastic, tinted glass, and coloured gelatin sandwiched between glass plates. The gelatin sandwich type is more reliable as the colours are more accurate.

The screen is fixed in front of the darkroom lamp. There are two kinds of darkroom lamp. In one, the light source shines directly through the screen; in the other, it shines on a reflector behind the screen while the direct rays are cut off by a baffle. Again, some darkroom lamps shine directly down on the work, while others shine on to the ceiling or wall.

The power of the light source depends on the type of lamp and how it is used; the safelight can become unsafe if the light source is too powerful. As a general rule, the lamp is fitted with the lowest power bulb that will give enough working illumination to eyes that have had some minutes in which to adapt themselves. The lamp must have good ventilation because the screen may change colour and become

unsafe if it is allowed to get hot.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

The following table gives the power of electric light bulbs recommended for various types of darkroom illumination.

POWER OF SAFELIGHT LAMPS

Illumination	*Maximum Watts*
Lamp with bulb shining directly through safelight screen:	
(a) shining directly on to work not less than 4 feet away	15
(b) with light from lamp reflected from wall or ceiling not less than 8 feet away ...	25
Lamp with indirect illumination from bulb screened by baffle:	
(a) shining directly on to work not less than 4 feet away	25
(b) with light reflected from wall or ceiling not less than 8 feet away	40

Where negatives are likely to be held in front of the lamp for inspection it is an advantage to use a safelight screen bound up with an opal diffusing screen. In the gelatin sandwich type of screen one of the sheets of glass enclosing the gelatin is usually opal.

Coloured Light Sources. The light given out by certain light sources is restricted to a narrow band of frequencies. Such sources can be employed as darkroom safelights for materials which are insensitive to the particular frequencies emitted.

The principal light source of this type is the sodium vapour lamp which is used as a safelight in large printing establishments handling blue-sensitive materials—e.g., document copying and contact papers and negative materials.

Luminescent Panel Lighting. Dark room lighting is one of the principal applications of electroluminiscent panel lighting. This type of light source consists basically of a layer of electroluminescent phosphor sandwiched between two layers of conducting material, one of which at least is a conducting layer of transparent glass or plastic. When a voltage is applied to the outer layers, the phosphor glows and emits light through the transparent surface. At present the light output of such sources is low—about 5 watts per square foot—but as it is of a deep green, it is particularly suitable for use in commercial darkrooms where large quantities of parchromatic material are handled.

Self-Powered Light Sources. Luminous paint may be used without risk of fogging the sensitive material for marking the position of objects, controls, clock dials and so on. Another form of self-luminous marker coming into use consists of a sealed glass tube coated internally with a phosphor and containing a small amount of the rare gas tritium. This gas is an isotope of hydrogen which emits low energy beta particles. When these strike the phosphor they cause it to glow. The visible radiation is brighter than luminous paint and has a life of 20 years.

Sizes. Safelight screens are made in a range of standard sizes so that they can be interchanged in the same darkroom lamp according to the sensitized material being handled. The sizes normally available are:

SAFELIGHT SCREEN SIZES

Inches	*Centimetres (approx.)*
5 × 7	13 × 18
8 × 10	20 × 25
10 × 12	25 × 30
5½ circular	14

The darkroom lamps are also of standard sizes.

Testing Safelights. The most satisfactory test for a safelight is to expose a specimen of the relevant sensitized material to it under working conditions.

A piece of the material is laid, sensitized side up, on the darkroom bench with a small opaque object—e.g., a coin, lying on it. The darkroom lamp is then switched on for about twice as long as the material would normally be exposed to it—from the moment of opening the packet to the end of development.

The material is developed for the normal time well away from the safelight and then fixed and examined by white light.

If the light is not safe, the shape of the test

SAFELIGHT LAMPS. Left: *Lamp for indirect illumination, to be suspended from a white-washed ceiling.* Centre left: *Direct overhead lamp; adjustable for direction.* Centre right: *Simple cover for amateur darkrooms; utilizes existing light fitting.* Right: *Shelf or bench lamp giving diffused indirect light from lamp behind opaque slide. Slide withdraws for white light.*

CC-0. Agamnigam Digital Presevation Foundation Chennai and eGangotri

SAFELIGHT FILTERS. Transmission curves (per cent transmission for different wavelengths of light) of safelight filters as used for various types of sensitive materials. A, yellow for chloride contact papers and contact lantern plates. B, orange for bromide and chlorobromide enlarging papers, normal lantern plates, and very slow blue-sensitive materials. C, brown for X-ray films. D, deep green for panchromatic negative materials (for inspection only, not continuous exposure). E, deep red for orthochromatic films and plates.

object will stand out lighter in tone than the surrounding emulsion. In that case the lamp must be fitted with a less powerful bulb, or a deeper screen, or moved farther away from the work bench.

This method of testing does not reproduce the working conditions exactly because the actual print has already been exposed and is therefore more sensitive to further unsafe light than the fresh test piece. So the test tends to be optimistic. This is why the test piece should be left for at least twice the normal period that the printing paper is exposed to the safelight. F.P.

See also: *Filters; Spectral sensitivity.*
Book: *Developing*, by C. I. Jacobson (London).

SAFETY FILM. Negative or positive film support which is not readily inflammable, (by contrast with highly inflammable nitrate films, which were used at one time).

Usually consists of cellulose acetate; sheet film supports often consist of polyester or similar plastics.

See also: *Supports for emulsions.*

SAL-AMMONIAC. Another name for ammonium chloride; constituent of some high speed fixers.

SALOMON, ERICH, 1885–1944. German doctor of law. Became a freelance photo-reporter in 1928, after working in the publicity department of a large publishing house in Berlin. With the Ermanox camera, he pioneered modern photo-journalism and is famous for his candid photographs of politicians at international conferences, taken in available light conditions. Aristide Briand called Salomon "le roi des indiscrets". Died in Auschwitz extermination camp, 1944.

SALON. Exhibition which, in photography, is usually of international status. The recommendations made by at least one national photographic organization state that, for an exhibition to be called a salon, it must allow entries from anyone (i.e., is an "open" exhibition, not confined to members of one society) and should be held in a suitable public building such as an art gallery.

See also: *Exhibitions and salons.*

SALT. Term in general use for sodium chloride (common salt).

In chemistry: the name for the class of compound produced by the reaction of an acid with a metal or molecular group of similar characteristics to a metal—e.g., silver nitrate is the salt of silver produced by the action of nitric acid on metallic silver.

SALTED PAPER. Old term for papers sensitized by the user. Their appeal lay in the fact that they allowed the photographer to use papers of a special type and surface, like Whatman paper and other hand-made papers.

The paper was first coated with a solution of common salt and gelatin in water. It was then sensitized in a silver nitrate solution and dried in the dark. The sensitized paper was then exposed under the negative in daylight to give a visible image. This was toned in a bath of potassium chloro-platinate, fixed in hypo, and washed.

See also: *Fabric printing; Printing processes (obsolete).*

SARONY. OLIVER FRANCOIS XAVIER, 1820–79. Canadian born professional photographer. Settled in Scarborough in 1857 and became the most prosperous provincial photographer in England during the carte-de-visite period. A square in the town still bears his name. In the early 1870s Sarony did good business selling licences for his secret enlarging process.

SATELLITE PHOTOGRAPHY. Recording of the flight of space satellites and rockets. Usually requires complex camera installations with telephoto optical systems and precise means of aiming the camera at the missile and keeping it in view.

See also: *Missile photography.*

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

SATURATED SOLUTION. Any liquid containing the maximum amount of a substance that can be dissolved in it. The amount required to produce saturation depends upon the temperature of the solution.

SAYCE, B. J., 1837–95. English amateur photographer in Liverpool. Introduced with W. B. Bolton the collodio-bromide of silver emulsion—the first workable photographic emulsion—1864.

SCALE. In a photograph, the relation between the size of the subject and the size of the negative image. If a doorway 7 feet high is reproduced as an image ¼ in. high on the negative, the scale of the image is (7 × 12 × 4) : 1 or a reduction of 336 : 1.

In an enlargement, the scale is the relation between the size of the negative image and the size of the enlargement. If a negative 2¼ ins. square is enlarged to fill the long side of a print 6½ × 8½, the scale of the enlargement is 2¼ : 8½, or 9 : 34 or a magnification of approximately 1 : 4 (usually written, 4×).

When the subject and image are equal in size—e.g., in document copying—the scale is usually indicated as s/s (same size).

In all these cases the scale of enlargement or reduction is a linear one; in terms of area, the linear scale has to be squared. For instance a linear magnification of 4× is equal to an area magnification of 16×.

See also: *Magnification; Optical calculations; Scaling for reproduction.*

SCALES. Instrument for weighing chemicals, etc. Actually a scale is a dish or pan on such an instrument, but the plural term is commonly used to indicate the complete apparatus whether it uses one or two pans.

See also: *Balances and scales.*

SCALING FOR REPRODUCTION

In the photo-mechanical reproduction of photographs there is inevitably some loss of detail whatever process is used. To offset this loss as far as possible it is advisable for the process engraver to work from a photograph larger than the size of the proposed reproduction. The size of reproduction is often limited by the width of the printer's column. It is therefore necessary to have some convenient means of scaling down the photograph which will indicate the actual size at which it will reproduce within the limitations of the printing process.

When a photograph is scaled down, all dimensions of the original are reduced in the same proportion, and it often happens that the result cannot be made to fit the printer's requirements without losing some part of the original photograph. Such a situation arises when, for example, a photograph measuring 6 × 8 ins. is required to measure 4 × 6 ins. in the reproduction. This is an impossibility, for one dimension is required at three-quarters original size and the other at two-thirds. Possible dimensions are, amongst others, 4½ × 6 ins. or 4 × 5⅓ ins., so that in either case some portion of the original will have to be trimmed off. In many instances, of course, such trimming can be done without impairing the picture, but in any event it is still necessary to mark the photograph clearly but without damaging it.

Scaling by Diagonal. The best-known way of scaling rectangular illustrations is by the diagonal method. It is only necessary to draw a rectangle the same size as the original photograph and rule in the diagonal. This diagonal is also the diagonal of any other rectangle, larger or smaller, of the same proportions. It is therefore only necessary to take a set square and measure off the width of the required reproduction from the edge of the original to the diagonal. The corresponding depth of the reproduction can then be directly read off at right angles.

By using the diagonal principle in reverse and

SCALING BY DIAGONAL METHOD. To determine to what size an original will reduce or enlarge, a diagonal is drawn through the required portion. This is then also the diagonal of any other rectangle with the same proportions. On measuring any required width from the edge of the original to the diagonal, the depth from that point is the corresponding depth in proportion to the measured width.

CC-0. Panjab Digital Preservation Foundation, Chandigarh

working back from the proportions of the reproduction, one can ascertain how much of an original must be trimmed off so that it can be reproduced in the required size. This is best done by scaling up the reproduction proportions on a piece of tracing paper. When this is laid over the original it will at once show the portion to be trimmed.

If the photograph is not rectangular, or if a portion is to be cut out—e.g., for insertion of a caption—the principle is difficult to apply, and it is better to use one of the alternative methods.

Norman's Rule. This method involves the use of a scale of equal units of length drawn on a strip of elastic and held in a simple frame so that it may be stretched to any desired length and held there. One side of the elastic may conveniently be marked in $\frac{3}{4}$ in. divisions and the other in $1\frac{1}{2}$ in. divisions by holding the unstretched elastic along a foot rule and making marks on both sides at the required intervals. The short divisions may be used for proportions around the same size and the longer ones for reductions to avoid stretching the elastic unduly.

To use the rule, the elastic is stretched until the original apparently measures the correct size required according to the rule. If the setting of the rule is not altered, all other dimensions of the original can then be measured off against the expanded rule, the resulting readings being in the correct proportion. Thus if a 6 × 8 ins. photograph is required for reproduction at approximately 4 × 6 ins., the rule is stretched so thats the longer dimension apparently measure 6 ins., the shorter dimension, on being measured against the expanded rule, will then be found to be $4\frac{1}{8}$ ins. long.

NORMAN'S RULE. The rule is marked out on elastic held in a frame which can be stretched in use. For scaling, the rule is extended until the original apparently measures the correct size in one direction. If the setting of the rule is not altered, all other dimensions of the original will measure the size to which they will reproduce at the set proportion.

The great value of this method is that it shows at once just how much of the picture must be trimmed off to obtain the 4 ins. depth, and alternatively how much will be included if it is decided that the reproduction for instance can be $4\frac{1}{4}$ ins. deep.

Another advantage of Norman's rule is that it can be used to discover how many pictures of a batch will "go together"; that is, how many of them it will be possible to reproduce at the same scale so that they can be processed together and afterwards separated into individual printing images. Such a set of subjects, mounted together, is sent to the blockmaker marked "photo together and separate" and can thus be put through at a lower charge than would apply if the pictures were reproduced individually. The pictures which are required at the same scale are found by first scaling one with the rule, then any others which measure their required size without altering the rule can be photographed together with the first.

The different lengths of the units on either side of the elastic rule make it possible to deal with any scale from enlargements to considerable reductions. The longer divisions stretch out to give even bigger units, and so deal with reductions, while the shorter divisions deal with slight enlargements and scales around same size. For scales beyond the scope of the rule it is easy to read two inches as one, or vice versa for enlargements.

The only drawback of Norman's Rule is that it is not absolutely accurate. However one can size up a job to within about $\frac{1}{16}$-inch, which is close enough for most purposes. When the elastic becomes worn, it can easily be replaced.

Slide Rule. A slide rule provides an easy and completely accurate scaling device which in addition indicates the percentage scale of reproduction. On most slide rules reproduction sizes are, however, given in the decimal system but it is possible to obtain special slide rules marked in the more convenient inches, eighths and sixteenths, and in printers' 12 point ems.

Computer Disc. A computer disc, consisting of two concentric scales rotating independently on the common centre, may be used instead of a slide rule. The outer disc is calibrated for the original size, the inner for the reproduction size, and a scale number pointer is provided on the former indicating the percentage magnification. To use the computer disc, the actual width (or depth) of the original is set on the outer scale against the desired width (or depth) on the reproduction scale. All

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

other readings are then in proportion, and the percentage magnification is indicated on the scale by the pointer.

The percentage magnification value has two important applications. If several photographs are to be reproduced, all those with the same percentage value can be placed in the process camera at one time, with a corresponding saving in time and cost. Many modern process cameras are scaled directly in percentages and provided with automatic focusing, so that it is only necessary to pre-set the instrument to the required percentage figure and all calculation is eliminated.

Scaling Rule. At least one special scaling rule is available for calculating the relative dimensions of original and reproduction. There is a duralumin rule of the slide rule type with two adjustable pointers. One pointer is set to a dimension of the picture and the other to the size required. This sets the rule for the particular scale of reproduction so that when the first pointer is moved to the length of the other dimension the rule indicates what size it will be when reproduced to that scale. The rule covers any sizes from 1 to 150 (inches or centimetres); it indicates the percentage magnification and it can also be used for calculating the size required to give a certain fraction of the area of the original picture or the dimensions which will produce a stated area.

Marking up Prints. The safest procedure, to avoid damaging the face of the print, is to mark the back of the print with ink and a brush. Alternatively, a piece of tracing paper stuck along the top back edge and folded over the front is useful for indicating the portion to be included and the size. On no account should a ball pen be used for either writing or marking up on either front or back of the print, as the resulting marks can never be erased and will show up in reproduction. Instructions to the process engraver may be lightly written on the back of the print with a soft pencil; this is safer than writing them elsewhere, as they cannot then get lost.

If the whole picture is to be reproduced it is often sufficient to write "reduce to X inches wide" so as to conform to the particular column width, and leave the depth to work out in proportion. Very often the depth of a block does not matter within reasonable limits, as a fraction of an inch one way or another can be taken up by leading the text above or below at the make-up stage.

Marking up Transparencies. On no account should marks be made on the transparency.

The best way with any transparency, monochrome or colour, positive or negative, is to make a simple bromide print from it, preferably to the required size, and to indicate precisely what is required on the print. Whether the print is negative or positive, and whether the tone-values are falsified by the lack of colour sensitivity of the bromide paper, is of no importance, as photo-engravers are accustomed to such effects and they will of course make the reproductions from the transparency itself.

If the whole of the picture is to be included in the reproduction, the dimensions can be stated on the envelope enclosing the transparency, but very often it is necessary to indicate the portion of the picture to be reproduced. This can be done by cutting a paper or card mask and taping the transparency upon it, but it has to be removed for the reproduction work (and probably colour-masking); it is also particularly inconvenient with a miniature transparency. F.H.S.

Book: *Photographs and the Printer*, by F. H. Smith (London).

SCHEELE, CARL WILHELM, 1742–86. Swedish apothecary and chemist. In 1777 he discovered that the blackening of silver chloride was due to the reducing action of light, and that the black deposit was reduced silver. He also noted that silver chloride blackened more quickly in the violet end of the spectrum than in other colours, but was not influenced by heat rays. He was the first to name the ultra-violet and most refrangible rays of the spectrum the "chemical rays". Also discovered that ammonia was a solvent for silver chloride that had not been affected by light.

SCHEINER, JULIUS, 1858–1913. German astronomer and professor of astrophysics in Berlin. Described a sector-wheel sensitometer using a benzine lamp (1894); an improved version was proposed by Eder in 1898. The Scheiner sensitometer scale, reduced to candle power per second per metre and starting with the threshold value, was largely used in Germany and Austria (and partly in other European countries) for film speed measurement until replaced there by the DIN scale.

SCHEINER SPEED. Logarithmic system of rating the speed of negative materials, introduced by Julius Scheiner.

The Scheiner speed is derived from the formula: speed = C − (10 × log Exposure) where C is an arbitrary constant and the exposure is the least that will produce a visible image on development.

This system, in which the speed of the emulsion is expressed in degrees—e.g., 32° Sch.—gives an artificially high rating to the type of emulsion which has a characteristic curve with a very long toe.

See also: *Speed of sensitized materials.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

SCHINZEL, KARL, 1886–1951. Austrian scientist. Inventor of numerous colour photography processes (250 patents). Lived in a small town in Moravia and worked during most of his life without any contacts or assistance from outside. He started in 1905 with work on the three-colour Katachromie process on mono-pack material and put forward many original and fruitful ideas on subtractive colour photography processes; lost his chance, however, by publishing them too late. Later consultant to the Eastman Kodak Company.

SCHLIEREN PHOTOGRAPHY. Schlieren is a German word meaning streaks or striations. It is applied to a class of optical systems which make it possible to see small local changes of refractive index or thickness in transparent media. Schlieren systems are refined methods for observing those disturbances which in everyday life are seen by virtue of the apparent distortion of the background—e.g., warm air over stoves or imperfections in glass windows.

Many variations of the system are applied to problems such as the flow of air at high speed past aircraft wings and bodies in wind-tunnels and in flight, the flow of heated or cooled gases and liquids, the mixing of different gases and liquids, the movement of sound waves, and the examination of glass. The great value of seeing what is invisible to the naked eye is obvious: that it can be done with simple optical systems is not as well known as it should be considering that Toepler and Mach knew how to apply them almost a century ago.

Typical Arrangement. A typical system for schlieren photography may employ a parallel beam of light formed by a small source at the focus of a lens or spherical mirror. This passes through the transparent object and is brought to a focus again by a similar lens or mirror. Part of this image is obscured, or cut-off, by a knife edge and the light which passes falls on a screen on which the image of the transparent object is focused by an auxiliary lens. If any part of the light is deflected in a direction at right angles to the knife-edge by refractive index gradients or differences in thickness in the object, the image of the source at the knife-edge will be displaced in that direction. More or less light will pass over the knife-edge, and corresponding areas of the image on the screen will lighten or darken in proportion to the displacement (so long as it does not exceed the extent of the image source). Thus the refractive index gradients in the object are represented in light and shade in the picture on the screen, which can then be photographed.

In many cases it is the density variations in the medium which are of interest and, fortunately, the density (d) and the refractive index (n) are simply related:

$$\frac{n^2 - 1}{n^2 + 2} \times \frac{1}{d} = \text{a constant}$$

or, when n is near unity,

$$\frac{n - 1}{d} = \text{a constant}$$

The image can thus be easily interpreted as a picture of a density field.

Special Methods. Schlieren systems are used most often for obtaining a qualitative picture, but it is possible to obtain quantitive results in certain cases by relating the change of illumination in the picture with the deflection produced in the object, and thus to the refractive index gradient. Practical difficulties have limited the usefulness of these methods.

By using a multi-coloured filter instead of a knife-edge it is possible to obtain a picture in which the different refractive index gradients are represented by different colours of the spectrum. Similar results can be achieved with a dispersing prism in front of the source and a slit in place of a knife-edge.

It is also possible to achieve special effects by suitable choice of the type of knife-edge or filter arrangement and many such systems have been described.

In recent years a new class of instruments has been developed which are analogous to Schlieren systems in that they record refractive-index gradients but which are really interferometers: they are known as schlieren-interferometers. In one such instrument, the two beams of the interferometer are produced by means of a Wollaston prism. The two beams are of equal intensity, polarized at right angles and laterally separated by a small distance. After passing through the object under observation they are recombined in a similar Wollaston prism and an image is formed on a screen, with fringes representing lines of constant refractive index gradient. With a white light source the fringes are coloured, the scale of colours being those characteristic of Newton's rings and not of the spectrum as in the case of colour-schlieren systems. Sensitive schlieren-interferometer systems are not so much affected by diffraction phenomena as conventional schlieren systems since the sensitivity does not depend on the use of small sources and a knife-edge (or other type of cut-off or filter). However, the image quality is limited by the doubling of the image due to the two beams, and, as the sensitivity of a given system increases with beam separation, the apparent advantage is often illusory.

Photography. There are no special problems in the photography of schlieren images except insofar as spark light sources are concerned. Such sources are often used because they combine the small dimensions necessary in a sensitive system with very high brightness and a short duration otherwise difficult to achieve. The combination of the very short exposure time (10^{-7} second) and the unavoidably low contrast of the schlieren image (about 10 : 1) may give rise to difficulty if an unsuitable emulsion is

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

used. A prolonged development in a high energy developer will give beneficial increases of both speed and contrast. Of two emulsions with the same speed the one with more contrast will be easier to use. Since the output of the spark is concentrated in the blue region of the spectrum there is no advantage in using panchromatic emulsions if blue-sensitive types of equivalent speed are available.

When using colour materials with spark light sources some problems of colour balance may be encountered and compensating filters may be required due to the combined effects of reciprocity-law failure and the spectral quality of the light. With modern colour emulsions and modern spark sources, these effects are small and can usually be ignored. R.J.N.

SCHLIPPE'S SALT. Constituent of some intensifiers and toners. Another name for sodium thioantimoniate.

SCHMIDT CAMERA. Astronomical camera practically free from chromatic aberrations. It was developed about 1931 by Bernhard Schmidt, maker of reflecting telescope mirrors. The camera, rather like a reflecting telescope, uses a spherical mirror instead of a lens and has a thin aspherical glass corrector plate placed in front of the mirror at its centre of curvature.

The corrector plate has one plane surface while the other is slightly convex around the centre and slightly concave at its rim. Its purpose is to deform the path of incident light rays from an object at infinity—e.g., an astronomical body—to compensate for the spherical aberration of the mirror.

SCHMIDT CAMERA. The essential components are: A, corrector plate; B, film plane; C, mirror. The image is formed on the sensitive film by the spherical mirror. A stop in the centre of curvature restricts the width of the beam and ensures equal reflection at all angles. The only aberration is spherical aberration, which is corrected by deforming the incident rays by means of an aspheric corrector plate. The plate is placed in the centre of the curvature of the mirror.

The image from the mirror is formed on a spherical sensitized surface. This is placed halfway between the mirror and its centre of curvature. Schmidt cameras or cameras of a similar type are now widely used by observatories—including the Mt. Palomar observatory where a 48 ins. aperture Schmidt camera has been used for a complete survey of the sky, comprising about 1,800 exposures.

SCHOOL. Term applied to a group of workers who share the same aims and techniques or whose style and technique exhibits strong national or cultural similarities.

SCHOOL PHOTOGRAPHY

Photography is associated with school life in three principal ways: it can be taught as a creative hobby, it can be used by teachers and pupils for recording school activities, and many commercial photographers make a profitable business or sideline of taking official photographs of school classes, teams and similar groups.

There are many sound reasons for teaching photography to boys and girls at school. It is an excellent introduction to artistic appreciation; it is a practical demonstration of the laws of optics, and the preparation and use of processing solutions gives scope for budding chemists.

By no means the least important reason for encouraging children to take up photography is that a schoolchild who takes the right kind of photograph is laying up for himself a store of memories for the future.

Instruction is best carried out through a school photographic club, the minimum requirements being a knowledgeable and enthusiastic leader, and some funds with which to buy essentials such as a safelight, printing frame, and dishes.

If a darkroom equipped with an enlarger is available the value and interest of the club is considerably enhanced. There will be no lack of premises for meetings.

Suitable Cameras. Beginners should start with a simple, robust camera taking standard roll film and giving either eight or twelve exposures per reel. If possible, the lens should have a focusing movement and an iris diaphragm, and the shutter be provided with variable speeds. A large waist-level viewfinder, such as that fitted to many cameras yielding negatives 2¼ ins. square, is more likely to produce a good proportion of results than the more common eye-level type, which frequently reduces the scale of the image considerably and is rarely fully reliable, especially at close range.

In spite of its obvious attractions, particu-

larly in relation to colour photography, the miniature camera using 35 mm. film is not suitable for children. The negatives need considerable enlarging, general manipulation of the camera occasionally needs special care, especially where precision instruments are concerned, and processing technique throughout is much too critical for young beginners.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Cameras with automatically-coupled exposure meters might yield a higher percentage of satisfactory results, but with such equipment the user does not obtain the valuable experience and knowledge of the basic principles of photography gained by using simple, manually-operated eqiupment.

As the young photographer advances he will need to decide on equipment to suit his aspirations; he may require a technical camera, or a 35 mm., or possibly a single-lens reflex, together with accessories, interchangeable lenses, etc.

Choosing Subjects. Young people need guidance in choice of subjects. Their natural tendency is to snap off the camera on things which seem exciting and novel to them, such as racing cars, aeroplanes and other moving objects. Not only are simple cameras unsuitable for such work even in expert hands; such subjects will lose all interest as the photographer grows up. School children should on the contrary be taught to find their subjects among the incidents of their everyday lives. These may not seem worth recording at the time, but the photographs will appreciate in value as the years go by.

They will find plenty of material inside and outside the classroom and many interesting records to make of the various activities of their classmates and themselves. In particular they should be encouraged to tackle interiors and thus learn how to estimate and use brief time exposures.

Any temptation to use flash as a short cut to correct exposure should be resisted until the basic principles of exposure calculating in daylight are understood.

Young photographers can obtain much instruction and encouragement from studying good photographic work. This should take the form of actual prints, not merely half-tone reproductions, good though the latter may be. They should also be encouraged to follow the progress of their contemporaries studying the other graphic arts. In this way they will learn the essential unity of all art. If they have these opportunities of study, schoolchildren will soon grasp the easier conceptions of good composition and the need to avoid unbalanced arrangements, competing interests and distracting backgrounds.

A pair of L-shaped guides is a most useful tool for instruction in trimming to improve composition.

Darkroom Work. Any small room which can be effectively darkened is adequate for loading tanks and cassettes, but for proper instruction in darkroom technique a good-sized room is needed.

It should have ventilation that is unaffected when doors and windows are sealed, also electricity, water and drainage.

Instruction in processing should begin with contact printing in a box-type printer. After that the pupils can tackle film developing (with ready made-up solutions or powders); and next enlarging to one fixed size, e.g., postcard. Film developing can be carried out in one of the many excellent developing tanks; pupils should practise loading the tank with an unwanted film until they can handle the apparatus in total darkness. It is wise to use a commercially made developer with the appropriate time and temperature tables; those who wish to make up solutions from their own formulae should first experiment with developers for prints or lantern slides, where the developing process can be visually inspected.

Scrupulous cleanliness should be insisted on, and the need for avoiding contamination of one solution by another explained and demonstrated. The children should be taught to use print paddles and tweezers as much as possible and to avoid immersing their fingers in solutions. Failure to do so may result in irritation or poisoning among those with sensitive skins.

In the darkroom special care is needed to guard against electric shocks and short circuits, as these may have serious consequences. All electrical equipment should be earthed and there should be proper fuses and an accessible master switch. On no account should any switch or plug be so placed as to be within reach of anyone standing beside a water pipe. The water supply should have a stop cock. A fire extinguisher is an essential item.

Apparatus. There are many items of photographic equipment which can be made up by the handyman and will give as good service as those in the shops at a fraction of the cost. Every encouragement should be given for their construction. They include: albums, camera cases, darkroom lamps, enlargers, filter holders, flash-guns, lens-hoods, picture frames, tripods and weights and measures.

School children should be taught from the outset to take special care of their equipment. As most things will inevitably get dropped sooner or later, specially fragile items such as cameras, liquid measures and dishes should be carefully chosen with this in mind. The cameras themselves should be of diecast metal rather than thin sheet metal or plastic. They should always be kept in a stout case; this need not be expensive, but can be home-made in wood. Dishes should be unbreakable and liquid measures of transparent plastic.

Colour Photography. There are many applications for colour photography in school, and

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

the filmstrip or slide projectors with which many schools are nowadays equipped provide an admirable means of displaying colour photographs taken by staff or pupils.

The most common projector size is 2 × 2 ins. so transparencies should preferably be on 35 mm. film or be of the superslide size (12 square exposures on size 127 film). Reversal film yields a direct positive and is the most economical means of obtaining a slide for projection; projected slides also usually give the most brilliant and faithful colour rendering. If duplicate colour slides and/or paper prints are required, the exposure is best made on negative film.

Projectors are designed for either 3¼ × 3¼ ins., 2¾ × 2¾ ins. or 2 × 2 ins. slides, or for film strips in the 35 mm. (full or half frame size). Adapters are available to enable the smaller gauge pictures to be projected in the larger projectors.

As exposure in colour photography is much more critical than in monochrome, those about to embark on it for the first time should learn how to use an exposure meter.

Record Photography. The teacher will find the camera an unrivalled tool for recording school activities of all kinds. A roll film camera with focusing lens of *f* 4·5 aperture or larger will give good results for most purposes. The miniature camera for 35 mm. film, with *f* 3·5 or larger aperture lens, is the ideal instrument, provided that the user avoids camera shake and takes special care in handling and processing films. With a miniature it is often possible to take classroom interiors without special lighting at instantaneous shutter speeds and with sufficient depth of field. For good quality interior work it is advisable to use a technical camera on a tripod, and to have a selection of lenses at hand, especially a wide-angle one. Portable tungsten lighting and flash equipment are valuable though not essential.

Examples of school record work are: staff; pupils—new entrants, leavers, houses, prefects; events—sport, excursions, dramatics, exhibitions of pupils' work: specimens of work in art, crafts, needlework, cookery, etc.

Commercial Photography. According to the subject, the equipment needed for commercial photography in schools varies very considerably. Groups of the whole school usually call for a rotating type panoramic camera. This work is highly specialized and is mainly in the hands of a few firms who possess the necessary apparatus and experienced operators.

Smaller groups, such as teams, classes and houses are best taken with a plate camera if large prints are required for mounting and framing. But if enlargements up to 6½ × 8½ ins. are adequate, smaller negatives, including the miniature size, can be used.

The school group photographer must be prepared to work under unfavourable conditions and in limited time. As conditions cannot always be predicted, it is an advantage to have lenses of different focal length available. To keep exposures short, flash equipment is often essential, and at least one extension flash unit will be needed.

Permission to work on school premises can in most cases be granted by principals, who will expect a copy of each group taken. Some teachers allow individual portrait work on their premises.

To obviate the long delays which are common on school orders, and fatal to interest and good business, it is most desirable to deliver finished prints within one week of taking. As an alternative to the usual procedure whereby proofs are first submitted, then orders taken, some workers make an advance estimate of the demand, and aim to produce a number of finished prints in the shortest possible time, supplying them on a sale or return basis.

If a large number of individual portraits are required, and first quality is not essential, it is possible to photograph two or three sitters at a time with a miniature camera against an improvised background.

All the negatives can then be printed and the results supplied on sale or return. The cost of material would in this case be a minor factor.

Interesting film strips can sometimes be prepared by re-photographing groups on 35 mm. film and making positives by reversal or contact printing. M.K.K.

SCHULZE, JOHANN HEINRICH, 1687–1744. German chemist and natural philosopher. In 1725, discovered that light, though not heat, could darken a solution of chalk moistened with silver nitrate; in this way he produced impermanent contact copies from stencils. Biography by J. M. Eder (Vienna 1907).

SCHUMANN PLATE. Photographic plate containing an emulsion with very little gelatin so that the silver halide grains actually protrude above the emulsion surface. Used by V. Schumann for photography in the far ultraviolet region (below 2,300 A) where the ultraviolet absorption of gelatin would make photography with a normal type of material impossible.

The emulsion of such plates is exceptionally sensitive to mechanical abrasion.

SCHWARZSCHILD, KARL, 1873–1916. German astronomer. Formulated the deviation from the Bunsen-Roscoe reciprocity law in the case of densities obtained by intermittent exposures (Schwarzschild effect, 1899–1900). His assistant E. Kron gave this theory of density a stricter mathematical formulation in 1913.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

SCHWARZSCHILD'S LAW. Law formulated by K. Schwarzschild which states that the exposure effect on a photographic emulsion is proportional to $I \times t^p$, where I is the intensity of the exposing light, t, the exposure time, and p, a constant. This is an attempt to formulate reciprocity failure quantitatively, but p is constant only over small ranges.

SCIENCE AND PHOTOGRAPHY

Scientific research is based on observations. Observations lead to the establishment of facts. Facts are grouped together to form theories or hypotheses and hypotheses are tested by further observations.

While observations can be made by means of any of the senses, the use of the sense of sight for this purpose is overwhelming. Whether it be the reading of the scale of a meter, the graduations on a burette or the change of colour of an indicator, the sense of sight alone is employed. It is true that the sense of smell is occasionally used to detect the presence of a chemical substance, the sense of hearing is sometimes useful, and touch plays an important but usually subsidiary part in many kinds of work, but no one would dispute the supreme position of the sense of sight in making scientific observations.

The human eye is a very remarkable instrument consisting as it does of a lens of variable focal length, an iris diaphragm automatically responding to the lighting conditions and a retina capable of presenting the brain with all the information necessary to analyse an image in colour. The retina is also capable of varying its sensitivity over quite a remarkable range.

The photographic camera is an instrument similar to the eye, comprising a lens, an iris diaphragm and a "retina" consisting of the photo-sensitive surface. Sharp focus is achieved in the camera by altering the position of the lens instead of its focal length; the iris is usually manually operated, but in the many automatic cameras now available a photocell determines the iris opening in accordance with the light reflected from the scene; and the photo-sensitive surface can vary in sensitivity also over a very wide range. It is not, however, safe to push the analogy too far; for instance the retina of the eye is responsive to the brightness of the subject viewed, whereas the photo-sensitive surface is responsive to the brightness multiplied by the time of exposure. Thus, if an object is not bright enough to be seen, it is of no help to stare at it for a long time, but an object not bright enough to be recorded on a film in 1 second may be recorded in all its detail by an exposure of 100 seconds. This is a fundamental and sometimes valuable difference as will be seen later.

In view of the use of the sense of sight in making observations it is hardly surprising that a process which is sensitive to light is of great value in research. Furthermore, since the photographic process in conjunction with a lens produces an instrument which has many points of similarity with the human eye, the camera may produce a result of a familiar and therefore easily interpretable form. In fact the camera can be looked upon as an extension of or aid to the eye in much the same way as a telescope can be so regarded.

The photographic process provides an extension of the faculties of the eye, for example by virtue of its sensitivity to ultra-violet light and X-rays; and it helps the eye by providing an image, similar to that produced by the eye, of an event which may be invisible to the eye or transitory.

The camera can never be a substitute for the eye since the eye will always be needed to interpret the result, but certain features of the photographic process make it a most valuable tool in research and an examination of the most important of these features will illustrate why photography is used in such a wide range of fields of work.

Permanent Records. Perhaps the most important feature of photography is its ability to produce a permanent two-dimensional record of an event. Though in most cases the eye can observe the same event it is often not possible for the eye to take in all the important features and it is difficult for it to make rapid and accurate measurements of the relative positions of objects.

Perhaps the commonest example of this is spectroscopy, the measurement of the wavelengths of the light emitted by the excited atoms or molecules of a substance. It is true that the eye can see the spectral lines as produced by a spectroscope, at least in the range of the visible spectrum; and by the use of a suitable graticule in the optical system the relative positions can be measured. But this can become very laborious, and quantitative analysis which depends on the relative amounts of energy of the lines would be well-nigh impossible visually.

In research on the behaviour of aircraft it is frequently necessary to employ a very large number of instruments in the aircraft and determine how their readings vary during certain flight manœuvres. It would in most cases be quite impossible to write down the

readings by direct observation at sufficiently frequent intervals to be of use. Photography, however, produces a permanent record for examination at leisure and the interval between photographs can be made as short as is necessary for the purpose in hand.

Straightforward photography from the air has been of great value in archaeological research. Air photographs taken under suitable conditions can reveal features of ancient settlements which are often quite invisible on the ground. In this way not only are new sites discovered, but the ground plans of known sites which can be obtained in detail and to scale are invaluable in subsequent excavation.

Spectral Sensitivity. The permanent photographic record which can be studied at leisure and in detail is of value in nearly all applications of photography and is often used in conjunction with other features. For example, spectrography usually makes use of the extended range of wavelengths to which the photographic process is sensitive. To confine spectrography to the visible spectrum would be a very serious limitation. In fact the ultra-violet region is of much greater general importance.

Photography is commonly used for ultra-violet spectrography, a technique of immense value for the quantitative analysis of metal alloys in which very small quantities of a metal may be present.

The photographic material can be made sensitive to all wavelengths of electro-magnetic radiation from the infra-red to γ-rays. The sensitivity, of course, varies a good deal over this range. In some regions the absorption is so high that only the surface layer of grains is affected, so producing a low density (ultra-violet), and in other regions the absorption is so low that long exposures are usually necessary to produce an adequate density (γ-rays).

In addition to sensitivity to this very wide range the photo-sensitive surface is affected by bombardment with charged particles such as electrons and this fact is made use of in the electron microscope. The electron microscope is similar to the optical microscope except that electrons are used in place of light (this, of course, necessitates the use of magnetic or electro-static lenses instead of glass). It has the advantage that a much greater resolving power is possible owing to the effectively very short wavelength of the electrons. The photographic material is sensitive to high speed electrons and is used to record the image in much the same way as it does in the optical photomicrograph. The electron microscope is a very valuable tool in many branches of science. By its use magnifications of more than 100 times those obtainable with the visual microscope can be achieved. Though the electron image can be made visible by means of a fluorescent screen, photography plays an essential part in recording the image by direct effect of the electrons.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Integration of Light. Apart from colour the eye distinguishes objects by virtue of differences in brightness. The effect on the retina is a function of the brightness of the object and not of the time for which it is observed. The effect on the photo-sensitive surface in the camera is a function of both the brightness of the object and the time during which it is exposed.

If the brightness of an object is gradually reduced there comes a time when the eye can no longer see the object in spite of the enormous increase in sensitivity which takes place in the retina on dark adaptation. With the photo-sensitive material, however, reduction in brightness can be approximately compensated by an increase in exposure time and in this way details can be recorded that are invisible to the eye by reason of their very low brightness.

The adjustment of the exposure to compensate for the brightness of the subject is commonly used in photography throughout nearly all applications from the snapshot upwards. However, in the field of astronomy it has been carried to such an extreme that images of stars and nebulae formed by large telescopes have been recorded photographically by means of extremely long exposures where the amount of light reaching the earth is so small that the stars or nebulae from which it originates cannot be seen by the eye even aided by the same telescope. Furthermore, the light from these bodies can be spread into a spectrum and recorded photographically to yield, for example, information on the velocity with which the distant nebulae appear to be receding from the earth.

At the other extreme, photography can record events in an extremely short time if the intensity of light is sufficient. This may be utilized to record events which are of extremely short duration such as lightning strokes, traces on the face of cathode ray tubes, etc. Similarly, fast moving events may be "frozen" by illuminating them with a pulse of light of short duration or by using a shutter capable of yielding a very short exposure (Kerr shutter). Much valuable work has been done in the sphere of ballistics using this feature. This high speed photography, as it is generally called, could equally well be regarded as making use of the ability of photography to record an event which cannot be properly observed by the eye because of the limited time during which it is available for study.

Inanimate Observation. One of the most valuable features of the photographic process is its ability to produce a permanent record of what the camera sees. This makes the camera superior to a human observer for many purposes: a photograph can record practically all aspects of a subject for study at leisure, whereas we can directly observe only a very limited aspect, especially if the scene is changing at all

rapidly. This facility enters into nearly all uses of photography, the camera becoming a sort of inanimate observer with an infallible memory.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The camera can also be sent where it is difficult, dangerous or inconvenient to send an observer, but here too the advantage of a full record to study at leisure is usually of primary importance. Cameras are used in rocket probes and artificial satellites, but only of course where recovery of a capsule containing the camera is intended. If the probe is expendable, such as the first Moon and Mars shots, television cameras relay pictures by a radio link to the Earth. These pictures, however, usually end up as a photograph of a television screen.

Sensitivity to Sub-atomic Particles. The first method used to reveal the actual tracks of particles such as electrons, protons, etc., was the so-called cloud chamber. This consists of a glass-sided chamber saturated with water vapour and capable of being suddenly expanded in volume so that the water vapour becomes super-saturated. If then a charged particle passes through the chamber it ionizes the gas and droplets of water are formed along the track. The track persists for a short time before breaking up and photography plays an essential part in recording the tracks during their brief life.

More convenient for some purposes is the use of the sensitive emulsion itself for recording the tracks direct.

Photo-sensitive materials are sensitive to the passage of charged atomic and nuclear particles as well as to a wide range of electromagnetic radiations. Such charged particles act in the same way as light—they lose energy in passing through the grains and release electrons after which latent image formation follows normal lines.

Any rapidly moving charged particle, an electron, proton, alpha particle or a large ionized atomic nucleus will affect a grain if it passes through a part of it. In this way the path the particle takes is revealed by a succession of developed grains rather like a string of beads. Moreover, the characteristics which affect the appearance of the track depend on the charge, mass and velocity of the particle and it is possible to determine these characteristics of a particle from measurements made on the track it produces.

Special photo-sensitive materials for this purpose are now manufactured and are available in various forms to suit the experiment in hand. They are characterized by the large number of grains per unit volume to minimize the space between the grains in a track, and great thickness to increase the length of track or chance of obtaining a long track.

Combining the characteristics of the photographic material with the ability to record for long periods without fatigue in places not easily accessible to the human observer, much work has been done in the investigation of the nature of cosmic rays.

As alternative methods of recording tracks, such as the cloud chamber, involve heavy equipment, photographic material is being sent up in balloons for recording cosmic ray phenomena at great altitudes. "Stacks" of emulsion weighing up to a hundredweight are used for this purpose. They are composed of many layers of gelatin emulsion with no separate support, clamped together and so marked that they can be taken apart after exposure and developed separately, yet tracks passing across boundaries can be followed and an accurate measurement of the length and angle of the track made. These stacks may be exposed for some hours at great altitudes before returning to earth by parachute. This enables information to be obtained on the nature and energy of the primary rays as they reach the earth's atmosphere and before they suffer the degeneration which takes place by the time they reach sea level and the normal terrestrial laboratory. These primary particles are endowed with more energy than it has been possible so far to confer on any particle in the terrestrial laboratory, though the gap is closing, and so events which are caused by such energetic particles can only be explored at these altitudes.

The technique of autoradiography is another illustration of the use of the photographic sensitive material in its own right. The availability of artificially produced radioactive isotopes has led to their use as tracer elements in all kinds of research. In some techniques the radioisotope of an element, say iodine, is introduced into the body where it is treated in just the same way as normal iodine and some finds its way to the thyroid gland. If then a section of the thyroid is cut and mounted in very close proximity to a photographic layer, the electrons emitted by the radioactive iodine affect the emulsion and produce a latent image. On development and examination with the thyroid section under the microscope the exact location of the iodine is clearly revealed. This technique is comparatively new and is proving a valuable tool, particularly in medical and metallurgical research.

Further Scope and Outlook. In the short space available it is not possible to do more than indicate the reasons why photography is such a useful tool in scientific research.

The applications are so widespread that it would need a volume to do real justice to the subject. There are many researches in which photography has been used for convenience, elegance or just preference. There are many in which photography has been the best available tool for the purpose. There are researches in which there appears to be no alternative to the use of photography, but the ingenuity of man is such that this might be difficult to maintain. However, photography is no longer used

solely to record portraits and other pictorial matter. Its value in radiography is quite well known, but it is not always realized that the photographic process has materially helped to bring us to the state of knowledge we have reached to-day, and has helped to develop many techniques which in turn contribute to the higher and still growing standard of living we now enjoy.

SCRATCH-PROOFING. Normal hardeners are generally used to prevent an emulsion being damaged while it is still wet—although in many cases the hardening effect will remain.

The emulsion surface, however, can be made specially tough and resistant to injury when dry, by treating it with a tannic acid hardener. This treatment is used to make films more or less scratch-proof. The effect is only apparent when the film has been dried. Films can be hardened in this way straight after washing, or, if they have been dried, after resoaking for 10–20 minutes. A formula for a scratch-proofing hardener is:

Tannic acid	1½ ounces	30 grams
Formalin solution (40 per cent formaldehyde)	4 ounces	100 c.cm.
Water to make	40 ounces	1,000 c.cm.

The tannic acid is dissolved in almost boiling water, and the formalin is added when the solution is almost cold.

Films to be scratch-proofed are immersed in a mixture of 1 part of the hardener solution and 14 parts water for about 5–10 minutes, and afterwards washed for a further 10 minutes.

SCREEN (HALF-TONE). Regular mesh consisting of sets of parallel lines normally ruled at right angles, used in blockmaking to break up a photographic or similar continuous tone original when photographing it on to the metal.

See also: *Half-tone screen; Photomechanical reproduction.*

SCREENING (HALF-TONE). Photography of a continuous-tone original through a special screen to convert the lighter and darker tones into areas of smaller or larger dots but of uniform blackness. This is the only way in which tone values can be reproduced in most mechanical printing processes.

See also: *Half-tone screen.*

SCREEN PLATE. Special type of plate used in colour photography consisting of a panchromatic emulsion covered with a "screen" of finely distributed colour filter elements. When processed by reversal and viewed as a transparency, the original colours are seen reproduced in the image by additive colour synthesis.

Some colour films are manufactured on the same principle. The main objections to the system are the serious loss of light and the texture of the colour filter elements which becomes visible on enlargement.

See also: *Colour materials; Colour photography history; Colour synthesis.*

SCREENS FOR PROJECTION

A good screen is essential to enable the best results to be obtained from any cine or still projector. Many different types of screen are made, some suitable for the home, some for the lecture hall or classroom. For front projection an opaque screen is necessary; for rear or oblique projection a translucent one. Opaque screens are available in different surfaces and translucent screens are constructed of different materials. In both cases the best choice will depend on circumstances.

Opaque screens can be considered under two headings, those that are portable and those that are fixtures.

Portable Screens. These are used by the amateur for showing cine films or colour slides in the home. They are also useful to the lecturer who travels from hall to hall, and is obliged to take a screen with him, and are convenient in any classroom or lecture hall where it is not possible to leave a screen in a fixed position.

Most portable screens are made to rest on a suitable table, ledge, or support or stand on the floor by means of a tripod. An essential feature is that they must fold down to a convenient size for storage and portability.

The simplest and cheapest type of screen meeting these requirements has a wooden platform, with feet screwed on underneath. The bottom edge of the fabric is secured to this platform, while the top is fixed to a roller which is supported by side stretchers hinged to each end of the platform. To close the screen, the arms are detached from the roller and folded inwards. The screen is wound round the roller, and the feet turned sideways.

A more elaborate screen is the self-erecting type. It is quicker and easier to erect and close, and less likely to cause wear or damage to the screen fabric. Here the fabric is wound automatically round a spring roller, which is secured at the ends, just above the platform. The screen is erected by lifting the top rail until the fabric is fully extended. Joining this rail to the platform are two arms, hinged and sprung at the centre, so that once fully extended

Digitized by Arya Samaj Foundation Chennai and eGangotri Digital Preservation Foundation, Chandigarh

they remain upright. To close the screen, a cord is pulled, or a lever depressed, causing the sidearms to fold inwards and the screen is gently lowered to the platform. Sometimes such screens are built into a box for protection.

Another useful screen also uses a spring-wound roller, which is built into a metal tube. The tube has a narrow slot through which the screen material is pulled. The top bar of the screen is secured to a metal rod which is extended to the required height and locked into position. This rod is hinged to the centre of the tube and folds away when the screen is closed.

Tripod screens, which provide their own support, are a variation of the last type. The tubular body is hinged to an extending bar which has a folding tripod foot. When closed, the tube folds against the extending bar. To erect, the feet are unfolded and the tube placed in a horizontal position. The top of the screen is hooked on the extending bar which is raised up as required.

Non-Portable Screens. A rigid screen is all that is required when it is to be used in a permanent position and does not need to be moved out of the way. In small sizes this may consist of a canvas screen stretched over a wooden framework. In large sizes the fabric is eyeletted and laced to a stout wood or metal framework to keep it perfectly taut and free from wrinkles.

A roller screen can be hung from a fixed position and lifted out of the way when not required. The screen hangs from a top batten, the bottom being attached to a heavy steel or wooden roller which pulls the surface flat. By operating a cord and pulley, the fabric is wound round the roller as it is raised.

Wall type tubular screens consist of a tube and spring-loaded roller fixed to the wall or ceiling while the screen is drawn down into position.

In some makes the bottom of the screen must be held down while the screen is in use, whereas in others a ratchet and pawl are fitted, making this unnecessary.

Screen Surfaces. There are three types of screen surfaces in common use: glass bead, matt white and lenticular.

A glass beaded screen is made by impregnating beads of crystal glass in the surface of the canvas. Such a screen is very directional, giving a brilliant image over an area approximately 15° from the centre. Beyond that angle, the illumination falls off appreciably, though not below that of a matt white screen until the angle is about 30°.

A glass beaded screen is therefore most effective in a long narrow room. For use at close range the beads should be as small as possible, otherwise the image will appear grainy. It is not advisable to allow a beaded screen to remain exposed to strong daylight for long periods, as it may turn yellow and lose efficiency.

SCREEN SURFACES. The audience should be a minimum distance of two screen widths away from the screen S. The area A is therefore not suitable for viewing with any screen. B, area in which matt white or lenticular screens give best results. C, area in which matt white and beaded screens give equal image brilliance. D, area of maximum brilliance with beaded screen.

Plastic beaded screens are a cheaper version of the glass type. They consist of a layer of plastic applied on a white surface and moulded (by special rollers during manufacture) into a fine bead pattern. These screens are not as efficient as glass beaded screens, and are halfway between the latter and matt white screens in effectiveness.

Silver surface screens used to be popular at one time, but have now largely gone out of fashion. This is because they are less suitable with colour film than a matt white or beaded screen. The silver surface is usually aluminium or other metal paint applied on fabric. The durability of such a screen, especially when rolled and unrolled frequently, is not very high and the surface eventually starts to crack.

The image on a silver surface is less brilliant than on a beaded screen when viewed from a central position, but is fairly even over an angle of approximately 30° from the centre. Beyond that the brilliance rapidly decreases.

Matt white screens are the most diffused form of opaque screen available. They are less costly than beaded screens, and are obtainable seamless in fairly large sizes. They can be viewed from quite a wide angle without any appreciable falling off in illumination, and are therefore favoured for wide rooms and lecture halls.

Lenticular screens are made with a series of vertical ridges and hollows over the surface. Sometimes, there are horizontal ridges as well. Lenticular screens are difficult to mass-produce, as the ridges must be of the right height and curvature, with accurate spacing. They act in much the same way as a number of very small

lenses, which is the reason for their name. Lenticular screens are usually painted silver, which gives greater reflection than matt white over a reasonably wide viewing angle.

Perforated screens are used in public cinemas where a large loudspeaker is placed behind the screen. Without perforations the sound would be muffled and lose quality. Naturally, some loss of light is caused by using a perforated screen.

Screen Materials. Opaque screens are usually made of canvas, plastic or linen. Plastic screens are apt to hang unevenly unless secured on all sides, particularly in the case of large sizes. Linen or calico screens are less opaque than canvas screens and consequently give a less brilliant image.

Screen Formats. Screens to be used for cine films or film strips are usually made with an aspect ratio—i.e., width : height—of 3 : 2 and are hung horizontally. In public cinemas the wide screen is now the vogue, but there is no indication yet that screens of this proportion will be used extensively for amateur films although they are available.

A square screen is usually necessary for slides, as pictures may be upright or horizontal.

Daylight Screens. For projection in normally lit rooms, translucent screens probably give the best results. The material may be either white or black plastic, or a special dressed linen or cotton. Plastic screens give a brilliant picture when seen from the centre, but are very directional. Viewed from a wide angle, the image may be almost indiscernible, though quite satisfactory when seen from the centre.

The projector can be placed directly behind a translucent screen, in which case the slide or film will need to be loaded the reverse way to the usual. Special screen units are obtainable in which the projector is placed to the side of the screen, the image being projected on the screen via a mirror.

This enables the operator to remain in the view of the audience, and with this method the film or slide is loaded in the same way as for front projection. It is also useful when the projection distance would otherwise be limited.

Translucent screens of dressed linen or cotton absorb more light than the plastic ones, but are more diffuse, enabling them to be viewed from a reasonably wide angle. As plastic screens are only normally available in fairly small sizes, the dressed fabric type is used when a large size is necessary.

Special back-projection screens exist with a high transmission but low reflection of light. In such screens the light falling on the surface from the front is not reflected back to the viewer to any appreciable extent. Hence stray light does not degrade the image and the screen is specially suitable for daylight projection.

An ordinary opaque screen with a silver or beaded surface can be used satisfactorily in a normally lit room if the size of the screen is restricted and the screen hooded and shielded from extraneous light. Some screens are sold complete with hood and side flaps for this purpose.

Ultra Directional Screens. A special screen type is the ultra directional beaded screen, used for producing studio backgrounds by front projection. The screen surface consists of highly refracting glass beads set in an opaque surface. The beads throw back the light only along the direction at which it reaches them. A projected image is thus visible virtually only within one or two degrees of the axis of the projected beam and is there very brilliant. The screen efficiency is around eight to ten times as great as with a normal beaded screen. From any other direction the image is virtually invisible. By adjusting the intensity of the projection beam it is possible to get a picture of normal brightness as seen in the projection axis, and ensure that any objects in front of the screen scatter the light sufficiently to leave no image visible on themselves.

When used for creating backgrounds by front projection methods, a beam splitter system ensures that the camera lens axis and the projection beam are coincident; the camera then sees the background image, but only on the screen surfaces and not on foreground objects.

Stereo Screens. Matt white or beaded screens are unsuitable for stereo projection systems

SCREEN TYPES. Left: *Portable screen on tubular stand with tripod support; easily transported and quickly erected.* Top right: *Self-erecting screen; supports held by spring when raised.* Centre right: *Framework for home-made rigid screen, made of 2 × ¾ ins. battens with plywood stiffening plates.* Bottom right: *Roller screen fixed to wall; pulled down from case to hangdown as shown by broken line.*

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

based on polarization, as they depolarize the light. A metallic or aluminized surface is necessary for front stereo projection, and in practice a screen with a silver surface is generally satisfactory. For stereoscopic rear projection a very finely ground glass screen is sometimes employed and a translucent plastic screen is also suitable. Various forms of this exist.

If the projection system employs the split beam method, the screen should be upright to suit the image.

SCRIPT. Shooting plan of a movie film, prepared from the story treatment. The script breaks down the entire action of the film from beginning to end into single shots together with detailed descriptions of the scenes, settings, camera positions, actors and shot durations—as well as other relevant information. Scripting is an essential part of the preparation of the film, since it enables the director to plan the required sets and properties needed, as well as the technical staff and actors for every scene. For the actual shooting the script is usually broken down into groups of shots using the same scenery or setting; these shots are then filmed together to save time and expense. A film is thus very rarely made in the original order of scripted scenes, but put together again afterwards by the editor. Scripts are sometimes also prepared in a similar way for features made up of still photographs, e.g. for a magazine story where the pictures required can be pre-planned.

SCULPTURE. The photography of sculpture calls for as great, if not greater, skill in the use of lighting and technique as most other branches of photography.

Most photographers have seen portraits with deep shadows in their eye sockets, or one side of the face a glaring white from over-strong backlighting; or distorted features as the result of using a lens of too short focus; or one feature over-emphasized to the detriment of the rest of the face because of a bad viewpoint.

Such mistaken technique and lighting would give as completely false an idea of a piece of sculpture as they do of a human face.

When photographing sculpture the aim of the photographer should be not only to give a correct record of its form, but also to interpret it in such a way as to lift the photograph from the "record" level and place it on the level of pictorial photography. This needs the right lighting, angle of view and background.

Equipment. A suitable camera is the field type with a triple bellows extension, interchangeable lens panel, and a ground glass screen for critical focusing. The single-lens reflex roll film camera which has a focusing screen and interchangeable lenses is also suitable.

The modern miniature camera may also be used very successfully. Its rangefinder and reflex focusing attachments allow for fine examination of focus, and interchangeable lenses and extension tubes permit close-up and long-range photographs. It is especially useful in places where heavier or more cumbersome cameras cannot be taken. A helpful lens to use would be a 13·5 cm. or 20 cm. These prevent the camera being employed too near the subject, which would result in distortion of form.

A firm tripod is necessary to eliminate any possible movement during the long exposures customary in this field. The tripod should also have a pan and tilt head. Reversible legs, spiked one end for outdoor work and rubber-tipped the other end for indoor work, are also useful.

Roll film cameras should have a film with an emulsion of fairly soft gradation—e.g. a fast panchromatic type. For plate cameras, a soft-gradation panchromatic plate is suitable. Miniature negatives require a great degree of enlargement and therefore a thin-coated film of low sensitivity should be used. This has very fine grain and gives a better definition than a double-coated film.

In the Studio. When photographing sculpture in the studio, the photographer has the choice of background, angle and lighting under his direct control. If, when the photograph is printed, any of these is at fault, he can duplicate the same conditions and eliminate the fault.

A spotlight gives hard lighting, casting sharp shadows, and is best for sculpture finished in a rough texture. The beam cast is easier to control than with other types of light. A floodlight, having a larger sized light source than a spotlight, gives a softer effect. Sculpture having a delicate form—children's faces for example—is better rendered with a floodlight. The hard light of the spotlight divides the highlight and shadow areas too sharply, while the soft fringe of the floodlight merges one smoothly into the other. Still softer lighting can be obtained if the floodlight is diffused. Overcast daylight has still greater diffusion.

The secondary light or fill-in calls for a fine degree of judgement. If it is too strong, it overpowers the main light; if it is too weak, the shadow areas lack form. The direction of this light is also important.

Backlighting, if used with restraint, can give sculpture an edge, which can add considerably to the effects of both modelling and texture.

Any shading of tone on the background is best done with lighting. On a plain, neutral

CC-0. Agrasen Digital Preservation Foundation, Chandigarh

background it is possible to merge gradually from black to white, or to merge gradually from a light tone on one side to a dark tone on the other. This shading can counterbalance the lighting on the sculpture: the light side can be set against the dark side of the background, and the shadowed side against the light part of the background. By arranging the lighting in this way the subject stands well away from the background and the whole outline is thrown in relief without the need for backlighting.

A patterned background is likely to detract from the sculpture, unless it is made part of the composition.

As a very general rule the angle of view should be approximately that from which the sculptor intended his work to be viewed. But very often, by choosing a high or low angle, the pictorial effect can be increased. Having a low angle gives a feeling of strength and height to a subject. A high angle has the opposite effect, which is useful if the height of a large statue needs to be minimized.

As sculpture is three-dimensional, a better idea of its full shape can be conveyed if separate photographs are taken of two or three sides of the subject. This also helps to give a better impression of its dimensions.

Outdoors. Good opportunities for photographing sculpture can be found in the outdoor exhibitions that many local authorities arrange. And even familiar statues, seen by everyone in their home towns, provide an exercise for the photographer's ingenuity in finding an angle that gives them fresh interest.

Unlike studio photography, the factors of background, angle and lighting are not under the photographer's control. When photographing out of doors, the background seen from a particular viewpoint depends on the position of the subject, and the photographer cannot always get the angle he wants. Again the right lighting conditions are generally a matter of luck or patient waiting.

Spring and autumn are probably the best seasons for photographing outdoor sculpture, and during the summer months the mornings and evenings are most suitable. The sunlight then is not too harsh and does not come from too high an angle.

In open places the sky is the simplest background. Some measure of control can be had in the choice of filters used. The deep blue of the sky on a summer's day can be controlled from a light tone (light yellow filter) to a dark tone (orange or red filter) using a panchromatic film. Light statues found near tall buildings can be taken with the dark shadowed side of a building as a background, whereas dark statues are best taken against a light background.

On large statues in particular a good photograph can often be had from one detail, a hand or a foot, or from a small group of details that together make a tight, well knit composition. It is useful to carry a large white folded card to act as a light reflector when photographing details, to balance the lighting of the highlight and shadow areas.

Very large monuments may have an architectural setting which needs a camera with a rising front lens panel so that all vertical lines can be made upright in the photograph. If a roll film camera is used and tilted up, the distortion of the verticals must be corrected on the enlarger. Correcting in this way may introduce some distortion but it is not likely to be very noticeable.

In Churches. Sculpture in churches provides another rich source of subjects. Fonts, effigies, decorations of roof bosses, and bas-reliefs offer an endless choice.

A rigid tripod is essential for taking photographs in a church; the use of a weak tripod may result in camera shake during long exposures. The roll film or miniature camera is quite adequate when taking photographs of subjects which have no verticals to be corrected, but, if there are verticals to correct, then the camera possessing the rise and swing movements is preferable. A telephoto lens is useful in obtaining close-ups of subjects out of reach of the normal focus lens, such as gargoyles and details in vaulted roofs, coats of arms, and the like.

Unless the church is well lit the photographer may have to provide his own lighting with portable equipment. Before attempting any photography the vicar's permission should be sought and, if lights are needed, the voltage of the electricity will have to be checked. Flash-lighting is convenient, but the number of bulbs needed for good modelling is apt to be rather expensive. If a single flash is used on the camera, the lighting will be flat and will not show the form of the sculpture; if it is used away from the camera, the lighting will be too hard, unless a fill-in flash is used. Electronic flashes, fired from a succession of points during a time exposure, are an effective way out.

When daylight can be used, which is usually better than flash, the ideal outside lighting conditions are those on a bright day with no strong sunlight. The diffused lighting from such conditions is often preferable to strong sunlight, which would need a bright fill-in light to illuminate the shadow detail. In a church where the light comes from many directions, the lighting is apt to be very flat. A floodlight in this case could be used as the main light source, and the natural light act as a fill-in. In winter months the daylight intensity may change rapidly. An exposure meter should be used constantly to check this.

If a subject has to be photographed in very poor light, it will sometimes be found on developing the negative that, although the correct exposure was given according to the meter reading, it is still badly under-exposed. This is due to reciprocity failure, when the intensity of light reaching the emulsion is too

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

low to respond to the reciprocity law. In such conditions it would be better to use artificial lighting or give a longer exposure.

A photo-electric exposure meter will not usually show a reading at all in a badly lit church and one of the visual extinction type meters is often more useful.

Wood and stone carvings high up or out of reach will need to be photographed with a long focus lens. The long bellows of the field camera are an advantage in this case to give the necessary extension. Wood carvings may need the use of a deep red filter to bring out their details.

SEASCAPE. Any general view, similar to a landscape, in which the sea, waves, or shore scenery is the dominant feature.

SEASIDE. The seaside is one of the best places to take photographs. The light is generally good, and there is such a diversity of subjects that whatever particular ideas the photographer has, he can always find something to take.

Seascapes. If the photographer is a landscape enthusiast, he will find that very much the same technique is needed to make a successful seascape picture. But it is not so easy to grade the tones of the picture to suggest distance, since the sea is of much the same tone all over, getting only a little lighter towards the horizon. First, to give the impression of depth, some large object is needed in the foreground. A medium or deep yellow filter will help to improve the tone rendering of both the sea and the sky. A lens hood is essential for all beach photography, but, even then, beware of light reflected from the water into the lens. If the hood is not deep enough to keep it out, the only thing to do is to wait until the sun is in a different position or until it is obscured by light cloud.

Those who prefer to take close-ups of still-life subjects will find that they abound on the beach. Pebbles, seaweed, patterns left by the tide on the sand, stranded starfish, are all excellent for close-up studies. Often the best way to tackle these subjects is to take them against the light. This not only gives them greater prominence against the background, but reveals their texture much better than flat lighting.

Here again a tripod is generally useful, although it is not always necessary since the light is usually bright enough for a fast shutter speed. But it is essential to focus accurately on the subject, because the lens has very little depth of field at close ranges. A filter is not necessary except when photographing brightly coloured specimens. To get close to subjects on uneven surfaces and slippery rocks it is best to crouch in the way which gives most steadiness.

People. Those who prefer the very lively scenes of holiday-making must be ready for a little more action. As a rule, people on beaches usually do one of two things: they either sleep or they jump about and play games along the sands and in and out of the water. Pictures of people asleep can often be amusing to look at later, and they make easy subjects: it is simply necessary to take an exposure reading, set the camera, focus and expose. But the viewpoint must be carefully chosen to avoid including confusing objects—e.g., beach-bags and clothing and other people—in the background.

People running about need a fast shutter speed. It is often possible to use about 1/300 second with a yellow filter on the lens since the light on the beach is nearly always very bright and the reflection from the sand helps to fill in the shadows. It is wise to use a low viewpoint to get the sky as a background. The best way to shoot is to pre-focus, follow the subject in the viewfinder and release the shutter as soon as the subject is in the right place. People running towards the camera are less likely to be blurred than if they were moving directly across the line of vision, so, even with a camera which has a shutter speed as slow as 1/125 second, it is still possible to take some action pictures provided the subject is not moving across the camera's view. People jumping must be snapped at the "dead point" of the movement—e.g., when they are at the top of their jump and have stopped going up but have not yet started to come down. At this point they are reasonably still.

People swimming, surf riding and generally enjoying themselves in the sea are good seaside subjects. Stand at the water's edge (or even in the water) and keep the camera rather low down. This cuts out fussy background and shows the subjects against the sky. Use a yellow filter and a fast shutter speed to stop movement of both the subject and the water being splashed about. (Take care that none of the splashes fall on the camera.)

Children. Make a tour of open-air entertainments like concert parties and Punch and Judy shows. Where there are children in the audience, concentrate on their faces; they will be much too interested in the show to take any notice of the camera. If pictures of children are wanted, do not forget to watch for incidents around the ice-cream trolleys on the beach or the promenade; pictures of children buying, eating, or wrangling over ices are always popular.

Children form one of the most worth-while subjects that the beach has to offer; they seem to belong to the beach scene as surely as the sand and the water, whether they are occupied in building castles or covering their sleeping parents with sand. They will generally be much too occupied to notice the photographer. So first take an exposure reading and set the focus at a pre-determined distance. Then just walk up and expose before the

CC-0. Agamnigh Digital Preservation Foundation, Chandigarh

subject has time to become aware of the camera.

There are a great many subjects on and around the seashore: interesting people, amusing sights, exciting events, minor tragedies, so it pays to have the camera ready to go into action at a moment's notice.

Boats. Be on the look-out for boats, either drawn up on the shore or riding at their moorings. They are one of the most popular forms of picture material. The best way to take them is to choose a calm day and hire a rowing boat so that a choice of viewpoints can be made. As well as the boats themselves, close-ups of various parts—coils of rope, anchors, blocks—taken with strong side lighting to reveal texture make excellent subjects. Use a shutter speed of about 1/100 second, unless the camera is on a tripod on firm ground to eliminate any risk of shake.

Most seaside resorts have a lifeboat station which is worth visiting. It should be possible to find out when there is to be a practice launch. Take up a position either near the water's edge or close to the ramp and in either case, use a fast shutter speed even though the lifeboat may be coming towards the camera. If the aim is to catch the bow wave as the boat enters the water, there will be no time to alter shutter speed after photographing the boat coming down the ramp. Pre-focus on a spot the same distance away in both pictures. This saves refocusing between exposures.

Care of the Camera. Keep the camera away from the sand and salt water. These two form a most deadly combination for the ruin of a good camera and lens if they come into contact with them.

A small grain of sand can put a shutter out of action and call for an expensive overhaul, while salt water will corrode plating, make screw threads foul and stick, and take the high polish off the surface of a lens.

So take care to avoid splashes falling on the camera and particularly on the lens. A yellow filter placed over the lens will protect it from sand and sea water and will be needed for most shots in any case.

Keep the camera in a case with a lining instead of an ever-ready case and this will help to keep sand out.

If taking photographs in really rough weather, or in a small boat where there is a very real danger of the camera being swamped, obtain a polythene sandwich bag big enough to hold the camera. Keep it in this until it is needed and it will be fully protected. G.S.D.

Book: *Camera Afloat*, by H. S. Newcombe (London)

SECOND-HAND EQUIPMENT

Nowadays most cameras and photographic equipment can be bought second-hand from private owners or photographic dealers and sold to the same people. Such buying and selling is frequently carried on through the classified advertisement columns of photographic magazines. Photographic equipment when intelligently handled suffers less from use than, say, a motor car or a radio set, and it is possible to buy cameras and accessories several years old that are for all practical purposes as good as new. If in good condition, they should also fetch a reasonable price on sale or exchange. At the same time the inexperienced buyer always runs the risk of throwing his money away on a worthless "bargain".

BUYING EQUIPMENT

Some photographic dealers specialize in selling only first rate equipment that they have dismantled and rebuilt, or at least thoroughly inspected, in their own workshops. This equipment carries a guarantee, and the prospective buyer is allowed a week or more in which to try it out.

This is undoubtedly the safest way of buying second-hand photographic equipment, but it naturally costs more—there are no bargains in this market.

The beginner should always protect himself by asking the advice of an expert before buying; the following hints are intended for those who must rely on their own judgement.

Cameras. If you know the make of camera you want to own, get a *Focal Camera Guide* about it if one is published. This will tell you the differences between the various models so that you will be able to recognize an early model from a later one. Remember that one model may be worth twice as much as another of the same make and superficial appearance.

Body. The condition of the plating and covering of the camera body—particularly on sharp edges—will show if the camera has had a lot of use. Burrs on the slots of any of the screw heads are a sure sign that someone lacking in mechanical skill has had the camera to pieces. In that case the camera would probably be dear at any price.

The most important point to watch for in the body of the camera is the rigidity of the lens-mount and erecting mechanism in the working position. The front should open smoothly and click into position positively and without any forceful persuasion. If there is any trace of slackness or wobble anywhere in the erecting or focusing mechanism the camera should be rejected.

Bellows. The bellows of a folding camera should be pulled out to their fullest extent and examined for signs of cracking, wear or repaired places. Even if there are no actual light leaks, the price of the camera should be reduced to cover

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

the cost of new bellows. If everything looks satisfactory, the camera should then be taken into the darkroom and the bellows checked for actual light leaks. Even in apparently sound bellows there may be pinholes that would let enough light through to fog the negative.

To test the bellows, the back of the camera is opened and an electric torch, with the head removed, is inserted. The torch is switched on and the back of the camera covered with a black cloth. With the head of the torch removed, the bulb can be pressed close up to the corners and into the folds of the bellows so as to show up the smallest hole or any thin spots that might give trouble later. It is not a good idea to examine bellows in this way with an ordinary electric light bulb because the heat in such a confined space may scorch the material or turn it brittle.

The leather bellows of large multiple extension cameras can be successfully repaired if they have been accidentally pierced or torn, but if the trouble is due to general wear, patching is never worth while. The bellows of smaller, hand cameras should always be renewed if damaged or worn. New bellows are not expensive, but they should only be fitted by the maker of the camera or by firms specializing in this type of repair.

Viewfinder. Check the accuracy of the viewfinder by comparing the picture seen in the finder with the image on the focusing screen (if there is one) or a piece of tissue paper stretched between the film rollers. It is fairly common for the viewfinder to include less than the image on the screen, but it must never cover more, and the centres of both pictures should coincide when the camera is focused at infinity. This will not hold at closer distances.

Rangefinder. Check the rangefinder calibration by ranging it on a series of objects from the closest distance that the lens will focus to about 30 feet away from the camera. The rangefinder reading should correspond to the distance measured with a tape measure. There must be no slack when the control wheel is moved slightly backwards and forwards.

Focusing Mechanism. Here again, there must be no trace of slack in the focusing mechanism of any camera that focuses by scale, although a certain amount of slack between the rack and pinion of a stand camera is not important. Check the accuracy of the focusing scale if possible by focusing an object with a focusing magnifier on either the focusing screen or a sheet of ground glass held across the negative opening in the back of the camera. Measure the distance of the object focused and compare it with the scale reading, with the lens at full aperture.

The focusing scale of any camera taking a negative smaller than 2¼ × 2¼ ins. cannot be checked with sufficient accuracy this way. The best way for the ordinary photographer to check the focusing scale of a miniature camera is by actual trial as follows. Stand a row of books on a table in front of the camera so that the line makes an angle of 45° with the line of sight. Focus on the lettering on the spine of a book near the centre of the row and make an exposure at full aperture. Do this for a series of camera-subject distances from the closest working distance to 10 feet or so.

When you examine the developed negative through a magnifying glass—or project it on the enlarger—you will see whether the focused book is consistently sharper than its neighbours, or if the book in front or behind is sharper. In this way you can see where the actual focused distance lies and decide either to re-set the scale, or make a suitable allowance when focusing. But the wisest course is to put the onus on the seller and refuse to accept the camera until the scale has been corrected.

Finally check the infinity position by taking a photograph of the horizon line or of objects silhouetted against the sky at least 200 feet away.

Shutter. All that you can do here is to set and release the shutter at each of the marked settings—including T. and B. and delayed action. While you can make your own test of the accuracy of the marked speeds, it is more satisfactory to pay a few shillings to have the shutter tested by any of the photographic dealers who maintain a shutter testing service. These tests are made with the help of equipment beyond the means—and needs—of the ordinary photographer.

Lens. The general condition of the lens can be judged by examining it with the back off the camera and the shutter held open at T.

Both back and front surfaces should have a high polish and be free from dust or grease. A single scratch is not a serious matter. But if the surface looks dull, it is probably covered with very fine scratches caused by rubbing it in the effort to get it clean. Scratches of this type ruin the performance of the lens, and although the surface can be repolished (preferably by the manufacturer) the trouble is a fairly clear indication that the camera has not been looked after and you would be wise to reject it.

Tiny air bubbles in the glass itself are not serious—in fact they are almost always present in high quality optical glass.

If the lens is fairly old and has cemented components it may have a slightly yellow tint. This is simply the effect of ageing on the Canada Balsam joining the glasses. You can ignore it for black and white photography. The tint might affect the rendering of colour, but a lens old enough to have yellowed to such an extent would probably not be fully corrected for colour work anyway.

Cemented lenses should be carefully examined to see if the balsam has "started", that is, if the two glass surfaces are no longer joined by

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

the cement. Starting is usually indicated by small, star-shaped patterns.

Actual lens testing, a special technique, is the only practical way of determining the performance of a lens.

Iris Diaphragm. Test the iris diaphragm with the camera opened up as when examining the lens. The control should work smoothly and in all positions; the leaves of the diaphragm should form a hole of regular shape. Reject the camera if any of the leaves tend to stick and give an irregularly shaped hole.

Bright edges or rubbed areas on the leaves of the diaphragm may cause flare patches or light fog.

Synchronizer Timing. Anyone can check the synchronizer timing for electronic flash quite easily. Simply open the back of the camera, plug in the flash unit and fire the shutter with the diaphragm fully open. Look through the lens at a sheet of paper held in front of the camera and illuminated by the flash and watch the shape of the lens opening.

If the timing is correct, the eye will retain an impression of a circular patch of light the full diameter of the lens aperture. If the impression is of a smaller area with a regular but non-circular outline, the shutter is firing early or late. Remember that the shutter may only be synchronized for electronic flash at one particular speed.

The easiest way to test the timing for flash bulbs is to connect up the flash gun to the camera shutter in the normal way and take a close-up of the bulb itself. The resulting photograph will show whether the shutter has caught the flash before, after, or exactly at its peak.

Plate Holders. See that the draw slides go in and out smoothly and without forcing and that the velvet along the face of the light trap is intact and has not lost its resilience. Reject metal holders that have been bent or buckled—it is practically impossible to repair them so that they will work smoothly and be light-tight again.

Never buy a camera with only two or three plate holders. So few holders are interchangeable that it may prove difficult or impossible to get extra holders to fit the camera. There should be at least six holders to enable you to work without frequent visits to the darkroom to change plates.

Enlargers. First make sure that the enlarger is mechanically sound. The column should be rigidly fixed to the easel and the head should travel up and down smoothly. All controls—focusing, negative tilt, and rise and fall—should work freely but without any slack or backlash.

It is particularly important for the image to remain steady, while focusing, so test this with the enlarging light switched on in the darkroom. Move the focusing adjustment gently to and fro and watch the light on the easel. If the picture moves as you reverse the movement of the control, look for another enlarger; image movement of this type at the critical point of focusing is a perpetual nuisance.

While the enlarger light is switched on, check the evenness of the illumination on the baseboard. To do this, focus a negative sharply and then remove it together with the negative carrier. This will show the performance over the whole working area.

Watch the illumination as you slowly stop down the lens. It may look uniformly bright at first, but presently dark patches and corners may appear. You may be able to get rid of the unevenness by altering the lamp adjustment. Or the lamp may be of the wrong type. But if the unevenness persists after you have checked these points, do not buy the enlarger.

The advice about the general condition of the finish, lens, diaphragm, focusing mechanism, etc., of second-hand cameras applies equally here. In addition, examine the lower face of the condenser for scratches or chips—any defects here tend to affect the image, particularly when the lens is stopped down.

To check the performance of the lens, cover a piece of exposed film with scratches and focus it sharply with a magnifier on the enlarger baseboard with the lens at full aperture. With a good lens, it should be possible to get sharp definition of the scratches all over the baseboard.

Next expose a sheet of bromide paper on the easel, develop it and check that the scratches are equally sharp in the print. This will show whether the lens is free from chromatic aberration.

Flash Equipment. When buying second-hand flash equipment, remember that you may have to renew the battery in a short time. With the ordinary flash gun the cost of a new battery is nothing to worry about, but with a battery capacitor type, and more particularly with a battery operated electronic flash, the cost of a new battery can be quite expensive.

Accessories. The only way to be sure that second-hand photographic accessories are worth buying is to try them. You can accept new equipment on the strength of the manufacturer's guarantee, but when you buy second-hand equipment you rarely have any right of redress if it gives trouble after you have paid for it.

Most dealers will allow you to take equipment away on trial against a deposit, and the classified advertisement departments of most photographic periodicals run a deposit system by which the money is not handed over to the seller unless the buyer is satisfied with the goods.

Price. As a general rule, second-hand equipment in first class order is worth anything from one-half to three-quarters of the list price of the new item. "Shop-soiled" equipment is sometimes sold at a reduction of 10–15 per cent or more.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Accessories made by a camera manufacturer to fit his own particular instrument usually cost more both new and second-hand than the equivalent proprietary items designed to fit any make.

SELLING EQUIPMENT

The photographer with equipment to sell can either take it to a dealer or try to find a private buyer. One way is used as often as the other and each has its special advantages.

To a Dealer. The dealer relies on being able to sell the camera or equipment again at a profit, but in the meantime he must store, maintain, perhaps recondition and often advertise it. So he is not likely to offer as much as a private buyer who wants it for his own use. Against this the dealer offers cash down and an immediate sale which is sometimes the more important consideration.

If the owner of the equipment simply wants to sell it so that he can buy something better, however, the situation is different. His wisest course then is to offer the equipment to a dealer in part exchange for the new outfit. Under these circumstances the dealer may sometimes offer a better price for the old equipment than he would in a straight cash sale and the customer gets what he wants without having to wait.

To a Private Buyer. The private buyer is generally prepared to offer more for any second-hand equipment he wants than the dealer. For the same article, he will expect to pay a price which lies somewhere between the dealer's buying and selling prices.

The private buyer of course has to be found, and there are three principal ways of going about finding him. If the seller is lucky, he may be able to find a buyer among his own circle of acquaintances or at his camera club. He can watch the wanted columns in the classified advertisement sections of the photographic press. He can insert a classified advertisement of his own in the for sale column.

In answering a wanted advertisement, he should first send a detailed and honest description of the equipment, but not, of course, the equipment itself. The deal can proceed from that point to the dispatch of the equipment on approval against the buyer's cheque, or through the deposit scheme of the publication.

If the seller decides to advertise his equipment, the best medium is almost always the classified advertisement columns of the photographic press. Anyone living in a large city or a densely populated area can often do equally well by advertising in the local press because his advertisement is likely to be seen by a fair number of prospective buyers in his own district. If he includes his address and telephone number, he has a good chance of closing the deal by personal contact instead of by laborious and time-wasting correspondence and written bargaining.

An advertisement in the photographic press should give all the essential information about the article briefly: what it is, model or year, condition, any extra items not usually covered by the opening description and price—e.g., Vinto IIIa *f* 2 coated Panchro, equal new (or "mint"), e.r.c., hood, three filters, £75. Name, address and telephone number should only be given if the seller lives in a district where the advertisement would be read by a large number of prospective buyers within calling distance—e.g., Greater London. In most advertisements of this kind a box number is enough. F.P.

SEEBECK, JOHANN THOMAS, 1770–1831. German physicist. Investigated in 1810 the photochromy of silver chloride: when this is exposed to white light and then to the spectrum colours, the spectrum reproduces itself on the silver chloride in its own natural colours. This interference process is one of the few direct processes of photography in natural colours, but it took 80 years and the work of many inventors before a practical process giving a permanent image was evolved by Lippmann.

SELENIUM. Used in certain toners, either by itself or with sodium sulphide.

Formula and molecular weight: Se; 79.

Characteristics: Reddish powder.

Solubility: Insoluble in water, but soluble in hot solutions of sodium sulphide and sodium sulphite.

Selenium is also the operative component of barrier-layer photo-electric cells, as used in exposure meters.

SELF-PORTRAIT. There are four ways of taking a self-portrait; by using a mirror, a delayed action shutter release, a remote shutter control, and by controlling the lighting.

Mirror Method. The mirror method is popular, but by no means the easiest. It usually means including the camera in the picture and this is not always desirable. The mirror must be fairly large—generally no smaller than 2 feet × 1 foot 6 ins.—and clean and perfectly flat, otherwise the reflection will be distorted. Most ordinary domestic mirrors are unsuitable, as a reflection is obtained from both the mirrored surface and the front glass surface, resulting in double images on the negative. The mirror should be supported in a secure position with plenty of room behind it to allow freedom in arranging artificial lighting (for daylight portraiture it is generally best placed with its back to the window). The lighting must be placed where it does not reflect off the surface of the mirror or shine directly into the lens.

CC-0. Kashmir Manuscript Preservation Foundation, Chandigarh

The photographer takes up his position in front of the mirror and arranges his distance from it, his pose, and the lighting until he is satisfied. This procedure calls for some imagination, because the camera will be looking at the effect from a different viewpoint. Even with a reflex camera it is not possible to see the final effect in the viewing screen because if he looks at the screen the photographer cannot see his own face. And unless the portrait is to show the sitter looking straight at the mirror, the effect of looking in any other direction can only be guessed.

If the camera is focused by scale, it is important to set it to the sum of the distance from the lens to the mirror and the distance from the mirror to the subject. (These two distances are not necessarily the same; the camera lens may be six inches or more closer to the mirror than the face of the "sitter", and in a fairly close-up portrait this would be quite enough to put the whole face out of focus.)

When the camera is focused by rangefinder the fact that the camera will be in a different position at the time of exposure must be allowed for.

If possible the photographer should set up the camera on a tripod and sight it on some substitute subject—e.g., a stool standing on the chair that he will be sitting on for his portrait—to make sure that he is not including too much or too little in the finder. It is of course always wise to allow a good working margin in this kind of portraiture.

Finally, the photographer looks in the required direction and releases the shutter. The exposure is the one normally given for the subject and lighting; the presence of the mirror in the set-up makes no difference.

There are two ways of keeping the camera out of the final print. One way is to arrange the picture so that the part where the camera shows can be trimmed off in enlarging. This method is suitable for a picture where the whole head is enlarged and the camera is kept just below shoulder level. The other way is to arrange for the reflection of the camera not to appear in the picture at all—i.e., to keep it well below or to the side. This method inevitably introduces some angular distortion of the image, and the picture that the camera sees is so different from the reflection seen by the photographer that it becomes difficult to visualize and arrange.

When making prints from the negative, this must be done in the enlarger and not by contact printing. This is necessary because the negative must be projected the wrong side up (i.e., emulsion away from the paper) to correct the reversal from left to right caused by the mirror. A negative contact printed in this way will have unsharp definition.

Delayed Action Release Method. The delayed action release offers much more scope and it avoids including the camera in the picture. It is an excellent aid in trying out lighting arrangements, ideas, etc., without having to rely on the co-operation of a model. It also relieves the photographer of worry about whether he is taxing the patience of his stand-in model by playing around with lights and props.

SELF-TIMER PORTRAITS. The camera is set up on a tripod or other support, and the self-timer set in motion. The photographer can then take his place in front of the lens. A mirror behind the camera permits observation of expressions.

Practically any type of camera is suitable; if it is not fitted with a delayed action release, it can generally be fitted with a supplementary one either in conjunction with a cable release or screwed straight into the cable release socket.

The arrangement is exactly the same as for taking a normal portrait except that the photographer, immediately after engaging the delay action and pressing the shutter release, takes up his place in the picture. As the average delay is 15 to 20 seconds, there is always plenty of time to get into position before the shutter clicks.

The safest way to ensure that the picture will include everything is to contrive some form of "stand-in" that the camera can be focused on. A cushion on top of a stool standing on the chair, or some such arrangement, is all that is needed. This substitute is then lighted, arranged and focused, preferably by scale. The lens is then stopped down to give a reasonable margin of depth of field, and the exposure made at leisure. It is better to make sure that the image will be sharp than to shorten the exposure by using a large stop and sacrificing depth of field.

If the portrait is to be focused critically—e.g., to give sharp definition to the front of the head alone, then this "stand-in" method of focusing must be supplemented by something more accurate. The simplest way is to stretch a piece of picture cord (ordinary string is too elastic) from a point behind the camera to the point focused on, marking this position with a knot. The photographer then sits in the chair

in front of the camera, pulls the cord taut with the knot against his forehead, and then lets it fall before the shutter clicks.

It is a help to set up a mirror behind the camera so that the photographer can arrange his expression and pose, but it must be remembered that the mirror will give a reversed picture—i.e., transposed from left to right—and will give no indication of the field included by the camera lens. Also, the mirror must be securely fixed so that it cannot fall forward on to the camera—a mishap that would probably prove disastrous for both.

Finally, when taking delayed action portraits, it is always worth while to make one or two "dummy runs" before actually making the exposure. There is a knack in releasing the delay, moving quickly into the picture area, and posing without a flustered air or, what can be just as bad, a look of triumph.

Remote Control. In many ways this is quite the most successful method of self-portraiture because it avoids the last-minute scramble from the camera station to the sitter's chair. The shutter in this case is released by any of the normal types of supplementary remote release—i.e., pneumatic tube, electrical, remote switch-controlled solenoid, extended cable release, or even a length of thread fastened to the release lever. The latter should be used only as a last resort, and then with great care, as camera-shake and even damage to the camera are a potential danger.

The preparations are exactly the same as for normal delayed action release, but when everything is ready, the photographer simply takes up his position and releases the shutter by hand in his own time. If he wants both hands to appear in the picture it is easy enough to arrange to operate the release with his foot.

The remote control connection (tube, wire, etc.) should be suitably hidden—for instance, underneath a ring—so that it does not appear in the picture of a full-figure view.

A mirror is a help also in a remote-controlled self-portrait. For pictures showing the sitter looking into the camera, the mirror may be set up in front of the camera lens with the latter photographing through a cleaned-off window of the silvering.

Lighting Control. This method has certain advantages in special circumstances. It requires the entire subject lighting to be under the control of a single switch which the photographer can operate from the sitter's chair. The ideal form of lighting is remote-controlled flash bulb or electronic flash. The photographer arranges the picture as for a delayed action release and then puts out all the lights. He then leaves the shutter open on Time and takes up his position in the sitter's chair, checking the distance with a knotted cord as described for focusing above. When he is ready to make the exposure he simply switches the lighting on and off, or presses the flash button.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The most notable application of this technique is for making a number of exposures on the same negative with the subject posed against a black background. For this purpose electronic flash is ideal because a succession of exposures controlled by the duration of the flash can be made without revisiting the camera. A typical montage made in this way would be a full face portrait flanked by profiles.

Groups. Although the mirror and lighting control methods are not really suitable for what is probably the most popular of all photographer-in-the-picture work—i.e., groups of the photographer's friends or relatives, the two other methods may be used. In practice the remote control method is not very suitable because the camera must be at a fair distance to include the whole group, and this calls for a control that is inconveniently long and more difficult to exclude from the picture.

The built-in or a supplementary delayed action release is the standard means of taking this type of picture. Where possible, the photographer should pose the group with a space left for himself between two of the members. If he allows space at one end, he may underestimate the width he is going to take up and find part of himself cut off in the picture. And since he will have some distance to cover after pressing the release, he ought to make sure that the way is clear and that the rest of the group know exactly what is going to happen. If they are not fully briefed in advance the picture may show all their eyes directed at the photographer. P.C.P.

SELLA, VITTORIO, 1859–1943. Italian mountaineer and alpine photographer from 1880. Like his father, Giuseppe Sella, who wrote the first text-book on photography to be published in Italy, 1856, Vittorio combined photography with alpinism. His exploits in the Alps, the Caucasus, Alaska, Central Africa and the Himalayas, some of them as official photographer to the Duke of Abruzzi's expeditions, made Sella's photographs world-famous. Biography: *The Life and Photographs of Vittorio Sella* by Ronald Clark (1948).

SELLING PHOTOGRAPHS

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Good photographs are frequently required by editors of the illustrated press and technical journals, book publishers, advertising agents, press agencies, and many other users. Methods of approach vary according to the market, and the fees paid vary even more.

When a photograph is commissioned by an editor or publisher, there is nothing difficult about the transaction; the photographer knows in advance that the prints will be accepted if they fill the agreed specification and he knows what he will be paid for them. (The only point he needs to watch is what rights he is selling—i.e., is he parting with the complete copyright, or simply selling permission to reproduce in one issue of the publication?)

The essentials of a successful sale are: the photograph must be technically perfect (but there are important exceptions to this, e.g., outstanding news pictures), considerably above average interest in its particular class, appropriate to the market, and of the right size.

Technical Perfection. This is taken for granted in prints offered for publication. The only exceptions are photographs of such outstanding news value that technical faults do not matter—e.g., an exclusive but badly focused picture of the assassination of a famous man would be accepted so long as the scene was recognizable. Generally the print should not be smaller than whole-plate and not bigger than 8 × 10 ins. It should be on glossy or glazed white paper with a full range of tones and with no tendency towards strong contrasts. (This holds good even for pictorial subjects; however well they may look on rough surfaced paper with a cream base, the editor is only interested in how well they will reproduce. The blockmaker always prefers to work from a glossy print with a white base.) Finally, the print must be dead sharp.

Interest. Millions of good prints are made every year and most of them are of interest only to the photographer's immediate circle of friends or relations, or to the people who have paid for them to be taken. Only a very small proportion are capable of making a disinterested stranger look twice and, unless a print can be relied on to do at least that, no editor will buy it for publication.

A technically excellent picture of a baby or a kitten or a motor-car, however much it may make the breast of the photographer swell with pride, has no market value. But if the baby is bellowing tearful disapproval just when it is being awarded first prize in a national contest; if the kitten is riding on the back of a tortoise, or if the motor-car is doing a somersault in a road race, then the picture has a good chance of selling in the right market.

The Market. The fact that the market varies according to the subject ought to be obvious, yet thousands of salable photographs waste everybody's time and earn no money simply because they are sent to the wrong type of publication. One of the commonest mistakes is to send a photograph to a national newspaper when its real market is the local press. Before submitting a print, the photographer should always try to forget that he took it and try to imagine himself coming across it for the first time in the publication he has in mind. If it does not take its place naturally alongside the typical contents of that particular publication, then no editorial magic can make it do so. This means that the photographer who hopes to sell a picture must either know the market from personal reading and observation or should study an up-to-date book on the subject. Then he will not make such elementary mistakes as sending a picture series to a magazine that never publishes more than one photograph per page, or sending a red-hot news picture to a week-end paper.

Suitable Presentation. The hard work should all be done by the photographer as far as possible; if he leaves anything that he ought to have looked after himself to the editorial or production staff of the publications he is spoiling his chances of making a sale. So all spotting and retouching must be done as carefully as for an exhibition print; the editor must not be asked to imagine how well the print will look after his art department has removed the blemishes. The print should arrive in perfect shape; if it is packed carelessly and arrives cracked and dog-eared it will call for more work than it is usually worth before it can be reproduced. It should be accompanied by all the relevant information, preferably typed out and stuck to the back; the editor cannot spare the time to hunt for missing facts himself.

When sending trimmed enlargements it is advisable to enclose a contact print as a guide to the editor. On the whole it is, however, better to send untrimmed prints—partly because it gives the art department of the publication more scope to adapt the picture to their layout and partly because the marking up carried out by the art editor will nearly always spoil one's special effect.

Colour. Everything that has been said above applies to both black-and-white and colour photographs, but the editorial requirements for colour are very much more stringent. The cost of preparing the necessary blocks for colour reproduction is so great that only a picture of the highest standard will merit it.

Generally speaking it is rarely worth while submitting miniature colour transparencies as the loss of definition in enlarging them for reproduction is too great. They may be acceptable for sequences (to be reproduced on a small scale) otherwise 2¼ × 2¼ ins. transparencies or colour negatives (accompanied by a colour print) are about the smallest suitable size.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Photographers who specialize in colour for reproduction should submit their work in the form of transparencies of at least quarter-plate size. Carbro or dye transfer colour prints made from three-colour separation negatives are also quite acceptable, but they should be much larger than quarter plate.

Selling Direct. When a print is offered to an editor or other prospective buyer without any conditions, it is understood that payment at the normal rate will be acceptable. The normal rate is the rate that the buyer normally pays for similar pictures from other sources used in a similar way.

Various scales of payment have been proposed in the past, but no definite agreement has ever been—or could ever be—established. The photographer must either be prepared to accept when he receives for the print or he must state how much he wants and what rights he offers. It is useless to protest after the picture has been published that the payment is too low. The only redress open to the photographer is the negative one of not offering further work in that quarter, which is an advisable course of action only when it is obvious that the buyer was trying to exploit the photographer unfairly.

If the reproduction fee asked is too high, the editor will simply return the print—always provided that the necessary packing and stamped and addressed envelope have been included. Where a print is submitted with no stipulation about the reproduction fee, the editor, if he wants to use it, will retain it without further acknowledgement. If he publishes the photograph, payment will normally be made at the beginning or at the end of the month following publication.

Editors sometimes keep prints for an unreasonable length of time without using them. This puts the photographer in a difficult position: if he sends in a bill for a reproduction fee, the editor will almost certainly return the print, and any hope that there might have been of selling it in that particular market will be at an end.

On the other hand, if the sender does nothing about it, the print may lie for months in the editorial office.

When the subject is highly topical, the situation is even more serious, because the print may be worth nothing unless it is published right away. With this type of picture the photographer should either telephone or call on the editor of the publication and negotiate the reproduction fee verbally or put the matter in the hands of an agency.

Selling Through an Agent. An agency will want the negative, not the print. Feature and news agencies will sell either exclusive rights to a single publication, or will submit the material to a large number of editors for reproduction at their standard rates. It is almost certain that the picture will make more money in the hands of an agent than if the photographer handles the sale himself. By knowing his markets exactly, an agent can often sell a picture, even of no great immediate interest, probably to a publication the photographer has never heard of.

The agent's commission will be around 50 per cent of the gross receipts for the picture, but even then the photographer will probably make more out of a topical shot than by his own efforts.

The agent has the advantage of experience in making the most of news pictures, and has the facilities for printing and distributing large numbers of copies of general interest pictures simultaneously to all prospective buyers.

Where the photographer is content with only occasional sales and does not mind how much trouble he takes to get them, there is nothing to prevent him from sending prints off himself to whatever prospective buyer he considers a potential market.

Choosing a Market. A detailed study of various magazines and journals is desirable before submitting any prints. The type of market should, however, first be selected and the following can be taken as a general guide: news pictures will find their best market with local or national daily newspapers; general interest pictures are mostly required by the weekly newspapers and magazines, as well as the monthly popular journals; technical photographs should be sent to the trade publication dealing with any specialized industry connected with the subject of the photograph; pictorial photographs involving human interest are best placed in the hands of an agent, who can circularize them to many customers among advertising agencies, manufacturers of photographic materials or postcard and calendar publishers.

When submitting prints, they should be addressed to the news editor in the case of newspapers, the art editor with general interest and technical magazines, and the art buyer with advertising agencies.

Reproduction Rights. It is always understood, when reproduction rights are offered, that the sender of the photograph either holds the copyright or is authorized to act for the owner. Very broadly, whoever takes the photograph owns the copyright, but he does not own it if he is paid to take it. When he is paid to take the photograph, the copyright belongs to the one who pays him—e.g., his employer or client.

When a print is submitted for publication, the sale of the copyright is not usually involved —only the right to reproduce. If a buyer wishes to purchase the copyright—e.g., to use as a trademark—he must say so, and be prepared to pay much more than he would for the simple right to reproduce. The fee in this case is always a matter for negotiation; there is no standard scale of charges. The purpose of the picture is however some basis for how much

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

to charge; if a shot is suitable for, say, a national advertising campaign it may be worth as much as £50–£100, while a calendar publisher may not be prepared to pay more than £5–£10. Here again the superior experience of an agent helps as he not only knows the most suitable market and the potentialities of the picture, but also the best time for submitting it.

When the photographer sells the copyright, he loses all control over the picture from that date; when he sells reproduction rights he can attach any conditions he wishes. It is usually understood that, when a print is submitted to a newspaper, it may be reproduced in all the editions of the paper on a given date at the normal rate of payment. If in addition the print is reproduced in other newspapers or periodicals of the same company, then each separate use must be paid for, also at the standard rates.

This is common practice, and if the photographer wants his print to be treated in any other way he must make it clear in the covering letter.

A number of prints from the same negative may be sent to a number of different publications and normal reproduction fees will be paid by each user. Unless the covering letter states that the print has not been offered elsewhere, the newspaper will assume that other publications may also be using it. There is no need for the covering letter to mention this, but it should point out if the picture is being offered exclusively.

Exclusive Use. When a print is offered exclusively, it is necessary to define more precisely what is offered than if the offer is simply one of many. The covering letter should say whether the picture may be reproduced on more than one day or in other publications belonging to the same group. It should state whether or not the photographer reserves the right to submit the print overseas, or to offer it for use in other media—e.g., for advertisements, posters, calendars, etc.

Frequently a picture offered exclusively has a very high spot news value, and there is no time for correspondence or haggling. The photographer will in all probability negotiate the sale over the telephone, but, even so, the terms should be discussed at the time and repeated in a covering letter sent with the negative, print, or undeveloped material. It should never be assumed that the copyright automatically goes along with exclusive reproduction rights; copyright sale should always be the subject of separate negotiation and is only effected by written agreement.

Sales Record. All prints offered for sale should be recorded systematically; the details of the system will vary according to the scale of operations. A notebook entry is enough where only a few prints are being sent out, but index cards are essential where more than say a dozen different prints are out at one time. Each card should carry the title and reference number of the negative and give the publication and date of sending of each print—e.g.:

SINKING YACHT AT COWES, p. 634

Publication	*Date sent*	*Result*	
Picture News	5.6.55	Returned	8.6.55
Photo-Recorder	5.6.55	Returned	10.6.55
Yachting Journal	9.6.55	Published	14.6.55
Cowes Review	5.6.55	Published	9.6.55
Sunday Reporter	5.6.55	Published	8.6.55

A check must subsequently be kept to see that all prints published are paid for. It is not normally necessary to send in an account, but if there is any delay beyond the end of the month following publication, an account should be submitted with the date and issue in which the print was reproduced.

The only foolproof way of knowing that a print has been published is for the sender to make a personal search of every issue of the publication in which the picture could appear. This is easy enough if the publication is one that the photographer takes in regularly himself or sees at his work—e.g., trade and technical publications—or at the library or club. But if he sends out numbers of prints to a wide variety of publications the expense and trouble of making such a check are out of all proportion to the rewards.

The photographer has two courses open to him: he can rely on the publications to pay without being prompted (which they usually do) and risk the loss of an occasional reproduction fee; he can place his business in the hands of an agent.

Appointing an Agent. The photographer who normally chooses to sell his own prints direct and only occasionally makes use of an agent when it suits him must be prepared to accept the agent's regular terms of business. If he accompanies an odd picture with a long list of conditions, he will almost certainly get it back. His surest safeguard lies in dealing with an established agency which has a good reputation.

But anyone who is regularly producing marketable pictures and wants to appoint an agent to take all the work of selling them off his hands should only do so on clearly stated terms. It is enough for these to be stated in writing in a letter from one of the parties and acknowledged by the other. The agreement should make clear on the one hand that the agent is appointed by the photographer, and on the other, that the agent agrees to act for him in that capacity. It should further define:

(1) The service expected of the agent.

(2) What prints the photographer is obliged to supply.

(3) An exact definition of the rights to be offered.

(4) Any restrictions on the territory covered.

(5) The period covered.

(6) The amount of commission to be deducted from the gross fees.

(7) Arrangement about credit lines or other acknowledgement.

This type of agreement is particularly necessary for photographers working abroad and sending their prints to an agency at home or for those who want to sell prints in other countries.

Fees. The fees paid vary according to the publication and the size or area of the reproduction. British newspapers have an agreed minimum rate, based on the number of square inches, but the rates for provincial newspapers are only half those paid by the nationals—e.g., for a print offered simultaneously to a number of newspapers, the fee for reproduction up to 30 ins. might be as much as 10 guineas or as little as £1 7s. 6d. On the other hand, for an exclusive topical news photograph, the reproduction fee paid by a national newspaper might be 20 guineas or considerably more.

Weekly and monthly illustrated magazines will pay anything from 8 to 20 guineas per page of photographs and some publications will pay considerably more.

Fees are higher in America—especially when the photographer works on assignment—and very much lower in countries outside Britain and America.

Advertising agents, calendar and greeting card manufacturers and the like will pay from 5 guineas up to about 20 guineas for good, usable prints submitted speculatively, but the photographer should be quite clear about what rights he is disposing of for the fee.

The market for good colour transparencies of high technical quality, and reasonable size, has increased considerably in recent years, and a transparency might sell for one of many purposes for a fee of between 15 and 50 guineas. Colour photographs produced for reproduction should ideally be no smaller than 4 × 5 ins. Expense makes it inadvisable to engage in work of this nature unless it is specifically commissioned.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Return of Prints. When a picture is reproduced, the publication retains the print and may dispose of it in any way except that it may not offer it for publication elsewhere.

In certain cases editors may be persuaded to return a print even after publication—e.g., if it is unique and irreplaceable. This is not, however, standard practice, and requires some preliminary arrangement. Generally, the photographer will have to put up with the fact that a print that has been through the hands of retouchers, blockmakers or engravers, and the various postal personnel between them and the editor, will not be in mint condition any more. It will certainly not be in an ideal state for submission to other publications.

When the print submitted is not accepted for publication, the office is not obliged to return it to the sender. Most offices, however, will return unwanted prints, but the sender should do everything he can to encourage the courtesy —i.e., he should use packing stout enough to stand the double journey and enclose a self-addressed stick-on label.

When submitting prints to a strange editor, it is advisable to include return postage and preferably a self-addressed label. Later, when the photographer becomes known to the editor and his prints are being accepted more or less regularly, this may be unnecessary.

Editors appreciate that the sender has gone to some trouble and expense in submitting the print and in any case most publications rely to a greater or less extent on freelance contributions to keep their picture pages interesting.

And because the print and the covering letter may part company, it is necessary to emphasize once again the value of printing the name and address of the sender on the back of each print with a rubber stamp. F.P.

Book: *How to Take Photographs that Editors will Buy*, by R. Spillman (London).

SENEBIER, JEAN, 1742–1809. Swiss librarian in Geneva, and early photo-chemist. Studied the effect of light on plants, and made photometric observations with silver chloride paper, extending Scheele's experiment with the solar spectrum and giving exact times for the darkening of silver chloride under each colour of the spectrum. Senebier also investigated the effect of light on gums and observed the hardening property of some on exposure to light.

SENSITIVITY. A photographic emulsion consists of light-sensitive silver halide grains distributed throughout a layer of gelatin. The grains are extremely small, and a typical emulsion might have grains with an average diameter of around 10^{-4} cm. One frame of a normal 35 mm. film probably contains more than 10^{9} of these grains. On exposure the grains react physically with light, and those grains which have received a sufficient amount of light are rendered black during subsequent development. Photographic sensitivity describes the amount of blackening resulting from a given exposure, and is thus closely related to photographic speed.

Originally photographic emulsions were sensitive only to light with wavelength in the violet region of the visible spectrum. Current emulsions are often sensitive throughout the entire visible spectrum and sometimes into the infra-red, and certain types of photographic plates can detect X-rays and nuclear particles.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Quantum Efficiency. When describing the interaction of light with these microscopic silver halide grains, it is instructive to do so in terms of the quantum theory of radiation. According to this, light has a discrete structure, and the smallest unit of light is the photon. Around 10^{11} of these photons are necessary to produce a uniform photographic density of unity over a 35 mm. frame of a medium speed film. The number of photons which are required to make a grain developable is sometimes expressed in terms of the so-called responsive quantum efficiency.

By this representation a 1-photon grain has 100 per cent efficiency, and a 5-photon grain has a 20 per cent efficiency. There is evidence that in modern emulsions the most efficient grains require only 4 photons for developability, but the least efficient grains may require more than a hundred photons. The amount of blackening, and hence the sensitivity, will obviously depend on both the responsive quantum efficiency and the grain size.

If speed were the only criterion of performance for a photographic material, then the best emulsion would be the one containing the most grains with the highest responsive quantum efficiency. But it is not usually sensitivity *per se* that is desirable but, rather, high sensitivity over an extended exposure range, since in most photographic applications the subject covers a large number of brightness levels. The wide spread of responsive quantum efficiencies, along with the spread in grain sizes, plays an important rôle in providing this exposure latitude. If all the grains were of equal size and sensitivity, then all would become developable in a narrow exposure region around the exposure level which provided that on average each grain received the requisite number of photons.

Such an emulsion would therefore have a high contrast and a low latitude, and would probably be unacceptable for most practical purposes, in spite of the fact that its sensitivity might be high.

But in fact there is not only a wide spread of responsive quantum efficiencies, but also a wide spread of grain sizes, and even grains of the same size have an appreciable spread of responsive quantum efficiencies. The probability of a grain receiving the requisite number of quanta is proportional to the size of the grain.

Granularity. Although photographic sensitivity is determined by the grain size and the responsive quantum efficiency, the useful sensitivity depends on a further important factor, which is a direct consequence of the discrete granular structure. For the grains are not distributed evenly throughout the emulsion layer, but are situated at random. Thus one small element of an emulsion may contain twice as many grains as an adjacent element.

This random grain distribution causes the visual phenomenon of graininess, the densitometric representation of which is known as granularity. The consequence is that any form of photographic interpretation is subject to an imposed degree of uncertainty. Generally speaking an emulsion with high speed has large grains and high granularity, and vice versa. It is found that the useful sensitivity depends on the speed-to-grain ratio rather than the speed alone.

Informational Sensitivity. The term informational sensitivity is sometimes used to describe the scientific measure of useful sensitivity. For a high speed-to-grain ratio means that accurate information may be recorded photographically at a high rate. If one emulsion has ten times the speed of another, but both have the same speed-to-grain ratio, then ten exposures of fixed duration using the faster emulsion would yield the same information as one exposure of ten times this duration using the slower one. Thus although the emulsions differ widely in sensitivity, they are rated equal from the point of view of informational sensitivity.

Following these same arguments it is easily seen that the ultimate sensitivity is of less significance than the ultimate informational sensitivity. The former is not a realistic concept, since even a 1-photon grain could be made more sensitive by increasing its size, although its responsive quantum efficiency would remain the same. A 1-photon grain the size of a football would be extremely sensitive, but completely useless for normal photographic purposes.

However the ultimate informational sensitivity is limited by the discrete photon structure of the exposure. The randomness of the photon distribution is similar to the randomness of the grain distribution, and the photographic granularity cannot thus be less than that imposed by the photons in the exposure.

Calculation shows that if the photographic process were capable of the ultimate informational sensitivity, then it would be possible to obtain a good quality photographic image exposure to starlight. At lower exposure levels it is still theoretically possible to obtain a strong photographic image, but the granularity would be very high and in general the picture quality would be unacceptable. R.Sh.

SENSITIZED MATERIAL. General term for all types of photographic material—plates, films and papers, etc.—that have been rendered light sensitive either by coating with an emulsion containing light sensitive silver salts, or by impregnation with a chemical sensitizer. The types of sensitized material vary considerably, from normal negative materials for use in a camera to special emulsions for scientific work.

See also: *Cine film; Colour materials; Films; Negative materials; Papers; Printing materials; Reversal materials; Supports for emulsions.*

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

For about the first forty years of the photographic process the photographer had to prepare his own sensitive material just before making the exposure. The division of labour between photographer and sensitive material manufacturer did not become general until *c.* 1880, although dry collodion plates had been put on the market as early as 1856.

Early Processes. Workable photographic processes were made public in 1839, almost simultaneously by Louis Jacques Mandé Daguerre in France and William Henry Fox Talbot in England. It is correct to honour Fox Talbot as the inventor of photography as the modern processes stem in a direct line from his work. Daguerre's process, although it enjoyed considerable popularity, did not prove capable of further development. Both the calotype, as Talbot called his improved process of 1841, and the daguerreotype are real picture making media and in skilled hands are capable of good results, though the nature of the process limits their applications. Professional photography was founded on the daguerreotype, while the calotype was originally preferred by amateurs who were attracted by the lower cost of the materials.

In the daguerreotype process a highly polished silver plate, or silver faced copper plate, was sensitized by exposing it in the dark to the action of iodine vapour or, in a later method, to bromine and iodine. After exposure in the camera, which might take several minutes in a good light, it was developed by the action of mercury vapour, which was allowed to condense on the surface of the plate and delineated the image. After fixation in a solution of common salt, or later hypo, the image was toned in gold chloride. Fine detail was well reproduced, and the daguerreotype had an attractive, jewel-like quality. The process, however, was expensive and not well adapted for the production of copies—an essential for a popular process.

In Talbot's calotype process, paper was coated with silver iodide by successive immersions in solutions of potassium iodide and silver nitrate, and exposed in the camera while wet. After exposure it was developed in a physical developer containing gallic acid and silver nitrate, and fixed in hypo. The vitally important step of using a developer was due to a suggestion from the Rev. J. B. Reade. The negative so obtained was printed on to similar paper so that multiple copies could be obtained and in this respect it was a great advance on the daguerreotype. The process was better for showing broad effects than for fine detail, but could be used in portraiture, the series of portraits made by D. O. Hill and R. Adamson of Edinburgh in the forties being particularly famous.

Wet Plates. The next important step was the introduction of the wet collodion process by Frederick Scott Archer in 1851. This process consists of coating a sheet of glass with a solution of nitrocellulose containing a soluble iodide, and sensitizing the plate by immersion in a solution of silver nitrate. While wet the plate is exposed in the camera and is physically developed in pyrogallol or a ferrous salt. As the collodion layer must not be allowed to dry it is a most inconvenient process to work, but the results are excellent. Wet collodion has survived to this day for certain applications in the graphic arts field.

With the introduction of the wet plate a sensitive material suitable for topical photographs had arrived, for although the manipulation is exacting, failures are few and for small pictures the speed is adequate for snapshots in a good light. News photography dates from the wet plate, notable early examples being Roger Fenton's photographs of the Crimean War and Brady's pictures of the American Civil War. It was also the medium for a great expansion in portrait photography; compared with the daguerreotype it was cheap and copies were easily made. Dagron's greatly reduced copies, used in the pigeon post which was operated from Paris during the siege in the Franco-Prussian War, were made by means of the wet plate.

Numerous attempts were made to modify the wet plate process so that the sensitized plates would keep. The introduction of collodion emulsion by Sayce & Bolton in 1864 was one of the more successful, but the sensitivity was low, and the method was not popular.

Dry Plates. In 1871 Richard Leach Maddox, an English physician, produced the first workable, though slow, plate using gelatin as the medium to hold the silver bromide. The discovery, after improvement by others, proved outstanding, gelatin dry plates having a great advantage over wet collodion. The plates can be prepared weeks or months before exposure; the sensitivity is far higher; the processing is simple and there is no need to develop the plate immediately after exposure.

It was no longer necessary for the photographer to make his own plates—very soon after Maddox's discovery he could buy them boxed and labelled ready for use. In 1873 gelatin emulsion was being offered for sale by Burgess. In 1867 the Liverpool Dry Plate Company was making plates in England, this being the second factory making sensitive material. By 1878 there were four dry plate manufacturers in England. Johann Sachs of Berlin is reputed to be the earliest manufacturer in Germany, and Carbutt of Philadelphia, 1879, the first maker in the United States. He was soon followed by Eastman, who founded in Rochester the enterprise now known as the Eastman Kodak Company. By the end of the century sensitive material manufacture had been established on

a considerable scale in most advanced countries.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Colour Sensitized Plates. In 1873 a discovery of the greatest importance was made by H. W. Vogel in Berlin. While testing some plates which had been dyed to reduce halation he found that they were sensitive to green light. He concluded correctly that this property was due to the dye, which was probably corallin, and set to work to examine a number of dyes. As a result he found several which could act as sensitizers, and predicted that it would in time become possible to photograph even by infra-red rays, with dye-sensitized plates.

In 1884 the first colour-sensitive plates were offered for sale. In the same year Eder discovered the sensitizing properties of erythrosin, which was used in the manufacture of orthochromatic plates for many years. In 1906 the first satisfactory red sensitizing dye was discovered by Homolka working at Hoechst, and was sold as pinacyanol. This dye was used in the first panchromatic plates manufactured in England by Wratten & Wainwright, and continued in use for many years.

The discovery of a great number of new types of cyanine dyes from 1926 onwards led to the introduction of the super-sensitive type of panchromatic materials which of recent years have displaced colour blind emulsions almost completely for ordinary photography and have made possible the production of fine-grained colour-sensitive emulsions, which are essential for miniature camera work.

Plates were used for radiography in the year of Roentgen's discovery of X-rays. In 1920 the plate was replaced by double-coated film, and X-ray films are now made in great quantity and variety.

In the early years of the twentieth century slow process plates were produced for use in the photomechanical production of pictures. A range of special sensitive materials is currently made for the graphic arts industry, an important item being the "lith" type emulsion introduced about 1938, which gives negatives of remarkably high contrast when used with a suitable developer containing formaldehyde.

Films. Fox Talbot used paper as a support for his negative material, but later glass became universal. Warnerke introduced a stripping film for hand cameras in 1875, and in 1889 Eastman started making films on a nitro-cellulose base. The flexible film base was a great advance as it made possible the construction of light daylight-loading cameras and led to the development of cinematography—1895 onwards. Nitrocellulose or celluloid was widely used until about 1930, when the much less inflammable cellulose acetate began to displace it. On account of its good mechanical properties, however, nitrocellulose remained in use for 35 mm. cine film as late as 1947, when it was replaced by cellulose triacetate base.

Printing Papers. The development of sensitive material for making prints proceeded on similar lines to negative materials. The plain paper impregnated with silver chloride introduced by Talbot was replaced about 1850 by albumenized paper which remained in use for over thirty years. It was inconvenient to use as it had to be immersed in a bath of silver nitrate and dried before being printed in daylight. Used with a strong negative, such as is obtained with the wet plate process, it gives good prints when gold toned.

Collodio chloride paper was introduced in 1868 and gelatino chloride printing-out paper was manufactured commercially in 1885. The first bromide paper was introduced by the Liverpool Dry Plate Company as early as 1873 and also by the firms of Morgan & Kidd and Mawson & Swan in 1880. Silver chloride and chlorobromide development papers date from 1883. In the years 1880 to 1914 the platinum process (which depends on the sensitivity of ferric salts, though the image is formed in platinum), and from 1866 on the carbon process (which depends on the sensitivity of chromate) were used to a great extent but are now obsolete. Silver halide development papers, particularly those based on silver chloride or chlorobromide and often dye-sensitized to increase the speed, are now the only important papers in photography.

Sensitized paper coated with diazonium salts, which is produced in great quantities for printing engineers' drawings and similar applications, derives from the discovery of light-sensitive diazo compounds by Green, Cross & Bevan in 1890, although the first practical application was by Koegel in 1923.

In recent years various special papers have been introduced. Among them variable contrast papers dating from 1940, direct positive (Herschel effect) papers dating from 1947, papers for the image transfer process dating from 1950, and papers such as those, introduced in 1952, which yield a direct positive by chemical fogging when used with a special developer.

Colour Materials. The first sensitive material for colour photography to be produced on a commercial scale was the famous Lumière Autochrome plate introduced in France in 1906. This was a screen plate with an irregular mosaic, and yielded colour transparencies by the additive method. A similar screen plate was produced by the Agfa Company some years later and a screen plate with separate screen was manufactured by the Paget Prize Plate Company about 1910. In 1928 Kodak produced 16 mm. colour film using a fine lenticular pattern which images a three component filter on the emulsion. A year or two later Dufaycolor, a film with mechanically printed colour screen which made duplicates possible, was produced.

Kodachrome, the first of the integral tripack films yielding colour transparencies by

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

the subtractive process, was introduced in 1935 and proved an immediate success for substandard cine film. In 1936 Agfacolor, a rather similar tripack material, was produced by the Agfa Company in Germany. It differs from Kodachrome in that the colour formers are included in the emulsion, while in the Kodachrome process the colour formers are in the developing solutions. In 1942 Kodacolor, a tripack negative with a corresponding tripack positive material for making colour prints, was produced in the U.S.A. Negative-positive Agfacolor for cine film was made in Germany at about the same time, followed by a paper print material.

Since 1942 a number of tripack films and printing materials have appeared. In 1949 Ektacolor film was introduced. This film contains colour couplers which are themselves coloured and by this means integral colour masking is obtained.

A rather similar form of integral masking is used in Eastmancolor negative cinema film, introduced in 1952.

The demand for colour in all forms continues to grow so that it is probable that a substantial proportion of the output of the sensitive material industry will soon be colour films. The manufacture of modern colour film is one of the most exacting and difficult forms of technology and is far removed from anything the photographer used to undertake for himself. W.H.D.

SENSITIZED MATERIALS MANUFACTURE

Photographic emulsions as we know them today were prepared by Maddox for the first time in 1871. In those days photographers sensitized their own materials, but soon after (in 1874) photographic plates became available commercially, and from then on the photographic industry developed rapidly.

The present-day photographic materials consist of a light-sensitive emulsion layer proper, containing a suspension of microcrystals of silver halides in gelatin (chloride, bromide, iodide, or mixtures of them), and coated on to a support—e.g., film, glass plates or paper.

Safelighting. From the moment at which silver halides are first formed, the resulting sensitivity to light requires special measures to ensure that the emulsion is not exposed to light which would result in emulsion fog. Any illumination used must be weak and of such a colour that the minimum photographic effect is produced in the emulsion, yet retaining the maximum possible visual brightness. The methods of illumination used are described as safelighting. In general, the same types of safelight are used in manufacture as in processing darkrooms and the same general principles apply.

As long as emulsions are blue-sensitive only, a red safelight will provide the brightest possible safe illumination. For orthochromatic materials a deep red safelight is used. With panchromatic and infra-red sensitive materials the only safelight which can be used at all is a dim green. This colour is chosen not only because many materials have a region of relatively low sensitivity in the green, but also because the dark-adapted eye is most sensitive to blue-green light. Green is therefore the best possible compromise, although for most purposes it is best not to use any light at all with fast panchromatic materials.

In manufacturing rooms light is allowed to fall on the sensitive material only where it is absolutely necessary to control the process. Lights at foot level are frequently used to guide the workers through the rooms; if the sensitive material is carefully shielded these footlights can be relatively bright.

Emulsion Making. The raw materials used in the preparation of the photographic emulsion must be very pure. The silver nitrate and alkali halides used (salts of potassium, sodium, lithium or ammonium) are amongst the purest chemicals available commercially.

The other most important raw material—i.e., the gelatin—is in many respects considerably purer than that used as food. Gelatin is an animal protein obtained from bones or skins of animals such as cows, buffaloes or pigs. The skins and bones are subjected to a liming treatment lasting up to 18 months. An alternative treatment for bones is in sulphuric acid. The material is then cooked in large vats. The resulting brew is boiled down in vacuum until the concentration of gelatin is sufficiently high for the "soup" to set on cooling. The gelatin solution is then evaporated and the resulting dry gelatin is available in the form of powder or flakes containing approximately 15 per cent water.

The next step is to incorporate the silver halide in the gelatin. The nature of the halide varies according to the type of material to be coated. For films and plates the halide is mostly silver bromide, with a few per cent of iodide. Slow papers are coated with a silver chloride emulsion and faster papers with a chloro-bromide, or even 100 per cent bromide or a film-type of emulsion.

The emulsion is prepared in large kettles of chemically inert material such as high-grade stainless steel. There are many ways of preparing the emulsion but the principle is the same in each case. The alkali halides are

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

dissolved in a solution of gelatin (about 4 per cent) and the silver nitrate is added. A chemical reaction takes place, precipitating the silver halide in the form of a very large number of minute crystals (grains) which are prevented by the protective action of the gelatin from sinking to the bottom of the kettle or clumping together.

Ripening. The emulsion crystals or grains are then grown in size to increase their sensitivity. This process of grain growth is described as ripening or cooking of the emulsion. It is carried out by heating the solution in the presence of a solvent for the silver halide. The effect of the solvent is to dissolve the smaller grains and deposit their substance on the larger grains. Different solvents are used for each of the different types of emulsion. Chloride emulsions require a surplus of potassium or sodium chloride, and iodo-bromide emulsions a surplus of potassium bromide or ammonia.

Further gelatin is next added until the concentration is approximately 7 per cent so that the emulsion sets to a jelly pudding on cooling to room temperature. The jelly is then put through a press, which squeezes it out in the form of noodles. In this state it is more easily washed.

Washing is necessary because the process of precipitation which forms the insoluble silver halide also produces soluble sodium or potassium nitrate. This must be removed from the emulsion if it is to be coated afterwards on glass or film base. Any free ammonia must also be removed since these chemicals would form undesirable crystals.

Digestion. The noodles are then melted and the emulsion subjected to further heat treatment known as digestion or after-ripening. No appreciable further grain growth takes place since no silver halide solvents are present, but the sensitivity of the emulsion increases considerably during this treatment for other reasons. Various chemicals are added in very small amounts in order to help increase the sensitivity—e.g., certain sulphur compounds, and more recently gold compounds. During the digestion treatment the chemical fog also tends to increase, so the heat treatment chosen must compromise between increasing sensitivity and keeping fog to a reasonable level.

Further chemicals may now be added to the emulsion to improve its characteristics. Sensitizing dyes extend the colour sensitivity to include, green, yellow, or red, or even the infra-red end of the spectrum. Stabilizers ensure good keeping properties. Hardeners give the coated product resistance to surface injury from scratching and abrasion. Plasticizers keep the dry emulsion layer supple, and spreading agents help to make the subsequent coating uniform. These are only a few of the additions that may be necessary to produce the required type of emulsion.

Films. Photographic film base used to consist of cellulose nitrate but in view of its inflammability it has been replaced in recent years by non-inflammable cellulose acetates, in particular tri-acetate, and acetate-butyrate. More recently, polystyrene, polyesters, and polycarbonates have been introduced. The thickness of the base may be between 0·003 and 0·01 in. with an emulsion coat of the order 0·005 to 0·002 in. Very often the emulsion surface is given a separate super-coat to protect it from abrasion.

Many films are multicoated—e.g., for amateur use there may be two emulsion coats, the bottom coat slow, the top coat fast, to give great exposure latitude. Modern colour films possess three emulsion coats often separated by clear or coloured gelatin—all of which involves highly complicated coating operations. X-ray films are often coated on both sides of the base.

To provide protection against irradiation and halation the emulsion may be coated on a grey-tinted film base. This absorbs much of the light that has penetrated the emulsion and prevents it from being reflected back into the emulsion to produce a halo around the true image. Alternatively film is often backed with a layer of dyed gelatin which is dissolved or bleached in processing. This gelatin backing also prevents the film from curling. The backing is usually applied before the film base is coated and there is also a "subbing" layer to ensure good bonding between the base and the emulsion. The subbing layer may consist of a weak solution of gelatin containing a solvent for the film base; it is so thin that it cannot readily be measured.

Film Coating. As a rule the photographic emulsion is applied to its support by moving the support material and keeping the point, or better, line of application of the emulsion stationary. A long web of the film base may be passed over a roller which dips into a pan containing the melted emulsion. According to the viscosity of the emulsion and the rate of movement of the film, a more or less thick uniform layer is picked up. The web of film then passes through a chamber in which cold air is blown on to it causing the emulsion to set, or the film may be passed over a large chilled metal roller. It is then dried, for example by being hung up in festoons from overhead racks which slowly travel through a drying room. Once it is thoroughly dry the film is spooled.

Papers. Photographic paper is produced on machines very like those used for film except that there is less need for chilling because the paper base takes up water and thus concentrates the gelatin solution causing it to set more readily. Paper emulsions are often not washed because the reaction products are absorbed by the porous paper base and do no harm.

The raw material of the base used for photographic papers is carefully selected to be

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

MANUFACTURE OF SENSITIZED MATERIALS. While production details depend of course on the particular manufacturer as well as on the product, this flow chart gives a simplified idea of the stages by which, for instance, sheet film is produced. 1. Essential raw materials: silver and nitric acid. 2. These are used to make silver nitrate. 3 and 4. Further raw materials: gelatin and sodium or potassium bromide and iodide. 5. Mixing of the emulsion under carefully controlled conditions. 6. Cooling to jellify the emulsion. 7. Shredding the jelly. 8. Washing of the shredded jelly to remove the unwanted salts (mainly sodium and potassium nitrate) resulting from the formation of silver halide. 9. Melting of the jelly and digestion (ripening) of the molten emulsion to build up speed and contrast. 10. Addition of colour sensitizers, stabilizers, plasticizers, hardeners, spreading agents, etc. 11. Coating on the film base. 12. Chilling to set the emulsion. 13. Drying. 14. Cutting of the continuous roll of film into required sheet film sizes. 15. Final inspection and packing for dispatch. Various intermediate stages taking place are not shown; these include backing of the film base to provide anti-halo protection and to counteract curling, application of protective supercoat, etc.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

photographically inert. In particular, it must be free from particles of iron or copper which would cause spots.

Special surface characteristics may be imparted both in preparing the base and during the coating operation. Smooth papers are coated on a base prepared in a continuous machine which brushes on several thin coatings of baryta (barium sulphate) in gelatin. For other purposes the surface of the paper base is embossed before coating.

The emulsion surface tends to be shiny if a gelatin supercoat is applied over the emulsion coat; it tends to be matt when there is no supercoat or when the ratio of silver halide to gelatin is relatively high.

The paper base may be tinted, and in recent years paper manufacturers have added fluorescent materials which give off blue light under the influence of the ultra-violet light present in ordinary daylight. This makes up for the slight yellowness of the gelatin and produces papers in which the highlights seem to be brighter than any ordinary white reflecting surface, thus considerably enhancing the appearance of the print. But such papers are not suitable for photomechanical reproduction, particularly of prints which have been retouched or worked up with ordinary process white pigment because the pigment does not fluoresce and it tends to reproduce as a grey tone.

Plates. Before coating, the glass must be subbed to ensure good adhesion of the emulsion. Often a backing layer is applied; it may consist of a dye in gelatin or other medium such as certain plastics which dissolve during processing. Plates are coated by running the melted emulsion through a slit on to sheets of glass. Careful control of the speed of movement of the glass results in a coat of uniform thickness. The glass sheets are then chilled and stacked in drying rooms through which clean, warm, dry air is passed.

Finishing. The film is received from the coating department in wide rolls. To make it into roll film widths it is slit on large machines with rotating knives which cut it into strips and automatically reel it up again. Sheet film is cut on guillotines. Some types of film—e.g., cine film—have edge perforations which are made in a separate automatic punching machine. Paper is finished in much the same way as film.

Plates often have to be cut from larger coated sheets because it is more economic to coat glass sheets in large sizes and because it is not easy to carry a uniform coating right to the edge of the glass.

Packing. Before being packed, the sensitized materials receive a thorough inspection (which is becoming increasingly difficult to arrange as the sensitivity of emulsion increases).

The packing is designed to supply the material to the customer in the most convenient form, and to protect it in transit and against adverse climatic conditions. The packing material itself is selected with great care to ensure that it is photographically inactive, especially where it is in direct contact with the emulsion surface.

Cine film, which is supplied in continuous lengths up to 1,000 feet, is spooled on the perforating machines which also cut it to length automatically.

Roll films are spooled on semi-automatic machines, loaded with long lengths of backing paper and film already slit to the correct width. The paper is supplied ready printed with frame numbers and indicator marks, and the machine automatically cuts the film into the corresponding lengths. These lengths of film are secured to the paper and sealed on the spool by hand. Further wrapping operations may also be carried out on automatic machines if the volume of production warrants it.

Paper packing can be carried out by brighter light and it raises no particular problems.

Plates are mostly packed by hand because the spacers or sheets of interleaving paper which keep the emulsion surfaces apart are easier to insert by hand than by machine.

Materials for tropical use are often packed in metal boxes which are closed by soldering. More recently heat-sealed packaging has been introduced. W.F.B.

SENSITIZER. Any substance which makes another react to light, or which extends the range of radiations to which a substance is sensitive, or increases its sensitivity. The two main types used in photography are chemical and optical sensitizers.

Chemical Sensitizers. These act by forming a light-sensitive compound with another substance, e.g., bichromates react with gelatin and other colloids under the action of light to produce a compound which is insoluble in hot water. In the early days of photography silver nitrate was also referred to as a sensitizer, because photographic plates and papers were prepared by coating a support with a solution containing, among other things, a soluble halide. This was then sensitized with silver nitrate, forming light-sensitive silver halide.

In the field of conventional silver halide-gelatin emulsions, "chemical sensitization" refers to ways of producing silver halide grains with a high inherent sensitivity to light in the

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

absorption band characteristic of the particular halide. The usual silver iodo-bromide grain is self-sensitive to ultra-violet and violet light. Chemical sensitization is, in effect, a matter of conditioning the silver halide crystal, or more particularly its surface, so as to render it more fertile for the production of development centres.

Sensitization can be achieved by the controlled production of specks of silver sulphide, of gold, of silver, or of a mixture of these. The gelatin itself plays a most important but not fully understood rôle in sensitization. Without gelatin—or a substitute colloid—the efficiency of the action of light in forming developable centres is very poor. The colloid stabilizes the latent image speck and prevents its spontaneous decay or fading.

Although chemical sensitization can yield emulsions of very high working speed, the sensitivity remains confined to blue light. In normal emulsions the gelatin itself acts as a dense filter against sensitivity to ultra-violet light. If the sensitivity of the emulsion is to be extended to other wavelengths in the direction green-yellow-red-infra-red, it is necessary to resort to "optical sensitization" by means of dyes.

Optical Sensitizers. Vogel found, in 1873, that by the addition of coralline dye the sensitivity of collodion dry-plates could be extended into the green band of the spectrum. Other early sensitizers were chlorophyll (red), eosin (green), and erythrosin (green). An advance in dye sensitization came with the introduction of cyanine dyes of which pinacyanol was notable. This dye was incorporated in the emulsion of the first panchromatic plates of Wratten and Wainwright. In the past 50 years innumerable organic dyes have been specially prepared and tested as sensitizers. In some cases improved results are found when two dissimilar dyes are used together. One dye acts as a supersensitizer towards the other.

In general, a sensitizing dye confers increased sensitivity to the silver halide grain at those wavelengths at which it absorbs light when it is adsorbed to the grain. The colour of the dye, when the latter is present as a close-packed layer of molecules on the surface of a silver halide grain, owes something to the close packing; it shows a marked absorption band at a higher wavelength than the absorption characteristic of the separated dye molecules. Thus, for efficient dye sensitization it is important to achieve a continuous layer, one molecule thick, over the grain surface. This layer of close-packed dye molecules can act as a conductor for light energy, allowing the excitation from an adsorbed quantum to be felt over a large area of grain surface, thus increasing the probability of a fruitful reaction with the silver halide. G.I.P.L.

SENSITOMETER. Instrument used in recording the response of a light-sensitive material to a range of exposures. There are two types of sensitometer; one which subjects the sample of material to a series of lengthening exposures under a light of constant intensity, and the other which exposes adjacent strips of the material for the same length of time to a range of light intensities.

See also: *Sensitometry.*

SENSITOMETRY

The science of sensitometry may be said to be founded upon a paper by Hurter and Driffield entitled *Photochemical Investigations and a New Method of Determination of the Sensitiveness of Photographic Plates*, published in 1890. Today the name is often used to describe the testing of photographic materials.

Sensitometry seeks to establish accurately the relationship between exposure and density for any given photographic material. (In sensitometry, exposure is the product of intensity of light and time of exposure, not just the time of shutter speeds as in common parlance.) This relationship between exposure and density is often very difficult to define in words and such indefinite terms as "high speed", "low contrast" and "poor blacks", etc., have a very limited use. The chief aim of sensitometry is to derive accurate numerical values for the exposure-density relationship of a material to enable guess-work to be eliminated and the results stated in units which can be universally applied and compared.

Many sensitometric standards have now been set up by the British Standards Institution and the American Standards Association as well as standards organizations of other countries, and sensitometry has become almost indispensable both to the scientific and the practical photographer.

Sensitometry is used mainly to measure the effects of the visible spectrum, ultra-violet, infra-red and X-rays, but some work is also carried out with gamma-rays, electrons and nuclear particles.

A sensitometric test on a given sample of light-sensitive material starts with subjecting the material to a series of standard exposures in a sensitometer. It is then processed under controlled standard conditions. Then the sample is examined in a densitometer which measures the densities recorded on the material. Finally a characteristic curve is plotted from the readings obtained in the densitometer. This curve shows the density values on a base of log exposure and provides a complete descrip-

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

tion of the response of the sensitized material to exposure and processing.

Control of Conditions. For sensitometry to be of maximum value, especially to the practical photographer, it is generally essential for the conditions to be identical with those used in practice. When this is difficult, a correlationship can sometimes be established between the results obtained under the sensitometric conditions and those obtained in the type of work concerned.

The spectral sensitivity of many photographic materials differs from that of the eye. There are four main photographic sensitizings available, blue (ordinary), orthochromatic, panchromatic, and infra-red, and in each of these groups, and sometimes between different manufacturers in the same group, there may be minor differences according to the exact requirements. Because of these factors it is very important that the colour temperature of the light source is suitably chosen when making a sensitometric test.

The exact method of exposure—i.e., whether by an intense light for a short time or a weak light for a long time, and whether steady or intermittent—is extremely important because of the reciprocity failure of photographic materials; the density obtained depends not only upon the product of intensity and time, but upon their individual values. In practice exposures vary widely because of the great differences in light intensity encountered; the astronomer may expose for hours, the studio photographer for seconds, and the sound-recording engineer for 1/50,000 second, while an electronic flash may only last a few millionths of a second.

SENSITOMETERS

The sensitometer is the instrument used to give the sensitized material under test a series of controlled exposures. It consists essentially of a light source, a method of modulating the exposure and a holder for the material being tested.

The Light Source. The unit of luminous intensity adopted within the last few years is the candela. This unit is based upon the light intensity emitted by solidifying platinum and only differs slightly in value from the international candle previously used. It is too inconvenient to use such a light source in a sensitometer and in any case the colour temperature of solidifying platinum is too low for most photographic purposes; correction filters would have the disadvantage of cutting down the light. Secondary standards, in the form of electric tungsten filament lamps, are set up by such bodies as the National Physical Laboratory in England or the Bureau of Standards in the United States of America. In commercial sensitometers, carefully selected and aged Class A projector bulbs are used,

being under-run to increase their life. These lamps are usually fed by a D.C. supply because of difficulties arising from the fluctuations in intensity with A.C. supplies. The supply voltage has a marked effect on the light intensity, so it has to be very accurately controlled.

It is very important to control the spectral energy distribution or colour temperature of the light source. Within limits the colour temperature of electric filament lamps may be controlled by varying the voltage across the lamp, but colour temperatures above 3000° K cannot be obtained without considerably reducing the stability and the life of the lamp. Further control of the colour temperature is achieved by light filters known as photometric filters. By their use the light from a stable filament lamp can be adjusted to the required colour temperature. The characteristics of such filters depend on the colour temperature of the source. They may be made of gelatin, glass, or they may be liquid filters. Of the three types, gelatin filters are usually the least accurate. To reproduce

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

daylight, the filter used is the Davis-Gibson liquid filter employed in the BSI and ASA speed systems.

Here a tungsten lamp working at 2360°K in conjunction with the filter gives a colour temperature of 5400°K, referred to as artificial mean noon sunlight.

Modulation of Exposure. The exposure received by any photographic material is dependent upon the product of the time of exposure and the intensity of the light. Consequently, exposure can be modulated either by a time scale or by an intensity scale.

Although time scale modulation is not very common in practical photography, time scale sensitometers are quite frequently used. This is because they are, perhaps, easier to make than intensity scale instruments and within certain limits the reading can be correlated with the intensity scale used in practice. Such instruments are often used for batch control of any one grade of sensitized material where any variations in sensitometric properties are likely to be small.

A common method of time modulation consists firstly of inserting between the light source and the material under test an opaque disc (called a sector wheel) from which has been cut out a series of accurately measured slots of varying length. On rotating this sector wheel at a constant speed for one revolution the material is exposed in strips for a series of times which depend upon the exact contour of the cut-out.

One well-known commercial instrument, widely used in the cine trade, uses a rotating drum instead of a sector wheel. In this case the drum carries a cut-out which gives a series of twenty-one stepped exposure times, each time being $\sqrt{2}$ longer than the previous one. The drum is horizontal and the light enters the inside of the drum and is reflected upwards by a mirror, through the cut-out, on to the material under test.

INTENSITY SCALE SENSITOMETERS. Top: *Goldberg wedge, of neutral dyed gelatin cast between two inclined glass plates.* Bottom: *Falling plate sensitometer.* A, *shutter consisting of plate with slot.* B, *wedge.* C, *sensitive material.*

An obvious method of setting up an intensity scale is either to expose adjacent strips of the material to light at varying distances or to cover the light with apertures of varying sizes. In both methods the intensity scale is governed by the dimensions of the apparatus. Neither system is very convenient, however, especially as it is desirable to make the whole range of exposures simultaneously on to a single sample of material of reasonable size. Sensitometers based on a range of apertures have been made, but the most common method of obtaining an intensity scale today is to expose the sample under test through a wedge of light-absorbing material.

A typical example is the Goldberg wedge which consists of a wedge of gelatin, containing a neutral colouring material, cast between two glass plates. The greater the density or thickness of the wedge the lower the intensity of the light reaching the material. This is a continuous wedge. Discontinuous or step wedges, where the density increases in discrete steps, are also in common use. The rate of change of density per centimetre in the case of a continuous wedge or the density increase per step in a step wedge is known as the wedge constant. The selection of the wedge constant varies with the job in hand, but for use with negative materials a typical step wedge might have a density range of three, comprising thirty steps, each step having a density 0·1 greater than the previous one. Silver wedges made by the photographic process are frequently used to-day. A section of the wedge may be covered by colour filters so that the spectral sensitivity of the material may also be studied.

Intensity scale sensitometers in addition to the step wedge require an accurate shutter to determine the exposure time that the whole wedge receives. If the exposure time is long, say 30 seconds, then it can be manually controlled fairly accurately, but when the time becomes short—e.g., 1/25 or 1/500 second—an automatic shutter is called for. There are three commonly used shutters: a sector wheel carrying a single wide slot, a falling plate shutter in which a heavy metal plate with a slot in it is allowed to fall under gravity, and a pendulum shutter in which the exposure is timed by allowing a pendulum carrying a disc with a radial cut-out to swing from a fixed distance.

Processing the Material. After exposure in the sensitometer the material must be processed in a uniform and reproducible manner. The development stage in particular has to be carefully controlled for time, temperature and degree of agitation. To reproduce the time and temperature of development used in practice is simple, but to ensure constant and suitable agitation of the developer is less easy. In practice development may be carried out in a deep tank with negligible agitation, in a dish

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

STANDARD DEVELOPMENT. For the B.S. method of sensitometric development the test material, strapped to a glass strip, is constantly and thoroughly agitated inside a vacuum flask containing the developer at standard temperature.

with poor agitation or perhaps in a machine with vigorous agitation. Here it is sometimes better to set up a correlation between laboratory conditions and practical conditions, choosing reproducible laboratory conditions.

In the laboratory, processing is sometimes carried out in a machine in which the sensitometric strips are fastened around a cylindrical drum. This drum is then rotated at a controlled rate in a cylindrical developing bath, the diameter of which is only slightly greater than the diameter of the drum. The agitation is increased by baffles on the inner surface of the developing tank. After development, the drum, still carrying the strips, is transferred first to a stop bath and then to the fixer, both of which are in vessels similar to that used for the developer. All solutions are thermostatically controlled by means of a surrounding water jacket.

Another carefully controlled method of development is that described by the British Standards Institution and the American Standards Association for the determination of speed. Here the development is carried out in a vacuum flask which is agitated systematically.

Fixing and drying conditions should also be constant.

DENSITY MEASUREMENT

After the material has received a series of exposures in the sensitometer and has been processed, it is necessary to measure the degree of blackening, or density, which corresponds to each of the known exposures. Quite a reasonable estimate of density may often be made visually by comparing the processed material with a wedge of known density values, although this method is not very accurate for very low or for high densities. For example, transmission densities between 0·1 and 0·5 can be estimated visually, with a little practice, to within ± ·02.

It is, however, often essential to have a precision instrument capable of measuring a wide range of transmission and reflection densities both accurately and quickly. Such an apparatus is known as a densitometer.

Transmission density (of negatives, etc.) is defined as the logarithm of the ratio

$$\frac{\text{incident light}}{\text{transmitted (emergent) light}}$$

reflection density (from a paper print) is defined as the logarithm of the ratio

$$\frac{\text{incident light}}{\text{reflected light}}$$

From this it will be seen that the densitometer must be able either to measure light intensities or, more often, to be able to adjust two light intensities so that they are equal. When the apparatus is used for such measurements of light in general, it is known as a photometer, but when adapted to the measurement of densities it becomes a densitometer. It is possible to tell when two light intensities are equal by adjusting the instrument so that the two resulting light fields are equally luminous when seen alongside each other in the eyepiece of the photometer.

The transmitted or reflected light must be measured in a special way if the resulting density measurements are to be of value, and diffuse densities are therefore normally employed. In the case of transmission density, the diffuse density based on the total light transmission is measured. This is because diffuse density is well defined optically whereas specular density, based on the portion of the transmitted light that passes through in a straight line, depends upon the optical details of the particular process concerned.

The densities used, for example, in contact printing are diffuse whereas in a condenser enlarger they are specular. When looking at a photograph it is the diffuse densities that are important and it is necessary to keep specular reflection to a minimum in order to avoid glare.

Diffuse transmission densities are readily obtained by placing the area to be measured in contact with a piece of opal glass. In measuring diffuse reflection densities in a reflection densitometer, the principal specular reflection is avoided by allowing the incident light to fall on the sample at an angle of 45° and measuring the light reflected at 90° to the surface.

Visual Densitometers. In one of the simple forms of densitometer a photometer head is used to determine when two beams of light from two similar lamps are of equal intensity. The density to be measured is inserted into one beam and into the other beam is placed a continuous wedge the density of which is known at each point. The position of the wedge is adjusted until the fields balance. At this point the unknown density is equal to the known

density of the wedge. The value can then be read from a scale on the instrument. If the density being measured is low, the intensity in the eyepiece will be high, whereas if the density is high the intensity will be low; for this reason such a densitometer is described as a variable intensity type. These instruments are by no means ideal because at low densities the eye is dazzled and at high densities the light is so feeble that the matching of the photometric field becomes difficult.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Another class of visual densitometer works at constant intensity, a well-known example being the Capstaff-Purdy instrument for measuring transmission densities. In this case one lamp is used and its light is split into two beams. One beam, suitably diffused to make it uniform, reaches the photometric head by reflection from mirrors. This is the reference beam and as such remains constant. The second beam of light passes first through a calibrated wedge and then through the unknown density before it reaches the eyepiece. The intensity of the reference beam, when the photometric field is balanced by adjusting the wedge, is equal to the intensity of the other beam after passing both the unknown density and the density of the wedge at the point of balance. It is then simple to calibrate the wedge so that the density value of the unknown sample can be read directly. With this type of instrument continual adaptation of the eye is not necessary and the sensitivity is constant over the whole range. The accuracy of this densitometer depends on the ability of the operator to balance the photometric field and on how carefully the wedge is calibrated.

Photo-electric Densitometers. Visual densitometers are rather slow and tiring to use and sometimes not sufficiently accurate. These drawbacks have been largely overcome by the design of photo-electric densitometers. In these instruments the balancing of the two light intensities can be carried out by means of a photo-electric cell instead of by the eye.

CAPSTAFF-PURDY DENSITOMETER. The unknown density is balanced against a constant one with a calibrated wedge. A, eyepiece. B, semi-reflecting mirror. C, unknown density. D, wedge. E, lamp. F, mirrors.

In one commercial densitometer the light transmitted by the test density falls on to a self-generating barrier layer cell. The current generated, which is proportional to the light intensity, is passed to a micro-ammeter calibrated in densities. Another instrument employs a photo-emissive cell coupled to a valve amplifier for the same purpose. E.F.T.

In another type of densitometer the current generated by a photo-electric detector is passed through a resistance, and the voltage across this resistance is balanced against a reference voltage on a potentiometer whose slide is calibrated in density. Photo-electric densitometers can generally be adapted to measure reflection density.

Recording Densitometers. In the manufacture of sensitized materials and in many photographic processes it has become essential to be able to plot numbers of characteristic curves accurately and quickly. Recording densitometers automatically plot such characteristic curves on to a sheet of graph paper.

There are two main types for use in conjunction with step or continuous wedge sensitometers. Step wedge samples are measured on a step densitometer which can consist of a visual or photo-electric densitometer with its manual adjustment control coupled mechanically to a recording pen instead of (or as well as) giving a scale indication. A table or drum holds the graph paper and moves it under the pen. The mechanical gearing from the manual control to the pen is arranged to calibrate the ordinate of the graph paper in density.

The table movement is coupled to the movement of a strip holder in which the sample step wedge is placed. In one action of a control the sample is moved by one step and the table moves a distance (measured on the abscissa of the graph paper) equal to the wedge constant of the exposing wedge, i.e. the abscissa is calibrated in log exposure. For each step of the wedge in turn a balance is obtained on the densitometer by the operator who then lowers the recording pen on to the graph paper to produce a series of points. These can be joined up to form the characteristic curve of the sample material.

Samples exposed in a continuous wedge sensitometer can be measured on a densitometer whose pen automatically plots the complete characteristic curve. A common design of continuous recording densitometer employs a beam chopper. This is a disc of transparent material divided into equal segments which are alternately left clear and silvered. The chopper rotates at high speed in front of a lamp so as to send alternate beams of light along the sample path and a reference path. The two beams are finally focused on the same photo-electric detector whose output is, therefore, a square-

wave of frequency equal to that of the beam chopper and amplitude proportional to the photometric difference between the reference and sample beams. The signal is amplified and can be used to drive a recording pen or, alternatively, it can be used to drive a servo-operated measuring wedge in either beam to adjust the amplitude to zero. This measuring wedge is coupled to a recording pen which draws out the characteristic curve of the material as the sample wedge and graph paper are moved continuously. The movements of the sample and the graph paper are linked according to the wedge constant of the exposing wedge. R.N.W.

APPLICATION OF RESULTS

Once the characteristic curve has been plotted, various parameters such as speed, gamma and fog can be evaluated.

Particular care has to be taken to ensure that the values derived from the curve are those significant to the process concerned. Sensitometry aims at replacing, at least in part, the skilled observer. The human eye, however, is very sensitive, and the practised photographer, comparing prints for example, can detect differences that are not easily evaluated sensitometrically unless the parameter used is carefully derived from the exact part of the characteristic curve concerned. The H. & D. speed, for example, is of little value to the press photographer when he has to work under very adverse lighting conditions and is only likely to expose on the toe of the characteristic curve; here the DIN speed is far more valuable. On the other hand, a worker in photo-mechanical reproduction is often concerned with the speed at the shoulder of the curve. A similar argument holds for contrast. One process may place more importance on the straight line portion of the curve, whilst others may be governed by the average slope of the toe or the shoulder.

In particular, sensitometry is one of the most powerful tools available to the research worker and is in constant use for investigations into the theory of the latent image, of development and of emulsion manufacture.

In Manufacture. The photographic emulsion on its support of film, paper or glass is an extremely delicate system and considerable vigilance is required to maintain the high degree of reproducibility from batch to batch that is found today. In controlling manufacture and testing the finished product, sensitometry is extensively used for obtaining precise figures for speed, contrast and fog. These figures for the finished product must fall within predetermined limits or the material is rejected.

Determining Speed. Sensitometric measurements form the basis of all methods of exposure determination because to arrive at the exposure required for any particular photograph it is necessary to know the speed of the sensitive material being used. The speed is derived sensitometrically in terms of H. & D., Scheiner, DIN, B.S. and A.S.A. units, etc.

Tone Reproduction. A paper print is often the aim of the photographer. In order to obtain the best possible tone reproduction the photographic process has to be well analysed. This has been done very successfully by a method first suggested by L. A. Jones. By considering in turn the luminosity range of the subject, the luminosity range of the image formed by the lens, and the negative and positive characteristic curves, it is possible to build up a tone reproduction diagram of subject luminosity plotted against print density.

Reversal Processes. The latitude of reversal films is increased by either using solvent developers or the method of controlled second exposure. Here the initial image is bleached out and the final positive image is obtained by fogging and developing the remaining silver halide. Without sensitometric control at each stage these processes would become almost unworkable.

Duplicate and Copy Negatives. It is often necessary to prepare duplicate negatives or negatives of a contrast differing from the original. A knowledge of the appropriate sensitometric values of a suitable range of materials enables this to be done without any guesswork and reduces waste to a minimum. This includes deriving the correct exposure time from the known exposure required through a given density.

Cinematography. In a sound film the picture and sound track have each to comply with certain conditions even though they are developed together—i.e., the picture must be uniform and suitable for projection, and the sound track, whether variable area or variable density, has to give the correct pitch, intensity and timbre, and be as free as possible from background noise. In addition a negative-positive process is involved and many duplicates of the film have to be prepared. Here, sensitometry is needed at each stage.

Processing. Characteristic curves provide a convenient way of comparing different developer formulae for speed and contrast. In large-scale developing baths, sensitometric control strips are used together with chemical analysis of the developer to determine the most effective and economical way of replenishing the bath in order to keep its activity constant as more and more material is developed.

By drawing characteristic curves, photographic reducers or intensifiers can be examined and divided into various groups according to the way in which they affect the various density levels. Reducers, for example, may be quickly classified as subtractive, proportional or superproportional. Some intensifying solutions alter the colour of the image with the result that the printing density is different from the visual density because of the difference

between the sensitivity of the emulsion and that of the eye. This aspect of photographic photometry, as it is called, can be evaluated sensitometrically.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Colour Photography. Sensitometric control enters into colour processes at many stages. With the most common colour materials, the subtractive integral tripack films, the three sensitive layers must be suitably balanced during manufacture.

The film is prepared so that the speed to blue of the blue-sensitive layer is the same as the green speed of the green-sensitive layer and the red speed of the red-sensitive layer. That condition must hold good over the whole scale of gradations the film can record; in other words, the gammas of the coloured images obtained must be virtually the same for all three layers when developed together for a fixed time.

Separation negatives also need sensitometric balancing to ensure correct colour reproduction. In practice this is best achieved by photographing on each separation negative a step wedge of known and increasing neutral densities at the same time as the subject. If the effective densities of each step (as measured on the coloured positives through a complementary filter) are identical, the component colour densities will balance and the wedge appears grey. For complete balance, the densities must be identical along the whole range. In other words, a curve plotting the density of each step on the positive as a function of the density of the corresponding steps on the original wedge must be a straight line for each positive. In addition, each curve must have the same slope, namely 1·0.

Although the whole cycle of negative—silver positive—colour positive must yield a correct set of wedge curves, the individual steps do not have to correspond. Thus the blue separation negative may have a lower gamma and be compensated in printing, or the positives may have different gammas if the method of dyeing makes this necessary. E.F.T.

SEPARATION NEGATIVES

It follows from the principles of colour photography that the complete range of colours can be reproduced by first analysing them into three black-and-white records, one to represent the reds in the subject, one the greens, and the third the blues.

Such analysis records can be made by making three separate exposures of a subject through red, green, and blue colour filters respectively, upon panchromatic emulsions. The three negatives obtained in this way are called colour separation negatives, because in them the spectrum has been separated into three parts.

The three colour records can then be synthesized into a colour print by printing the red record in a minus red colour, blue-green (cyan), the green record in a minus green colour, magenta, and the blue record in a minus blue colour, yellow. The three coloured images when superimposed will give the colour print showing the subject in more or less its original colours.

After printing the colour separation negatives, the three resulting colour records have to be superimposed to reform the picture into colour. The three colour component images must therefore be exactly the same size and shape, otherwise they would not register properly and the picture would show colour fringes.

Separation negatives used to be the basis for specialized assembly colour printing processes such as dye transfer. They are of course still the main method of printing plates or blocks for photo-mechanical printing.

Separation negatives can be made either direct from the subject or from colour transparencies. The former system gives the best results, but obvious practical problems limit its usefulness. The procedure of exposing separation negatives is therefore hardly ever used nowadays. Almost the only exception is the photo mechanical reproduction of paintings—where the original painting can be placed at the disposal of a graphic arts department.

It is still possible to take excellent separation negatives of still live subjects by making three successive exposures in an ordinary camera. There must be no movement either of the subject or the camera, otherwise the negatives will not register properly.

Few photographers use this procedure, since it is easier to take the picture on a colour transparency material. For the same reason one-shot colour cameras and repeating backs have been completely displaced by colour transparency materials as a starting point either for making separation negatives or for printing on multi-layer colour materials.

BASIC PRINCIPLES

The Three Colour Records. Colour prints are made by using three printing colours which are the complementary colours of the filters used when exposing the negatives.

A particularly bad habit which is unfortunately common in the printing trade is to call the magenta and cyan printing colours red and blue respectively. By using the C-M-Y terminology for the printing colours there can be no confusion.

TAKING AND PRINTING COLOURS

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Colour Filter for Exposing Separation Negative	Complementary Colour Reflects	Name of Complementary Printing Colour
Red (R)	Blue and green	Cyan (C)
Green (G)	Red and blue	Magenta (M)
Blue (B)	Green and red	Yellow (Y)

Equipment. For successively exposed separation negatives of static subjects the camera must be sufficiently rigid to remain set in exactly the same position while all three negatives are exposed. A very firm tripod is of course essential. The dark slides must be accurately made so that each slide holds the sensitive material in exactly the same plane.

Colour Filters. Separation negatives are almost invariably made on panchromatic material through red, green, and blue colour filters. The hues of the tricolour filters have been fixed for many years, although the exact depth of the filters varies slightly from maker to maker. One maker's filters will work perfectly well with another maker's sensitive material when taking separation negatives direct from the subject, although the filter factors will probably vary.

For colour separation work, it is generally better to use the inexpensive gelatin filters than glass filters of possibly doubtful quality glass.

When making successive exposures, the filters must be held in front of the camera lens by means of a holder which allows the filters to be changed without moving or shaking any part of the camera.

Filter Factors. The manufacturers of plates and films give approximate filter factors for each of the tricolour filters with their various materials. Although quite useful as a guide, these factors can only be accurate if they were determined under exactly the same conditions as will be used for making a particular set of separation negatives.

The reasons for this are as follows:

(1) The colour temperature of the light source may be different from that used by the manufacturer.

(2) The published filter factors are generally based on the same time of development for all three colour records, whereas in most cases the separation negatives need somewhat different times of development.

(3) The exact depth of colour filters varies from batch to batch.

(4) There are variations in colour sensitivity between batches of emulsions.

(5) Reciprocity failure may change the effective sensitivity of the material at different exposure levels.

Filter Ratios. In the past it has been usual to give filter factors, which by definition are relative to the unfiltered (white light) exposure. But now it is becoming increasingly common to speak only of filter ratios—that is, the ratio of the three filtered exposures relative to one of them.

For convenience, one of the three exposures —often the red filter record, being the shortest of the three—is taken as unity. But many workers prefer to consider the green exposure as unity, because the green filter negative looks most like a normal black-and-white negative, and its quality is more easily judged.

With filter factors of 3, 6, and 12 for the R, G and B exposures respectively, the ratios would be 1, 2 and 4, relative to the red, or ½, 1, and 2 when the green is taken as unity.

As reciprocity failure may upset the balance of filter factors when the exposure times are changed, it is preferable to work with the tricolour filters balanced to 1 : 1 : 1 ratios; then all three exposures are always of equal duration.

Tricolour filters can be balanced by adding a suitable neutral density filter to each of the two filters with the lower factors. Each of the three exposures then becomes as long as the longest. Neutral density filters are available in various depths, in increments of approximately 0·05 of density, up to a density of 1·00 (multiplying the exposure 10 times).

For quantity work it is well worth balancing the filters to 1 : 1 : 1 ratios. In some cases, the manufacturers will supply special tricolour filters with the neutral density of the required depth incorporated.

Materials. Plates have always been a good choice for colour separation work, because they cannot shrink or distort and give trouble with register. Nowadays however film is more popular and modern film bases of high dimensional stability (such as polyester) are perfectly satisfactory. Some care is needed to see that each of the three separation negatives receives exactly the same treatment as far as the total time of wet handling and the orientation of the picture when drying is concerned.

A medium speed panchromatic emulsion is the most suitable since it has a long tonal scale. Most manufacturers offer materials specially suitable for making colour separation negatives, sometimes designed to give substantially equal contrast on all three colour records with the same time of development.

Negative Balance. The three separation negatives must naturally bear the correct relationship one with the other, so that they can reproduce the various colours in their correct proportions.

The fundamental requirement of separation negatives is that any neutral present in the original (such as a white, or a grey, or a black) should be reproduced as an identical density on each of the three negatives. This assumes the absence of any colour cast.

A grey scale can be made with pieces of bromide paper, one white (unexposed and fixed out), several greys (lightly fogged and

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

developed), and one black (well fogged and developed). When exposing the separation negatives, the grey scale should be placed so that it is recorded somewhere near the edge of the negatives, but lies just outside the subject matter being photographed. The lighting on the grey scale should as far as possible be the same as on the subject.

The exposure and development of the separation negatives must be adjusted to give as near as possible identical reproduction of the grey scale on each of the three negatives.

Identification. When printing a set of separation negatives, it is of course necessary to know which is which colour record. To identify the negatives include three colour patches, red, green, and blue (marked R, G, B) in the subject, alongside the grey scale. When reproduced on the negatives, one of the three patches will appear dense, this patch indicating which colour filter was used for that negative. For example, in the green filter negative, the green patch will appear heavy, and the other two will be light.

Alternatively use patches of cyan, magenta, and yellow colours. In this case the lightest patch identifies the negative.

The colour patches can be made by using poster colours, and can be painted alongside the edge of the grey scale.

Some makers supply colour separation guides which contain a grey scale and identification patches already made. However, most photographers prefer to make their own in various sizes to suit different types of subject.

Lighting and Exposure. Lighting for colour separation negatives is basically similar to lighting for any other colour work. But where the picture is to be reproduced as a paper print, it is best to avoid harsh contrasts of lighting. All lights on the subject must be of the same colour temperature, or else some of the light will photograph either too blue or too orange.

The filter factors will vary according to the colour temperature of the light. The lower the colour temperature, the redder the light, and so the red filter factor becomes lower and the blue higher. By standardizing on a particular type of light source, the filter factors will always be the same under given conditions.

Colour separation negatives need correct exposure because colour prints show up errors in the negatives that would pass unnoticed in black-and-white work.

Inaccurate filter factors reduce the exposure latitude for the set of negatives. This is because some of the available latitude is used up by the filter factor error on one (or two) of the negatives.

Processing. The three negatives must receive even development to the correct degree of contrast.

Dish development gives the most even results. Three small plates can be developed at the same time, either in a dish with a separating case in addition to prevent them sliding over each other, or in three separate dishes side by side on a rocking platform. The three colour records are always kept in the same order in the dishes, so that each may receive its correct development time. The darkroom temperature should be as near as possible the same as the developer temperature.

First bring the dishes up to the correct temperature with water. At the same time, bring enough developer for all three negatives to the same temperature. Then pour the water from the dishes and divide the developer equally between all three.

The three negatives of a set should always be developed at one operation and receive identical treatment (except of course for times of development) to avoid variations in temperature, agitation, etc. A visible darkroom clock is essential to ensure accurate timing.

Most non-staining developers are suitable, the most common being a metol-hydroquinone developer fairly well diluted to bring the developing times to more than about five minutes. Shorter times are difficult to time accurately.

The developer should be used once only, and then discarded. By using fresh developer for each set of negatives, it is possible to standardize the degree of development quite accurately.

Development Times. Each of the three negatives of a set must be developed to the same degree of contrast. As the colour filters affect the contrast, the three negatives will almost certainly need different development times. Usually the red and green filter records are fairly well matched for contrast and need similar development times. But as the blue filter lowers the contrast, this negative needs increased development to bring the contrast up to the level of the other two.

If no information on processing conditions for a particular material is available, begin by making a suitable green record negative by trial and error. When this is satisfactory, use it as a guide to the others. It is usually safe to give the red record negative the same development time as the green, or a little less, and the blue about 25 per cent more for a first trial.

Checking the Balance. Having made a trial set of negatives, hold them side by side over a light box, and check the balance by comparing the grey scales, one with the other.

A more sensitive method of comparison is to print all three negatives together on one sheet of normal bromide paper. Cut out the prints of the three grey scales and compare side by side for equality of density and contrast. When the negatives are properly balanced, the grey scales will be identical on each.

The best and most scientific method of checking the balance is to measure the densities with a densitometer.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

When a densitometer is available, first make gamma-development time curves, and from them find the development time for each colour record to give the desired gamma. For separation negatives from original subjects, a negative gamma of about 0·80 will be required—the exact value depending upon the colour printing process and technique to be used, and on the optical system of the enlarger. A condenser enlarger calls for softer negatives than a cold cathode or diffuser enlarger, or than contact printing. At the gamma value given, the difference between the maximum and the minimum density on the reproduced grey scale will be approximately 1·05.

Having found the correct development times, make a trial set of separation negatives at what are believed to be the correct filter factors. After processing, check the grey scale density readings for equality between the three negatives. If necessary, amend the times, and make another trial set of negatives.

The green record negative, already judged to be correct, provides a standard against which to judge the changes to be made in exposure (to alter density), or in development time (to alter contrast), to improve the balance on future sets of negatives.

For example, if the three negatives are of equal contrast but of different densities, they have received the correct times of development but the filter factors need modification. But if one of the negatives is flatter than the others, it will need more development.

Slight variations in density between the grey scales on the negatives are tolerable and can be corrected in printing. But differences in contrast are much more difficult to correct without upsetting the colour printing technique.

SUBTRACTIVE TRANSPARENCIES

Separation negatives from colour transparencies will not give quite as good prints as negatives exposed directly on the subject. There is, however, the advantage that once the transparency has been prepared, all the work of making the separation negatives can be performed at leisure in the darkroom.

A transparency prepared for subsequent separation should appear of somewhat soft gradation, and slightly heavy, judged by normal transparency standards. The subject should be softly lit, and the transparency should receive about half a stop less exposure than usual.

The coloured image of a subtractive transparency consists of a combination of a yellow, a magenta, and a cyan image, representing respectively the blue, green, and red colour records. When making separation negatives from the transparency, each negative should ideally record only one of the three coloured images. For instance, the red record negative should record the cyan of the transparency, and nothing from the other two colours.

MOUNTING THE TRANSPARENCY. This is taped to the front glass of the printing frame, together with a step wedge, identification colour patches, and a registration mark.

Unfortunately this is never quite possible. All dyes are so impure that the red, green, and blue filters used for exposing the separation negatives cannot sort out one of the coloured images without also recording something of the other two.

So separation negatives made from transparencies tend to show some loss of colour saturation, and also some tone distortion because they are "copies of a copy". They can never be quite as good as negatives made directly from the subject.

Furthermore, all the commercially available transparency materials are made primarily for viewing, and their contrast is rather great for easy reproduction in separation negatives.

All but the softest transparencies therefore need masking to reduce the contrast before making the negatives. Owing to the imperfections of the dyes in the transparency and of the pigments used in most tricolour printing processes, colour corrected masks are generally used to obtain the best colour reproduction. Certain cases may even call for tone correction by means of highlight masks if the original transparency is very light.

Often it is considered more convenient to use unsharp masks because with them registration of mask and transparency is less critical.

Masking Procedure. Masks are almost invariably printed by contact from the transparencies. A robust printing frame should be used and, to ensure good contact, a sheet of firm ⅛ in. thick sponge rubber should be placed between the plate and the back of the frame.

An easily standardized set-up which is convenient for contact printing masks and separation negatives is an ordinary 60 watt pearl bulb in a pyramid type 8 × 10 ins. safelight, which is suspended 36 ins. above the work bench so that the printing frame may be placed immediately below it. (For transparencies

larger than about 3¼ × 4¼ ins., this distance should be greater, say 6 feet, and the exposure times lengthened accordingly.) In the safelight is fitted an opaque screen with a 2¾ ins. square aperture cut centrally in it. A piece of flashed opal glass is fitted over the aperture.

CC-BY. Adamnigam Digital Preservation Foundation Chandigarh

Provision must be made for holding 3 × 3 ins. colour filters over the aperture by fitting a slide into which each filter can be placed in turn. The filters should be fixed in a simple cardboard mount or held between two pieces of glass, with the desired size of aperture.

The lamp should not be left on unnecessarily, since the filters may be damaged by the heat.

Mount up the transparency, emulsion side down, with very thin adhesive tape on the glass of the printing frame and place a step wedge alongside. This wedge should be made by photographing a grey scale on the same type of transparency material. Any other type of wedge is not a reliable guide to colour balance in the final print (although it would of course be a useful guide to contrast). Mount small patches of tricolour filter, each marked with the initial letter R, G or B, alongside the wedge to assist identification of the separation negatives. The clear glass around the transparency, etc., is then masked off with black adhesive paper on the other side of the glass.

Expose the mask on a medium speed panchromatic emulsion. Plates are sometimes preferred to film, because glass plates cannot shrink so they give masks exactly the same size as the transparency, thus assisting registration. However, it is essential to maintain reasonably constant humidity or the transparency itself may change size slightly by shrinking or swelling.

CONTACT SEPARATIONS. Set-up for contact printing of masks and separation negatives. A, pyramid safelight housing. B, 60 watt pearl lamp. C, flashed opal sheet. D, opaque screen. E, colour filter in simple mount. F, printing distance: 36 ins. for small transparencies, 72 ins. for large ones. G, printing frame, with transparency and negative material for separation.

The mask is normally exposed through a red filter. When the two-mask system is used, one mask is exposed through a red filter, and another through a green filter.

Develop the mask to the very low gamma of about 0·35. As a guide: medium to fast emulsions will reach this gamma with about 3 to 4 minutes development at 68° F. in D.76 diluted 1 to 1, developed in a dish with continuous rocking in all directions.

A correctly exposed and developed principal mask will show detail in both highlights and shadows, but it will simply look like a low contrast negative. In general, the correct exposure for a principal mask (i.e., not a highlight mask) is the least that will record the shadow detail of the transparency.

To register the transparency, wedge, and identification patches, with the finished mask, they can best be manipulated over an illuminated ground glass, and a weight used to hold the transparency on the mask while the register is adjusted and checked with a magnifier. When register is correct, fix the transparency to the mask with adhesive tape, and fix the wedge and identification patches similarly in place on the mask. The mask plate is then blocked out, preferably with opaque medium which is physically thin and will not affect contact with the sensitive plate.

Using the normal single mask technique, the same mask is of course used when making all three separation negatives.

When the double mask technique is used, the red and green filter separation negatives are made with the red light mask, and the blue filter separation with the green light mask.

Exposing the Separation Negatives. The three separation negatives are made by printing the masked transparency on panchromatic plates, using red, green, and blue filtered light. The filters must be suited to the type of transparency material. In general, the manufacturer will recommend filters which have relatively narrow spectral transmission bands—so-called narrow-cut separation filters—with peak transmissions to match the spectral characteristics of the transparency material.

The three filters are preferably brought to 1 : 1 : 1 ratio of exposure times by masking down the area on the two filters with the lower factors. By adjusting the filters in this way to give equal exposures, the whole working procedure is greatly simplified. The exposure time can be adjusted to match the density of the transparency.

Expose the separation negatives with the printing frame on the bench under the light

source, in exactly the same position and the same way round in each case. This avoids trouble from uneven illumination.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The correct exposure time for an average density transparency is first found by trial, after which the most suitable exposure for other transparencies is estimated by eye, or by measuring the average density of each transparency.

If one transparency passes twice as much light as the standard, it should be given half the standard exposure.

A densitometer may be used to measure the average densities—that is, half of the sum of the minimum and maximum densities—of both the standard and the new transparency, the exposure then being determined from the normal density—transmission relationship—that is, each 0·30 increase in average density requires a 100 per cent (2×) increase in the exposure.

In the case of a transparency with a large brightness range, it is almost always best to expose to suit the highlights, even at the expense of losing the shadows. However, it will generally be found that the mask reduces the contrast enough for the transparency to be properly reproduced on the negative material without undue loss of quality.

The transparency must be graded for density when determining the mask exposure, and again for the separation negative exposures by reading the transparency plus the mask, compared with the standard transparency plus its mask.

Printing Negatives by Projection. It is generally preferred to make enlarged separation negatives from miniature size transparencies, since most workers find the larger negatives easier to handle.

However, it is more difficult to make good separation negatives by projection than by contact printing.

Projection printing inevitably brings in trouble from flare in the lens degrading parts of the wide brightness range of the transparency. This is most noticeable if one colour dominates in the picture. Conventional enlarger optical systems cause some loss of sharpness, particularly with a diffused light source. Condenser enlargers with small source lamps can reproduce all the fine detail in the transparency but will emphasize any scratches as well. And there is the difficulty of heat affecting the transparency.

In an enlarger fitted with the usual tungsten lamp, the density of the sharp-cut tricolour filters makes for long exposures, and a film transparency may heat and distort, or lose register with the mask, during the making of the three negatives. However, a well ventilated enlarger fitted with efficient heat absorbing glasses can be used. An enlarger with a cold cathode light source is even better as regards cool working, although it is less suitable for miniature transparencies as the diffused light source tends to give slightly less sharp results than a small source with a condenser.

A convenient method of projection printing the separation negatives in ordinary room light is to illuminate the transparency by a projection lamp in a horizontal enlarger with the lens removed. A diffuser may be placed immediately in front of the lamp, but the system must be set up to give even illumination first. Photograph the illuminated transparency with a camera accurately lined up in front of it.

The transparency may also be set up in the transparency holder of a process camera, and lit by open arcs shining on to white blotting paper some distance behind the transparency, or by a cold cathode lamp unit. The above remarks on diffuser type light sources of course apply here.

Processing the Negatives. Separation negatives from transparencies are developed in the same way as direct separation negatives. However, the gamma or contrast to which the negatives must be developed will be different. Generally separation negatives from transparencies need to be developed less than direct separations.

As a guide, direct separation negatives are generally developed to a gamma of about 0·80, while separation negatives from masked transparencies need to be developed to a gamma of about 0·75. For separations from unmasked transparencies the gamma need only be about 0·45. It is useful to check that the contrast is reasonably correct by printing a trial negative on a normal grade of bromide paper.

The gamma must of course be the same on all three negatives. This can be checked from the grey scales alongside the transparencies. The grey scales should appear identical in each of the three negatives. Note that this will only apply if the step-wedge was made on the same type of colour film as the transparency. Any other type of wedge will give a useful check on contrast but will not be a reliable guide to the density balance of the set of negatives.

Filter Factors by Sensitometry. Good separation negatives can be made from transparencies by rather tedious trial and error, or by using a manufacturer's specific data as a guide for initial tests. But a densitometer and a step-wedge make testing very simple and accurate.

One test using four plates or films (plus an extra one to establish reasonably correct conditions of working) will give the filter ratios and development times for equal contrast at any desired gamma.

The step-wedge may be a silver or dye type manufactured wedge, or it may be made by the colour worker himself. Preferably the wedge should be about 3¼ × 4¼ ins., and should have about eighteen steps each increasing by about 0·15 in density. Also required are strips of each of the same colour filters that will be used for making the separation negatives. The strips of filter should be at least ½ in. wide,

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

FILTER STEP WEDGE: A grey step wedge, together with strips of the three filters to be used for separation, is used for test exposures to establish correct filter factors and development times. The filter strips each cover the full step range.

and long enough to cover the length of the wedge. If the density increments of the wedge are even steps of, say, 0·15, it will greatly facilitate subsequent plotting of the graphs.

The step-wedge is used as follows. Expose four plates, using the step-wedge covered by the filter strips side by side as the negative in the printing frame. The exposures should be made to the light source described above for masking, but with no filters over the light source, and an aperture of 1½ ins. square. All four plates must receive the same exposure.

Develop the four plates for a sufficient range of times to be sure of covering a suitable range of negative contrasts. For example, if the developing time is thought to be about 5 minutes, develop the plates for 3½, 5, 6½ and 8 minutes. The conditions of development for these tests must be the same as will be used for the actual negatives. Fix, wash, and dry.

Read the densities on each of the three colour filter records on each of the four plates. Tabulate the negative density readings of each step vertically on the graph against the density readings of the respective steps on the original step-wedge, reading from right to left because the highest wedge density gives the least exposure. Both scales must be of the same order.

From these figures, plot the three sets (R, G, and B) of characteristic curves. Use a fresh sheet of graph paper for each set of four characteristic curves representing one colour record at the four different developments.

Having plotted the points on each curve, rule a straight line through the points on the straight line portion of each curve, and extend each line to cut the base line of the graph paper. Ignore the toe and shoulder regions of the curves. Mark off the gamma of each curve.

From the gammas of each record at each of the four developing times, plot the gamma-development time curves, which will give the developing times for each record to give any desired gamma.

Referring back to the three sheets of characteristic curves, choose on each the curve which gave as near as possible the gamma to which the negatives should be developed. Transcribe these three chosen curves of about the right gamma on to a fresh sheet of graph paper marked out just as before. Now the horizontal spacing between these three curves is a measure of the filter ratios which must be used to give balanced negatives.

With tungsten light, the red record will usually have received most exposure, and the blue least, with the green between them. Rule a line horizontally across the graph paper at a level of about 0·4 on the density scale. Now along that line, note the distance (in terms of step-wedge density units) between firstly the green and red record lines, then between the green and blue record lines.

To convert these "horizontal displacement" figures into filter ratios, look up the anti-logarithm of the displacement to the right. The anti-log is the filter ratio (that is, more than 1, in this case), relative to the green—that is, the green filter ratio is 1.

If, however, the displacement is to the left of the green record line, look up the anti-log and then look up the reciprocal of that. The latter figure is the filter ratio (now less than 1).

When performing this test for the first time, it is advisable to expose and process one plate to see that the conditions are about right for the green record image printed from the step-wedge to show a full range of densities from light to dark, with about the right gamma.

To convert the displacement figures to area changes required for the filters over the light source as already described, proceed as follows. For a displacement to the right of the green curve, look up the square root of the anti-log of the displacement figure. For a displacement to the left of the green curve, look up the reciprocal of the square root of the anti-log of the displacement figure. The final result in each case gives the factor by which the length of the sides of the square filter aperture must be changed to give balanced sets of separations with the same exposure time for each of the three colour records.

As the step-wedge used for these tests is not made by the colour transparency process in question, the precise filter ratios may need very slight modification. However, good negatives will be obtained even without this correction.

ADDITIVE TRANSPARENCIES

Since no additive colour films have been commercially available since the early 1950s, the need for making separation negatives from an additive transparency is very rarely likely to arise. The general procedure is similar to the

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

FILTER FACTORS BY SENSITOMETRY. Four negatives are exposed behind the filter step wedge, and are then used for sensitometric determination of the filter factors and development times for ideal working. The four negatives are developed for varying times above and below the normal time for the material. For instance if the normal time is 5 minutes, suitable test times would range from 3½ to 8 minutes. After processing, characteristic curves are plotted for each filter colour to establish the gamma obtained at the different development times. Top: *Typical curves of red filter densities, plotting negative density against wedge density.* Centre: *Gamma-times curves for the three filter negative strips, plotted from the characteristic curves. These give the development times for each record to yield any desired gamma.* Bottom: *Three curves of about equal gamma are finally transcribed from the original set of characteristic curves on to a fresh sheet of graph paper. The horizontal displacement (best measured at a level of about 0·4 on the density scale) is now a measure of the filter ratio required to provide balanced separation negatives. The actual filter ratios are usually based on green = 1. To obtain the blue filter ratio, measure the displacement of the blue filter curve to the right of the green filter curve in terms of step wedge density units. The anti-log of that displacement is the blue-filter ratio relative to green. For the red filter again measure the displacement of the red curve to the left of the green. As that displacement is negative along the exposure axis, the reciprocal of its anti-log is the red filter ratio.*

preparation of separation negatives from subtractive transparencies. One or two practical problems arise from the screen pattern or raster used for the additive colour reproduction.

To be suitable for reproduction, a transparency should appear slightly denser than for normal viewing, and ½ stop less than normal exposure is usually about right. The colour screen of an enlarged additive transparency tends to give a "granular" texture to the print, so large transparencies should be used in the first place where possible.

The additive transparency already carries the three colour records, red, green, and blue; it is only necessary to "sort them out" on to the three separation negatives. This is done by making one negative through a red filter, one through a green, and the third through a blue. Again narrow-cut tricolour filters are used to get good colour separation.

Printing Methods. Additive colour transparencies with an integral screen (the majority of additive transparencies produced) are suitable for printing by contact or projection, but contact printing is usually preferable. This avoids the optical imperfections inseparable from projection. Since the screen pattern prints through, variations of this pattern between the three separation negatives may give rise to interference effects leading to the appearance of a much coarser screen pattern on the final print.

With projection printing special precautions are necessary to avoid overheating the transparency, since the dense narrow-cut filters required lead to relatively long exposure times.

The emulsion side of an additive type transparency must face the lens of the enlarger or copying camera, to give negatives the correct way round.

The pattern of the colour screen of the transparency may be eliminated by using the enlarger or copying lens at a stop small enough to introduce just the right amount of blurring by diffraction. With an aperture small enough to do this the exposure time may be excessive unless a high intensity light source is used.

Processing. The degree of development of the negatives depends upon the contrast of the original and the printing process to be employed. As a guide, negatives from an additive transparency of average contrast should be developed to a gamma of about 0·70 to 0·80.

If no densitometer is available to check the gamma, make a green record negative by trial and error and check the contrast by making a print on a normal grade of bromide paper.

All three negatives must of course be developed to the same gamma. A.P.J.

SERIES-PARALLEL. Electrical circuit for connecting up two similar pieces of equipment through a two-way switch so that in one position of the switch the components are in series and in the other in parallel with the power supply. In photography the circuit enables the working life of Photoflood lamps to be extended by running them—in series (at half voltage) for arranging and focusing and in parallel (at full voltage and brilliance) for exposing.

See also: *Dimmer; Switches.*

SERIES PARALLEL CIRCUIT. The simplest arrangement for switching over two lamps from series connection into parallel consists of two two-way switches. They are linked together and in the position shown (solid line) the two lamps are in series. On switching over to the dotted positions the lamps are in parallel. The contacts can also be closed separately by means of a rotary four-way switch. In the case setting AC would correspond to series operation, the switches in positions A and D would switch off the first lamp and run the second at full power, positions B and C combined would run the first lamp at full power and switch off the second one, and the setting BD would run both lamps in parallel.

SEYMOUR, DAVID, 1911–56, American reportage photographer born in Poland. Founder member of Magnum Group, 1947 became a free-lance journalist and photographer in Paris, mid-1930s. After the fall of France, 1940, went to New York and joined U.S. Air Force. Returned to Paris, 1944. Made photographic pictures stories in many countries, and was killed while covering the invasion of Egypt during the Suez crisis, 1956.

SHADING AND SPOT PRINTING. Negatives are often reasonably well exposed, except for a few small areas of the image which are either too light or too dark. When exposing the print, the density over such areas can be adjusted by local exposure control called shading, spot printing or "dodging".

This can be done in contact printing or enlarging, but the latter process of course offers far wider scope for control.

Shading consists of holding back a part of the image so as to make it print lighter. Spot printing means over-printing a comparatively small image area to make it darker in the enlargement. The distinction between the two lies mainly in the relative areas in question, since spot printing one part of the picture necessarily involves shading the rest, and vice versa. In practice, the mechanical aids employed for the two techniques are also slightly different.

Sky in Landscapes. One common example of the need for local control is the landscape print in which there is a great disparity between the densities of the foreground and the sky. Both must be given different exposures if they are to print through in the same depth. In this case the whole print is first given the correct exposure for the foreground. Then extra exposure is given to the sky, which is the densest part of the negative and needs the longest exposure. This is done by shading the foreground portion with the hand or a black card and allowing the light to fall on the sky area alone. The hand or the card must be slightly moved during shading, in order to avoid leaving a sharp-edged boundary.

More involved shapes, e.g., a complicated sky line, can be produced by cutting special masks. A duplicate print will serve admirably for that purpose; it should however be slightly smaller so that when held above the enlarging paper at a convenient distance, its shadow is the correct size. Such masks—sometimes with counter masks—are usually essential with most forms of combination printing.

Progressive shading—e.g., when correcting converging verticals—is a similar process, except that shading starts at one edge of the paper and the hand or card is gradually moved across until the whole print is covered.

Local Control. Small areas of the print that would come out too dark are shaded during part of the exposure. The most obvious means of shading are one or both hands which, if held suitably in the path of the light beam from the enlarger lens, will cast almost any shadow outline on the baseboard. (When using both hands, a foot switch or other independent means of working the enlarger light is an advantage.)

For areas in the centre of the picture, suitably-shaped pieces can be cut out of black card and held just above the surface of the paper on the end of a length of stiff wire or a knitting needle.

It is convenient to keep an assortment of such cards of various shapes (squares, circles, triangles, ellipses, etc.), handy to deal with areas of a range of shapes and sizes. Sets of this type can be bought or they can be made from stiff card or thin sheet metal.

The distance of the card above the enlarging paper determines the size of the shadow. The closer the card is to the enlarging lens, the larger and also the more blurred will be the shadow.

The angle of the card can also influence the shape of the shaded area. Thus a circular card held obliquely will throw an ellipse-shaped

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

CONTROL TOOLS AND METHODS. Left: *Suitable shading shapes which clip on the end of a thin wire holder.* Centre: *Methods of shading and spot printing.* 1. *Shading large areas with a card.* 2. *Overprinting small area with hole in a card.* 3. *Shading with the hand.* 4. *Spot printing with hands.* Right: *Flashing, i.e., darkening areas of the print by white light, with the aid of a shaded torch.*

shadow, a regular triangle can be compressed in either direction, and so on.

If the card is held in position during the whole of the exposure, the result is a vignette.

Small areas of the print are given extra exposure when necessary by means of a black card with a suitably small hole cut in it. The card is held close enough to the lens to shield the whole of the print, and the spot of light that passes through the hole is moved about the area to be over-printed. This is the technique of spot printing.

Flashing. An alternative method of over-exposing a small image area is to shine white light on it. This is the technique of flashing. The difference between it and spot printing is that during flashing the whole image area concerned is fogged—to complete blackness if desired. In spot printing the tones of the image are darkened in proportion to their density, i.e., the area is simply over-exposed.

A useful way of flashing is to wind a narrow tube of paper round a torch bulb so as to produce a thin pencil beam. The flashing exposure required will vary widely according to the conditions and usually has to be found by trial and error.

Applications of flashing are the production of black edges round a photograph, and vignetting an image to disappear into black near the margins or corners.

Automatic Methods. Electronic enlargers use a flying spot scanner—a light spot that moves over the different parts of the negative—instead of a light source illuminating the whole negative at once. The intensity of this light spot varies according to the density of the image portion being scanned; for this purpose a photo cell system monitors the light coming through the negative. As a result dense negative areas receive more exposure on the print than thin ones. This provides a kind of automatic shading, though it cannot be used selectively for specific negative areas. There are also other methods for controlling the illumination locally, with similar results. Such automatic shading systems are largely used for printing aerial and other photographs where a negative of great brightness range has to be accommodated within the tone range of the printing paper. L.A.M.

Book: *The Complete Art of Prniting and Enlarging*, by O. R. Croy (London).

SHADOWLESS LIGHTING. Diffused, uniform type of frontal illumination which presents the subject completely without shadows when viewed from the camera position. It is arrived at by disposing light sources and reflectors evenly around the camera and directing them towards the subject.

Daylight forms the most convenient source of shadowless lighting. A subject photographed out of doors in light-toned surroundings when the sunlight is diffused by a continuous layer of cloud will be free from shadows.

This type of lighting normally produces a softly-defined high key image.

Shadowless lighting is suitable for high key portraits of babies, children, girls, and young women. It is also useful for playing down lines and wrinkles in portraits of older people.

Catalogue illustrations which must show the maximum amount of detail—e.g., photographs of ceramics, glass and silverware—are best taken by this type of illumination.

When the object is simply to eliminate the shadow cast on the supporting surface, the subject is placed on its side on a sheet of glass mounted some distance above the bench—e.g., bridging two stacks of books—and photographed with the camera looking down on it. The bench is covered with a sheet of white paper and the lighting is arranged so that no shadows are cast on the paper inside the picture area. If necessary, lights can be directed on to the sides of the subject from below the glass support. A sheet of opal glass illuminated from below provides another suitable base for shadowless lighting. This method of lighting is widely used for catalogue illustrations of small parts and "exploded" assemblies because it makes it unnecessary to block out or retouch to get rid of the background.

CC-0. Agamnigam Digital Preservation Chandigarh

Ring Illuminator. For special—mostly close-up—subjects, shadowless lighting can be achieved with an electronic flash tube bent in a circle to surround the camera lens. The tube is mounted in a circular trough-section reflector which increases the light falling on the subject and stops it from spilling on to the front of the lens. This type of flash lighting is used largely for medical and dental close-ups and for macro-photography. The lighting gives the best results when the subject detail is marked by differences in colour. This is the nearest practical approach to truly shadowless illumination, i.e. where the light is virtually co-axial with the lens, so that all shadows cast are hidden entirely behind the objects casting them.

RING ILLUMINATOR. A ring shaped light source in a reflector—either a tungsten lamp or an electronic flash tube—surrounds the camera lens and kills all shadows on the subject side facing the lens.

Lighting Tent. Some subjects like glass, silverware and jewellery that are best photographed by shadowless lighting may be taken in a lighting tent of white muslin or any similar light-diffusing material. The lens is poked through a hole cut in the tent to avoid getting a recognizable portrait of the camera reflected in the polished surface of the subject. Lights are directed from the front and sides on to the tent which diffuses and reflects the rays.

Shadowless lighting can also be provided by a light source consisting of a number of parallel fluorescent tubes mounted behind a diffusing screen of translucent plastic sheet.

Book: *Camera Close-up*, by O. R. Croy (London).

SHADOWS. The shadows in a photograph are represented by areas of more or less dark grey silver deposit; they correspond to the parts of the subject that received no illumination from the light source and in consequence could not reflect any light into the lens. In most photographs completely black shadow areas are undesirable; they should be noticeably darker in tone than the rest of the picture but it should be possible for the eye to discern the details of the subject even in the apparently unlighted areas. This is only possible if they receive some degree of illumination—either reflected from the principal source or provided by a separate (fill-in) light. It is also necessary for the exposure to be sufficient to allow the shadow detail to record on the sensitized emulsion.

Control of the distribution, shape, and density of the shadows in a picture is an important part of photography for whatever reason it is practised.

CONTROL TOOLS AND METHODS. Left: *Suitable shading shapes which clip on the end of a thin wire holder.* Centre: *Methods of shading and spot printing.* 1. *Shading large areas with a card.* 2. *Overprinting small area with hole in a card.* 3. *Shading with the hand.* 4. *Spot printing with hands.* Right: *Flashing, i.e., darkening areas of the print by white light, with the aid of a shaded torch.*

shadow, a regular triangle can be compressed in either direction, and so on.

If the card is held in position during the whole of the exposure, the result is a vignette.

Small areas of the print are given extra exposure when necessary by means of a black card with a suitably small hole cut in it. The card is held close enough to the lens to shield the whole of the print, and the spot of light that passes through the hole is moved about the area to be over-printed. This is the technique of spot printing.

Flashing. An alternative method of over-exposing a small image area is to shine white light on it. This is the technique of flashing. The difference between it and spot printing is that during flashing the whole image area concerned is fogged—to complete blackness if desired. In spot printing the tones of the image are darkened in proportion to their density, i.e., the area is simply over-exposed.

A useful way of flashing is to wind a narrow tube of paper round a torch bulb so as to produce a thin pencil beam. The flashing exposure required will vary widely according to the conditions and usually has to be found by trial and error.

Applications of flashing are the production of black edges round a photograph, and vignetting an image to disappear into black near the margins or corners.

Automatic Methods. Electronic enlargers use a flying spot scanner—a light spot that moves over the different parts of the negative—instead of a light source illuminating the whole negative at once. The intensity of this light spot varies according to the density of the image portion being scanned; for this purpose a photo cell system monitors the light coming through the negative. As a result dense negative areas receive more exposure on the print than thin ones. This provides a kind of automatic shading, though it cannot be used selectively for specific negative areas. There are also other methods for controlling the illumination locally, with similar results. Such automatic shading systems are largely used for printing aerial and other photographs where a negative of great brightness range has to be accommodated within the tone range of the printing paper. L.A.M.

Book: *The Complete Art of Prniting and Enlarging*, by O. R. Croy (London).

SHADOWLESS LIGHTING. Diffused, uniform type of frontal illumination which presents the subject completely without shadows when viewed from the camera position. It is arrived at by disposing light sources and reflectors evenly around the camera and directing them towards the subject.

Daylight forms the most convenient source of shadowless lighting. A subject photographed out of doors in light-toned surroundings when the sunlight is diffused by a continuous layer of cloud will be free from shadows.

This type of lighting normally produces a softly-defined high key image.

Shadowless lighting is suitable for high key portraits of babies, children, girls, and young women. It is also useful for playing down lines and wrinkles in portraits of older people.

Catalogue illustrations which must show the maximum amount of detail—e.g., photographs of ceramics, glass and silverware—are best taken by this type of illumination.

When the object is simply to eliminate the shadow cast on the supporting surface, the subject is placed on its side on a sheet of glass mounted some distance above the bench—e.g., bridging two stacks of books—and photographed with the camera looking down on it. The bench is covered with a sheet of white paper and the lighting is arranged so that no shadows are cast on the paper inside the picture area. If necessary, lights can be directed on to the sides of the subject from below the glass support. A sheet of opal glass illuminated from below provides another suitable base for shadowless lighting. This method of lighting is widely used for catalogue illustrations of small parts and "exploded" assemblies because it makes it unnecessary to block out or retouch to get rid of the background.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Ring Illuminator. For special—mostly close-up—subjects, shadowless lighting can be achieved with an electronic flash tube bent in a circle to surround the camera lens. The tube is mounted in a circular trough-section reflector which increases the light falling on the subject and stops it from spilling on to the front of the lens. This type of flash lighting is used largely for medical and dental close-ups and for macro-photography. The lighting gives the best results when the subject detail is marked by differences in colour. This is the nearest practical approach to truly shadowless illumination, i.e. where the light is virtually co-axial with the lens, so that all shadows cast are hidden entirely behind the objects casting them.

RING ILLUMINATOR. A ring shaped light source in a reflector—either a tungsten lamp or an electronic flash tube—surrounds the camera lens and kills all shadows on the subject side facing the lens.

Lighting Tent. Some subjects like glass, silverware and jewellery that are best photographed by shadowless lighting may be taken in a lighting tent of white muslin or any similar light-diffusing material. The lens is poked through a hole cut in the tent to avoid getting a recognizable portrait of the camera reflected in the polished surface of the subject. Lights are directed from the front and sides on to the tent which diffuses and reflects the rays.

Shadowless lighting can also be provided by a light source consisting of a number of parallel fluorescent tubes mounted behind a diffusing screen of translucent plastic sheet.

Kodak Company. Studied with C. E. K. Mees in London. Both worked with Trueman and Wainwright in Croydon and then went to Rochester to found the Research Laboratories of the Eastman Kodak Company (1913). Sheppard's work covered almost every aspect of photographic science, especially latent image theory and chemical sensitization. In 1923 discovered the organic sulphur compounds in photographic gelatin which act as natural sensitizing agents, and thereby founded a new emulsion technique. He received the Progress Medal of the Royal Photographic Society in 1928. Has some 250 publications to his credit.

SHIMOOKA, RENJOH, 1825–1914. Japanese photographer. Was a pioneer in professional photography in Japan, working in Yokohama in 1862.

SHOP WINDOWS. Reflections present the major difficulty when photographing shop windows. During daylight hours the windows reflect people and passing traffic, the opposite side of the street and, of course, the photographer. At night the reflected lights of passing traffic may reproduce as streaks, while the photographer's lighting represents a further problem.

Whenever possible a good quality polarizing screen should be used to reduce reflections and obtain maximum clarity of detail behind the window glass. It should be borne in mind that light reflected at approximately 33° from a glass surface is polarized to the maximum extent, and that the effect is less at other angles, and non-existent at 90°. The angle at which the window must be taken is often dictated by its shape and position relative to pavement width, lamp-posts, adjacent property, etc.

The most attractive window display photographs are those taken by artificial light.

Possibly the best time to photograph a shop window is reasonably late at night, when passers-by and traffic begin to decrease in number and the photographer will have greater freedom of movement.

At such times an assistant should accompany the photographer. Apart from helping with equipment he will be able, for example, to request drivers not to park their vehicles where the lamps will reflect into the lens.

Camera. For commercial work use a technical camera which takes negatives no smaller than 4 × 5 ins. to allow for the degree of enlargement often required and the need for maximum detail.

A firm and rigid tripod is also essential.

Coated lenses are desirable, and should include one of normal focal length, a wide angle and a long focus lens. The latter may be useful when the camera has to be positioned some distance away from the window—e.g., on the opposite side of the road. An extending lens hood adjustable to fit all lenses, or individual hoods for each lens, should always be

The shutter should be of the type operated by ball and tube, or by a long flexible cable release. Alternatively, the exposure may be made by means of the lens cap.

A spirit level is desirable for checking the side-to-side and front-to-back levels of the camera.

Photographic Materials. A fast panchromatic anti-halation backed plate or sheet film is best for black-and-white photography, while a reversal colour emulsion is most suitable for colour work where the pictures are to be used for advertising. (Most blockmakers prefer to work from colour transparencies rather than colour prints.)

Lighting. The illumination may be either

(1) Daylight;

(2) Window lighting only;

(3) Window lighting plus high intensity photographic lighting; or

(4) High intensity lighting only.

The photographic lighting may be either Photofloods in reflectors, flash, or a combination of both.

(1) Daylight: a polarizing screen should, under appropriate conditions (i.e.—suitable angles of reflection), be used for daylight exposures to cut reflections to a minimum. Some window lights may be switched on if they are necessary to obtain a more even lighting to the rear, or if they help to give a desired effect to the display.

If the window is accessible, several direct readings should be taken with an exposure meter and a mean selected. If the window is not accessible, similar meter readings should be taken with the meter placed close to the glass and shaded from top light to avoid a false reading from reflected sky.

(2) Window lighting: in the majority of shop windows the lighting tends to give a much brighter illumination to the front of the window. If possible some of the lights should be switched off to obtain a more even balance. The exposure meter reading should be taken close to the window glass to avoid reflected light from street lamps.

(3) Window lighting can be supplemented by high intensity photographic lighting such as Photofloods or flash. Care must be taken to ensure that the lights do not reflect into the lens and that the lighting is even. To avoid sharp shadows, Photofloods may be moved from side to side during exposure, always ensuring that the lights and their reflections remain outside the field of view of the lens. The meter reading should be taken close to the window so as to avoid the reflections of Photoflood lamps.

With flash, invariably more than one flash bulb will be needed to obtain adequate coverage, and the position of each flash firing point must be pre-determined, and marked with chalk. A

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

torch held by an assistant and observed on the focusing screen is a good guide as to whether flash positions are outside the field of view of the lens.

Flash positions should be selected to ensure adequate and even coverage of the area.

As each flash will nominally expose one section of the window, the stop to be used should be calculated in the normal way from the guide number of the flash bulb used.

(4) The procedure for photographic lighting only is the same as for combined light.

Different light sources should not be mixed when taking pictures in colour, as they would produce different colour rendering in various parts of the image. The appropriate colour compensating filter should be used if the film is not balanced for the light source employed.

Exposure and Development. As a rule exposure should be full and a soft working developer used to ensure retention of all the shadow detail without excessive highlight density.

The aperture used should be small to ensure maximum definition and depth of field, and the resultant exposure will frequently be long. In twilight and after dark the lens will have to be shaded from the reflections of the lights of passing vehicles.

People walking between the camera and the window will not register on a long exposure provided they do not pause.

An efficient shield may be made from black photographic paper mounted on a card, or the hand may be used. On no account should the lens be capped or the camera touched.

If the lens cap has to be used for the exposure, it is wise, after removing it, to hold it close in front of the lens for a few seconds, until all vibration has died down, and then remove it completely.

A slight degree of under-development is to be preferred to any degree of over-development. A.E.S.

SHORT FOCUS. Description of a lens indicating that its focal length is shorter than the diagonal of the negative it is designed to cover—i.e., shorter than the focal length of a normal lens.

SHUTTER

Mechanical system for controlling the time during which light is allowed to reach the sensitive material in a camera. The shutter consists of some means of covering the lens or the film or plate light-tight, uncovering it for a pre-set time and covering up again.

The early cameras did not need shutters. Plates were so slow that the exposure could always be made by removing the lens cap and replacing it after the required time. As the speed of sensitive materials increased it became possible to use shorter exposures than could be given by hand in this way, so some form of mechanical device became necessary for uncovering the plate for exactly determined periods of less than a second.

DESIGN AND FUNCTION

At first the shutter was manufactured as a separate accessory which could be fitted in front of the lens or, more rarely, between the lens and the plate. In time cameras were manufactured with the shutter included as a part of either the lens assembly or the body.

Nowadays the main types of shutter are the sector and the diaphragm (or leaf) shutter on the one hand and the focal plane shutter on the other.

Most diaphragm and several sector shutters have the iris diaphragm built into the shutter housing to regulate the lens aperture. On cameras with focal plane shutters the iris is of course built into the lens.

Sector Shutters. The sector shutter is simply a circular plate pierced with a hole, mounted in the path of the light entering the camera. When the shutter release is pressed, the plate rotates and the hole uncovers the lens for a period depending on the speed of rotation.

This type of shutter may be mounted in front of the lens, behind it, or even between the components. It is generally fitted to the cheaper cameras with simple lenses.

Tensioning. There are four ways in which the shutter can be re-set for the next exposure:

(1) The shutter lever is arranged to operate in both directions—i.e., downward pressure causes the hole to cross the lens and make the first exposure; the film is then wound on to the next frame and the second exposure is made by pressing the shutter lever upwards.

Used in this way the shutter does not need any arrangement for capping the lens, and a simple mechanism is adequate. Shutters of this type are fitted to the cheapest box and folding cameras.

(2) A second metal plate is arranged to cap the lens while the shutter plate returns to its original position. Before the shutter starts to operate, the capping plate is automatically held out of the way.

This is found in the everset type of shutter. In such shutters the release lever or button is spring loaded and returns to its original position after being depressed. During the return stroke the lens is automatically capped and the shutter plate turned back ready for the next exposure.

The everset shutter is convenient in being always ready for action without first having to be tensioned. It is superior to the simple non-

SHORT FOCUS. Description of a lens indicating that its focal length is shorter than the diagonal of the negative it is designed to cover—i.e., shorter than the focal length of a normal lens.

SHUTTER

Mechanical system for controlling the time during which light is allowed to reach the sensitive material in a camera. The shutter consists of some means of covering the lens or the film or plate light-tight, uncovering it for a pre-set time and covering up again.

The early cameras did not need shutters. Plates were so slow that the exposure could always be made by removing the lens cap and replacing it after the required time. As the speed of sensitive materials increased it became possible to use shorter exposures than could be given by hand in this way, so some form of mechanical device became necessary for uncovering the plate for exactly determined periods of less than a second.

DESIGN AND FUNCTION

At first the shutter was manufactured as a separate accessory which could be fitted in front of the lens or, more rarely, between the lens and the plate. In time cameras were manufactured with the shutter included as a part of either the lens assembly or the body.

Nowadays the main types of shutter are the sector and the diaphragm (or leaf) shutter on the one hand and the focal plane shutter on the other.

Most diaphragm and several sector shutters have the iris diaphragm built into the shutter housing to regulate the lens aperture. On cameras with focal plane shutters the iris is of course built into the lens.

Sector Shutters. The sector shutter is simply a circular plate pierced with a hole, mounted in the path of the light entering the camera. When the shutter release is pressed, the plate rotates and the hole uncovers the lens for a period depending on the speed of rotation.

This type of shutter may be mounted in front of the lens, behind it, or even between the components. It is generally fitted to the cheaper cameras with simple lenses.

Tensioning. There are four ways in which the shutter can be re-set for the next exposure:

(1) The shutter lever is arranged to operate in both directions—i.e., downward pressure causes the hole to cross the lens and make the first exposure; the film is then wound on to the next frame and the second exposure is made by pressing the shutter lever upwards.

Used in this way the shutter does not need any arrangement for capping the lens, and a simple mechanism is adequate. Shutters of this type are fitted to the cheapest box and folding cameras.

(2) A second metal plate is arranged to cap the lens while the shutter plate returns to its original position. Before the shutter starts to operate, the capping plate is automatically held out of the way.

This is found in the everset type of shutter. In such shutters the release lever or button is spring loaded and returns to its original position after being depressed. During the return stroke the lens is automatically capped and the shutter plate turned back ready for the next exposure.

The everset shutter is convenient in being always ready for action without first having to be tensioned. It is superior to the simple non-

capping sector shutter because the release lever always works in the same direction. But it has the disadvantage of needing a heavy release pressure to compress the return spring. This and the limited range of speeds restrict the everset shutter to cheap cameras.

(3) The shutter may be re-tensioned by a separate tensioning lever. This system makes it possible to operate with a light release pressure. The tensioning lever automatically brings a capping plate over the shutter aperture as it returns to the set position.

(4) The shutter plate can be arranged to rotate always in the same direction—i.e., after uncovering the lens, the plate continues to rotate until it gets back to its starting point. There is no longer any need to cap the lens as the aperture does not uncover it on the return journey. Shutters of this type can be designed as everset or they may be tensioned by a separate lever.

One make of rotating disc shutter is operated by releasing a previously wound spring which provides the power for a number of releases on one winding. As this spring also advances the film after each exposure, it is possible to take a succession of pictures as fast as the release can be pressed.

Diaphragm Shutters. The diaphragm shutter consists of a ring of inter-leaving light metal or vulcanite blades which are pivoted at their outer edges so that they can open outwards and leave a clear hole for the light to pass through. These shutters are designed so that the proportion of the total exposure time occupied by the action of opening and closing is as short as possible—i.e., so that the shutter efficiency will be high.

This principle is widely used in modern cameras, sometimes for shutters of the everset type but chiefly in more complex shutters which require a separate tensioning for the driving spring and operate with very light release pressures. On some cameras the tensioning movement is linked with the film transport, so that the action of advancing the film also tensions the shutter for the used shot.

In most modern diaphragm shutters there are three to five thin metal blades which come together to form a diaphragm between the lens components. On some cameras the blades may be in front of or behind the lens. The latter arrangement permits the use of interchangeable lenses with this type of shutter. On pressing the shutter release the main spring moves a ring which makes the blades swing out to the edge of the aperture and allows the light to pass through the lens. The blades are designed so that the opening starts as a star or a small hole, letting light through the lens more or less uniformly from the centre to the circumference. At the end of the exposure, as

EARLY SHUTTER TYPES. A, *simple drop shutter; the plate slides down under its own weight and uncovers the lens opening.* B, *roller blind shutter for use in front of the lens; blind wound up on spring-driven roller.* C, *rotary shutter, used in modified form (with capping plate) on some box cameras.* D, *double flap shutter mounted in front of the lens. The two flaps are linked together and move in unison. The exposure is not very uniform, the centre of the plate receiving about 40 per cent more than the top and bottom.* E, *multiple flap shutter with flaps pivoted on horizontal axes and overlapping at their extreme positions. The flaps always cut off either some horizontal or some oblique rays, and the efficiency is never more than 33 per cent.* F, *bellows shutter, with hinged bellows on metal frames. Almost noiseless, and used at one time by portrait photographers.*

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

DIAPHRAGM SHUTTER. Usually mounted between lens elements, sometimes also behind or in front. Left: *Simplified layout of main components: A, tensioning arm joined to main driving ring, in tensioned position; B, pin to disengage driving pawl; C, driving pawl; D, inner ring opening shutter blades; E, return spring; F, blades; G, main driving spring; H, delayed action escapement, used also to obtain synchronizing delay; I, release catch; J, flash contacts.* Right: *Shutter blade shapes; blades partially open.* Bottom: *Shape of the lens opening during the opening and closing of the blades of a three-bladed diaphragm shutter.*

the blades close, the hole becomes smaller or changes to a broad-rayed star which becomes thinner and finally disappears, leaving an opaque diaphragm once again.

On a typical diaphragm shutter the time taken by the shutter blades to open fully is about one to two milliseconds.

Shutters of this type are highly complex mechanisms in which all the components are housed in a narrow ring surrounding the lens.

The main spring driving the ring which moves the blades determines the top speed at which the shutter will operate. At the slower speeds an escapement arrests the ring for a given period when the blades are open.

Older shutters of this type use an air-brake (i.e., a piston pushing air out of a cylinder through a small hole) to retard the movement of the blade ring at slow speeds. This system is practically silent, but is less reliable.

On some shutters an additional spring provides extra tension for the fastest speed.

Electronic shutters utilize an electric circuit and a solenoid in place of an escapement to control the shutter time.

Certain diaphragm shutters use a differently shaped set of blades. Each blade is double the normal size, more or less symmetrically shaped and rotates about a central pivot point. During the opening of the shutter one half of each blade moves out of the way to uncover the lens (usually five such blades make up the shutter), while during closing the other half of the blade moves in again to obstruct the light path. Since this design does not involve the reversal of a very fast movement as in conventional diaphragm shutters (where the blades swing out and then back again), inertia problems are greatly reduced and shutters of this kind can yield faster top speeds.

The Release. Most diaphragm shutters carry a special lever to release the shutter, but on some models this is combined with the tensioning lever—movement in one direction tensions the shutter, and movement in the opposite direction fires it.

On the majority of modern cameras a linkage connects the release lever on the shutter with a body release button on the camera body. This makes releasing more convenient and reduces the risk of camera shake. The body release may be linked with a double exposure lock to prevent accidental double exposures.

Usually a threaded socket is also fitted, either on the shutter itself or incorporated in the body release button, to take a flexible cable release. This is used for releasing only; the tensioning must still be carried out separately.

Shutter Speeds. The simpler sector shutters are made to give nominal speeds of 1/25 to 1/75 second. On these cheap shutters there is usually a choice of two speeds obtained by

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

changing the tension on the operating spring. Shutters of this type are never very accurate and their real speeds may vary as much as ± 100 per cent of their rated speeds.

The better—and more expensive—sector shutters have a greater range of speeds and incorporate systems of gear wheel trains to give reliable slow speeds down to 1 second and accurately stressed springs for fast speeds up to 1/500 second.

Diaphragm shutters have speed ranges from 1 to 1/500 second, or in one or two isolated cases up to 1/1000 second. Speeds up to 1/2000 second have also been achieved by allowing the blades to open only part of the way; at this speed the maximum effective aperture is about *f* 8.

The simpler types carry three or four speed settings, usually 1/25, 1/50, 1/100 and 1/200 second. In better shutters the top speed may be 1/250 or 1/300 or even 1/500 second. Shutters with a range of slow speeds include speeds of 1 to 1/15 second.

Currently most shutters are standardized with the speeds 1, 1/2, 1/4, 1/8, 1/15, 1/30, 1/60, 1/125, 1/250 and 1/500 second (or 1/300 instead of 1/250 and 1/500 second). In this series each time is exactly half the preceding and twice the succeeding exposure time.

The speeds are set either by moving a lever along a scale engraved on the rim of the shutter, or by turning a milled ring which forms part of the rim. The speeds are then marked on the ring which is set to an appropriate index mark on the front of the shutter. Alternatively, the speed scale may be marked on the front, and the index mark on the movable ring.

The speed can generally be altered before or after tensioning. The top speed can in some shutters only be set before tensioning.

Intermediate Settings. Where the shutter speeds depend only on the spring tension, as with the simpler sector shutters, intermediate settings between two marked speed figures will yield approximate intermediate speeds.

If the speeds are controlled by an escapement, intermediate speeds may be possible if the selector cam inside the shutter is continuous. In many shutters this cam, which fixes the escapement delay, is stepped and the shutter can only be set to marked speeds.

Even where intermediate speeds are possible, they are not always continuous throughout the range. For instance, many shutters have a definite gap between 1/10 and 1/25 second where either a different cam or a different gearing of the escapement comes into action. Similarly, where the top speed involves an extra spring, no intermediate setting is possible between the top speed and the next slower one.

Certain types of shutters designed for coupling to built-in exposure meters have a completely continuous speed range—from say 1/30 to 1/500 second.

The aperture scale, where the iris diaphragm is built into the shutter, is usually arranged around the edge of the shutter housing.

Exposure Value Settings. In addition to normal shutter speed and aperture scales, some shutters carry a scale of exposure or light values. Each exposure value represents an exposure in terms of a range of aperture-shutter speed combinations. The aperture and shutter speed controls are coupled mechanically; for a given exposure value, altering the shutter speed automatically adjusts the aperture, and vice-versa, so as to keep the effective exposure constant. For any required subject and lighting conditions the exposure can therefore be set directly on the exposure value scale, using the aperture and shutter speed scales merely to control depth of field and subject movement respectively. The exposure value scale system necessitates the use of a constant ratio shutter speed scale (e.g., where each speed is twice the preceding speed setting) as well as equally spaced aperture settings.

Programmed Shutters. To simplify the selection of aperture-speed combinations for correct exposure some shutters have the two adjustments permanently linked together. This then yields a continuous series of settings (e.g. exposure values) without the choice of alternative combinations at each exposure value setting. Thus the shutter may start with a combination of 1/30 second at *f* 2·8, and then give—with progressive adjustment of the

SHUTTER PROGRAMMING. On a programmed shutter—frequently built into cameras with fully automatic exposure control—aperture and shutter speed settings are interlinked and change together from the biggest to the smallest exposure. The usual programme goes in alternate steps of aperture and speed (solid path) some shutters progress first from the slowest to the fastest shutter speed and then from the largest to the smallest aperture (broken path). Apertures can be selected individually at the slowest shutter speed setting for flash shots (dotted path).

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

setting control—1/30 second at *f*4, 1/60 second at *f*4, 1/60 second at *f*5·6, 1/125 second at *f*5·6, and so on up to, say, 1/500 second at *f*22. In this arrangement the aperture and shutter speed settings are interlaced, so that each shutter setting yields progressively less exposure on the film. The shutter then carries only an exposure value scale or—when coupled with an exposure meter—no scale at all. This entails a certain loss of versatility, since the choice of slow speeds with a small aperture for great depth of field or of fast speeds with a large aperture for maximum movement stopping ability is absent. Instead each setting is a compromise combining the most generally useful shutter speed with the most frequently used lens aperture for a given exposure level.

The loss of versatility is particularly marked in the middle of the exposure range; at low exposure levels and high ones there would in any case be considerably less choice of alternative combinations. In between the two extremes the actual combinations used as a compromise depends on the programming chosen. With a fully interlaced programme the apertures and the shutter speeds progress in alternate steps. In a fully consecutive programme the shutter speeds may be increased first to the top speed, followed by a reduction of the lens aperture. The latter system therefore always yields the fastest shutter speed usable under the prevailing lighting conditions; this compromise favours movement stopping ability at the expense of depth of field.

Programmed shutters of this kind are mostly associated with cameras featuring exposure automation, where the exposure setting is directly selected by the reading of a built-in exposure meter. They frequently carry a fully continuous adjustment range of apertures and exposure times, yielding actual combinations not provided in orthodox aperture and speed ranges (for example 1/90 second at *f*7·2, etc.).

An alternative programming system dispenses with the use of an iris diaphragm and instead employs the shutter blades to regulate the effective lens aperture as well. Here the shutter blades only open partly at the higher exposure value settings, and so close sooner. On varying the shutter adjustment thus both the effective shutter time and the lens opening decrease continuously and simultaneously. The shutter incorporates only a single adjustment which may again be coupled with an exposure meter or automatic exposure control system.

Programmed diaphragm shutters with separate iris and shutter blades usually permit independent adjustment of the aperture at two fixed shutter settings. One of these is a time exposure setting where the shutter opens and stays open until closed again. The other is a fairly slow speed such as 1/30 second and is used for flash exposures where independent control of the aperture is necessary.

Time Exposures. Even the cheapest sector

PROGRAMMED SHUTTER SYSTEM WITHOUT IRIS. The aperture and the exposure time are determined simultaneously by the degree to which the shutter opens. For the smaller exposures the shutter curve starts from a point high up and is thus shorter horizontally (representing shorter exposure times) as well as vertically, letting through less light. The effective exposure is given by the area under the curve. Thus at f5.6 the time interval (from 7 to 26 milliseconds) is 19 milliseconds. The effective exposure time—corresponding to the area below the curve at that level—is half this value or about 9.5 milliseconds. Similarly at f11 the total shutter time is about 5 milliseconds, but the effective exposure 2½ milliseconds. The point M and X represent the firing point at M and X synchronization of flash respectively.

shutters have some means of halting the aperture in the open position for making time exposures. The shutter may have to be held open by pressure on the release button, or it may stay open after the first release pressure and close when the button is pressed a second time. The first method is suitable for making brief time exposures and is marked B on the shutter setting control; the second method is more suitable for longer exposures and is indicated by the letter T (Time) on the setting control. Some shutters may be set to give both T and B; most have only a B setting.

Shutters fitted to cameras with a double exposure lock usually have only a B setting for time exposures. The reason is that the double exposure lock blocks the release button once it has been pressed and no second pressure (as required to close the shutter at T) is possible until the lock is freed by advancing the film.

Focal Plane Shutters. A focal plane shutter consists of a blind with a slit in it which travels from one roller to another close to the focal plane of the lens—i.e., just in front of the surface of the sensitive emulsion. The blind is the full width of the negative frame and may move up, down, or across from right or left.

Older types of focal plane shutters have one long continuous blind with slits of varying width at definite intervals. The different speeds are obtained by winding the appropriate slit into position for release. The lens

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

FOCAL PLANE SHUTTER. Two separate blinds move across the picture area just in front of the negative, exposing it from one end to the other. The interval between the blinds (right) determines the exposure time—the wider the effective slit, the longer the time. The main components of a typical miniature camera shutter are: A, shutter speed setting dial; B, second blind; C, main drum; D, gears to transport mechanism; E, tape of first blind; F, tape of second blind; G, first blind; H, rollers on which the two blinds are wound up after the exposure. The blinds move across the film with a slight overlap during tensioning, so that no light reaches the film (self-capping system), and are released one after the other in short succession during the exposure. The interval in the release of the two blinds is controlled automatically by an escapement set according to the selected shutter speed.

has to be capped while winding the shutter.

Most modern focal plane shutters have two blinds, and the slit through which the exposure is made is provided by a gap between the blinds. During rewinding the blinds cross the film or plate closed, i.e., without a gap between them. Such a shutter is self-capping, and the lens does not need capping during rewinding.

As the slit travels across the picture area it exposes each part of the sensitive surface in turn. The amount of exposure that any particular part of the film or plate receives depends upon the width of the slit and the rate at which it travels.

The normal sizes of focal plane shutter usually have some means of adjusting both the width of the slit and the speed of the blind. One knob on the side of the camera gives a choice of slit widths while another alters the tension of the spring which controls the rate of travel. Focal plane shutters on miniature cameras usually operate with a spring of constant tension and the exposure can only be adjusted by altering the width of the slit.

Where both the width of slit and tension can be adjusted, the camera usually carries a printed or engraved table showing the exposure times that can be obtained for any combination of slit and tension. Where only the slit width can be altered, the adjusting knob is calibrated directly in shutter speeds.

Focal plane shutters are also arranged to give T and B settings for which the blinds open up to expose the whole of the negative frame at once, instead of exposing it through a narrow slit. The slower speeds in fact are usually obtained by uncovering the whole frame while an escapement mechanism holds back the second blind for the appropriate time.

The blinds of focal plane shutters are generally made of thin black fabric impregnated with rubber to render it completely opaque, but metal is sometimes used.

Various other designs have also been tried, using folding or hinged multiple metal leaves in place of roller blinds.

Shutters of this type, designed for small roll film and 35 mm. cameras, usually have a range of speeds from 1 second to 1/1000 (1/2000 in special cases) with T, B and delayed action, and incorporate a train of gears, escapement or governor device for slowing down the mechanism for the slower speeds.

Focal plane shutters for the larger formats—e.g., quarter-plate—rarely have speeds below 1/10 second, but the fastest speeds are usually 1/500 or 1/1000 second.

Delayed action may be provided by a separate mechanism which retards the release.

While diaphragm shutters are comparatively independent units which are fitted into the camera or even into an interchangeable lens, focal plane shutters are generally an integral part of the camera body. Thus the same diaphragm shutter, generally made by a specialist manufacturer, may be used in a variety of

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

different camera models. Focal plane shutter designs on the other hand are nearly always tailored to the camera in which they are used. One or two attempts have however been made to produce separate unit focal plane shutters for miniature cameras. Here the whole shutter system is self-contained in an appropriate frame and can be fitted into different camera models. Such shutters generally work with moving metal leaves that swing across the picture aperture in unison, yielding effectively a travelling slit like the roller-blind design.

Acceleration. All focal plane shutters tend to accelerate as the operating spring first overcomes the inertia of the moving parts and then begins to speed them up. The effect of this acceleration is to shorten the effective exposure time progressively as the shutter proceeds across the picture aperture.

There are several ways out of the difficulty. Some shutters are designed so that the width of the slit increases as it traverses the picture aperture, the extra width being calculated to offset the increased speed. Other shutters incorporate some arrangement of a simple governor brake that keeps the speed constant.

Many focal plane shutters—particularly those on the larger size cameras (bigger than 2¼ × 2¼ ins.) have no provision for offsetting the acceleration. In such cameras the slit travels from top to bottom of the plate, so that the lower part of the plate is slightly under-exposed. As this often corresponds to the sky area, under-exposure may be an advantage.

Acceleration effects do not, in any case, tend to be as serious on the larger and less accurately made shutters as on the comparatively delicate and finely adjusted mechanism in, say, a precision miniature camera. On the larger shutters, friction and other imperfections limit the speed that the blind can attain as it crosses the picture area.

Image Distortion. As the slit in the focal plane shutter travels across the sensitized material, the time it takes to expose any particular point on the surface is less than the total time it takes to expose the whole surface—i.e., the total exposure takes longer than the local exposure. When the slit width and shutter tension are set to give an exposure of, say, 1/1,000 second, the slit may easily take 1/100 second or longer to travel across the plate.

The rather long total exposure time of a focal plane shutter is not important with subjects that are still, or moving only slowly in relation to the film or plate. But with rapidly moving subjects, a special type of distortion may occur. If the image is moving across the film at right angles to the travel of the slit, then the image will move appreciably between the exposure of the first and last sections. So the last part to be exposed will be displaced in the direction of motion, and intermediate points will be displaced in proportion.

The result is that the subject appears to be leaning backwards or forwards, depending upon which way the slit moves in relation to the image.

If the slit moves from the top to the bottom of the image, then the bottom of the image will appear to have moved forward during the exposure, and the subject will appear to be leaning backwards.

If the slit moves from the bottom of the image to the top, then the subject will appear to be leaning forward.

This explains why the wheels of racing motor cars, photographed as they pass across the field of the lens, appear oval and lean either forwards or backwards. The shutter in such cases is almost always arranged to expose the bottom of the subject first, because the resulting forward tilt lends an impression of speed.

Focal plane shutter distortion can also be observed in the curved appearance of the air-screw blades of aircraft photographed with their engines running.

If the slit moves in the same direction as the image, it draws it out and makes it look longer in the direction of its motion. If the slit moves in the opposite direction to the subject, it squeezes it up and makes it look shorter in the direction of movement.

Generally, it is better to hold the camera so that the shutter slit moves in the opposite direction to the inverted image on the plate or film—i.e., in the same direction as the subject itself. The effect of shortening the subject in its direction of motion is usually more tolerable than drawing it out.

The distortion produced by a focal plane shutter follows the same rules as the blurring produced by subject movement—i.e., it is worst when the subject is moving across the

INDEPENDENT FOCAL PLANE SHUTTER. This type of shutter construction is a separate unit for building into cameras. 1. Blade position before exposure. 2. Shutter open. 3. Shutter closed after exposure. CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

FOCAL PLANE SHUTTER DISTORTION. When the blind of a focal plane shutter and the image of a moving object travel at right angles to each other, a special type of image distortion appears. As the slit of the blind takes longer than the effective duration of the exposure to cross the whole negative area, the image will be in a different position at each instant during the travel of the slit. The assembled effect of all these component images is a picture of the object leaning forward or back. Although undesirable in some cases, it can improve the impression of speed in the picture.

field, when the subject is close to the camera, and when the subject is moving quickly.

Flash Synchronization. Most modern shutters are internally synchronized for flash by means of suitable contacts which close the firing circuit as the shutter runs down. The contacts are generally connected to a suitable flash socket or outlet on the shutter or camera. This socket then takes the flash cable or lead from the flash gun.

The synchronization of sector type shutters is generally very simple, and permits flash shots at shutter speeds up to 1/25 or 1/30 second. This corresponds to X- or F-synchronization.

Simple diaphragm shutters are generally X-synchronized, while precision models may have separate sets of contacts for X- as well as M-synchronization. The latter permits flash shots with most bulbs up to the fastest speed of the shutter.

Focal plane shutters may have one or more sets of flash contacts, often with separate outlets, and corresponding to X- and M-synchronization. Owing to the time of travel of the blinds, special long-flash bulbs are required for synchronization of fast speeds.

Special Shutters. Shutters normally give an audible click when they are released. This noise is undesirable in some branches of photography—e.g., when taking pictures of animals, birds, and children. For such work special silent types of shutter are available. These are usually diaphragm shutters with two or more leaves operated by a pneumatic release. They are not suitable for high speeds and are designed for hand-operated exposures of one or two seconds.

Silent shutters are made to be fitted in front of the lens of the camera to supplement the normal shutter. The camera shutter is set at T and left open while the silent shutter is in use.

Supplementary shutters are also used for making intentional double exposures on cameras where the normal shutter is interlocked with the film transport mechanism.

Cinematograph cameras have rotary shutters of a special type that work immediately behind the lens at a constant speed. Exposures are varied in this case by changing the lens aperture.

The Kerr Cell shutter works on a completely different principle from any of the above. In this a high voltage is used to alter the polarization of a liquid mounted between crossed polarizing screens so that it allows light to pass through it. The Kerr Cell shutter can give exposures as short as 1/100,000,000 second.

Ultra short exposures are also obtained with various other shutter systems. They depend on obstructing the light path by rendering an optical unit in it suddenly opaque, for instance by an ultra-fast discharge or miniature explosion.

Shutters and Interchangeable Lenses. Since a focal plane shutter operates closely in front of the image plane of the camera and has no mechanical connection with the lens, it permits virtually unlimited interchangeability of lenses. The focal lengths that can be used depend only on the size and design of the camera mount.

Diaphragm shutters, being built into or fitted just behind the lens raise problems in lens changing. With the lens mounted just in front of the shutter the complete lens can be changed but the range of usable focal lengths is limited. Since the shutter is fitted a fixed distance in front of the film, the back focus of the lens must not be either too small (hence limiting the shortest available focal length) nor too long (to avoid serious vignetting and loss of shutter efficiency), thus limiting the longest usable focal length. Usually special lens designs are necessary for such systems.

Where the shutter is built into the lens itself with the blades between the lens components, two possibilities of interchangeability arise.

CC-0. Vasishtha Tripathi Digital Preservation Foundation, Chandigarh

The first is to change the focal length of the lens by using alternative front components, with the rear unit and the shutter remaining firmly fixed to the camera. This has been used for certain miniature cameras. The other alternative—employed on large-size professional cameras—is to have a separate shutter with each lens. The complete lens and shutter assembly is then changed. Such an arrangement is very versatile, but also rather expensive.

Obsolete Types. A number of shutter systems, devised in the earlier days of photography, are now of purely historical interest. One or two have still survived for use in, for instance, studio portrait cameras where neither the high speed nor the ultra high precision of modern shutter designs is essential.

One of these is the roller-blind shutter—in its simplest form an opaque fabric blind running between rollers mounted at opposite ends of a wooden frame. When the shutter is released, the blind is drawn from one roller on to the other by a tension spring.

The roller blind shutter is made in various forms to be attached in front of the lens as a separate component. There is either a gap or a circular hole in the blind and as this passes in front of the camera lens it exposes the film. The tension of the spring can be adjusted within limits to make the blind travel faster or slower and thus shorten or lengthen the exposure. The positions of the spring tension adjusting screw are marked with the corresponding exposure values—usually ranging from about 1/10 to 1/50 second. The control mechanism usually includes a means of halting the blind in the open position for time exposures.

The blind may be either continuous, or two blinds may be used as in focal plane shutters. In the latter case the roller blind shutter will be self-capping.

Roller blind shutters are sometimes used in front of the lens on field and studio cameras taking the larger sizes of plate. Where such cameras work with a range of interchangeable lenses, the roller-blind shutter can be switched from one lens to another.

Designs of other earlier shutter types varied widely; a number of types, after a short run of popularity, soon became either obsolete or confined to certain specialized fields.

The drop shutter was simply a plate with a cut-out aperture. It dropped or was moved by a spring across the path of the image-forming rays which passed through the aperture and made the exposure. Various shapes were tried for the opening, but the shutter was never very efficient and the range of speeds was limited and too low for modern materials.

The drop shutter was also known as a guillotine shutter. It was later modified by adding a second plate which "capped" it for setting, and also made instantaneous exposures possible.

The rotary shutter was an extension of the drop shutter principle in which the plate carrying the aperture rotated to produce the same effect. It was the forerunner of the various present day sector shutters.

Flap shutters were all elaborations of a simple hinged flap covering the lens and operated by a pneumatic release. The flap could be outside or inside the camera, and it was simply raised and lowered to make the exposure. Some portrait cameras to-day are fitted with internal flap shutters. A modified type has a number of flaps which open and close simultaneously, like the slats of a Venetian blind.

Bellows, or eyelid shutters, consisted of two concertina-like units which when closed formed a dome-shaped cover over the front of the lens. When the pneumatic release was pressed, the two halves of the dome separated and opened like upper and lower eyelids to make the exposure.

F.P.

SHUTTER EFFICIENCY

The efficiency of a between-lens sector or diaphragm shutter is the ratio of the light it actually transmits during the exposure to the amount that it would transmit if it were fully open for the whole duration of the exposure. In practice, no shutter is 100 per cent efficient. The reason for this is that between-lens shutters take some time to reach their maximum opening and some time to close, so they are not fully open all the time. At slow speeds, however, the efficiency of the average between-lens shutter closely approaches 100 per cent.

The efficiency of a diaphragm shutter largely depends upon the time taken to move the shutter blades from one limit of their travel to the other. For this reason shutter blades are always made as light as possible to keep their inertia low.

A small shutter is usually more efficient than a larger one because the blades are smaller, lighter, and have a shorter distance to travel. These advantages, however, may be cancelled out by the reduced power of the mechanism.

Shutters which require separate tensioning can use more powerful driving springs than everset shutters where the same lever tensions and fires the shutter. They are thus more efficient.

The actual times of opening and closing of the blades of a diaphragm shutter do not change much over the range of shutter speeds, and the efficiency is thus higher at low speeds. When the lens is stopped down, the shutter blades do not have to travel as far before uncovering the aperture, and the efficiency is increased.

The efficiency of a focal plane shutter depends on its distance from the film and on the *f*-number of the lens aperture. The optics of the system make it impossible for a focal plane shutter to be 100 per cent efficient.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

DIAPHRAGM SHUTTER EFFICIENCY. Top: *A diaphragm shutter is fully open only during part of the time of its operation; the periods of opening and closing take up some time, and thus result in a certain loss of light. The shutter opening is here plotted against time.* Bottom: *Comparison of shutter efficiencies. The dotted square represents an ideal shutter opening and closing instantaneously.* A, *modern shutter at 1/10 second. The time marks represent 1/100 second intervals.* B, *reduced efficiency of same shutter at 1/250 second. Time marks at 1/1000 second intervals.* C, *increased efficiency at smaller apertures, as blades clear lens aperture earlier.*

The image on the film or plate lies at the tip of a cone of light which converges on it from the lens. When the blind sweeps through this cone of light at a short distance from the film, the light intensity on the film does not become zero instantly, but is reduced to zero as the blind cuts off more and more of the cone of light.

This loss of efficiency is reduced by having the blind as close to the film as possible. As with between-lens shutters, the efficiency increases as the lens is stopped down.

The efficiency of a focal plane shutter can be calculated from the equation:

$$E = \frac{W}{W + d/f}$$

where W = width of shutter slit
f = *f*. number of lens
d = distance of shutter slit from camera focal plane.

The efficiency of the roller blind shutter operating very close to the lens is determined by the slit width and the lens aperture. The greater the slit width compared with the aperture, the higher the efficiency. The efficiency varies with aperture—i.e., it is higher with a small stop which can be uncovered and covered quickly—but for a given slit width, it is the same for all shutter speeds.

Measurement of Efficiency. The efficiency of a shutter is arrived at by comparing the amount of light actually transmitted from the beginning of opening to the end of closing with the amount of light that would have been transmitted if the shutter had been fully open for the whole time.

There are two principal ways of measuring the amount of light actually transmitted by the shutter: by sensitometry, or by using a cathode ray oscillograph.

Sensitometric measurements may be carried out by the following methods:

(1) The shutter can be used to expose film to a standard light source, and the amount of light passed can be calculated from the density of the resultant image. This method has many faults; it is difficult both to calibrate the light source and to control processing with the necessary accuracy. The interpretation of the resultant density is not easy.

(2) A more modern variation of this method is to put a photo-electric cell in place of the film and measure the light falling on it electronically. The interpretation of the result is difficult as the light source must be calibrated and allowance has to be made for the lens aperture. The method is useful, however, for making a quick comparison of shutters against a laboratory standard.

All methods depending on this principle measure the effective shutter speed.

The simplest method of using a cathode ray oscillograph for testing shutters is to photograph a pattern on the tube screen.

A more involved method enables the complete shutter characteristics to be determined almost instantaneously. In this method, light transmitted by the shutter falls on to a photoelectric cell. The signal is amplified and deflects a luminous spot vertically on the screen of the cathode ray tube. The spot may at the same time be deflected horizontally at a known speed to give a time base.

As the shutter opens, the spot is deflected upwards and at the same instant the "time" deflection begins, with the result that the spot draws a graph on the screen of the tube. The "time" deflection is calibrated in fractions of a second either by a grid in front of the screen or by an extra light pattern on the screen.

The whole picture on the screen can be photographed if a permanent record is required. By this means, therefore, the total time of opening, the efficiency, and the effective

exposure time may be determined very quickly. Erratic or faulty operation is also obvious.

A graph of the light transmitted by a shutter, recorded in this way, shows how the amount of light increases as the shutter opens, remains constant at full aperture, and then decreases as the shutter closes. The full aperture of the shutter may have been used for 1/100 second during a total time of opening of 1/80 second.

If the shutter had been ideal, it would have wasted no time in opening and closing, and the graph would rise vertically to fully open, remain at that level for the total time of exposure, and then drop vertically to zero. In practice the graph slopes more or less gradually from zero to the maximum and then more steeply back again.

The amount of light passed by the shutter is proportional to the area enclosed between the graph and the base line. The efficiency is then simply the area enclosed by the shutter performance graph expressed as a percentage of the area enclosed by the graph of an ideal shutter open for the same total length of time.

FOCAL PLANE SHUTTER EFFICIENCY. The ideal focal plane shutter operates in the plane of exposure with an efficiency of 100 per cent. Actual shutters operate some distance away from the exposure plane, and thus cut the cone of light coming from the lens plane. This reduces the efficiency; the effect is an increase in the length of the exposure, the total amount of light passed is unchanged. 1. Exposure begins with actual shutter, no exposure with ideal shutter. 2. Actual shutter has already passed appreciable light, ideal shutter none. 3. Ideal shutter just uncovered film, actual shutter nearly uncovers full cone of light. 4. Actual shutter reaches maximum flood of light which is same condition in case of ideal shutter.

Comparison of Shutter Types. The performance of shutters varies very greatly from type to type, from make to make, and from shutter to shutter, and it is difficult to generalize about performance. Calibration, especially of the cheaper everset shutters, is not always reliable. It is only recently that quick and accurate methods of shutter testing have become available, so that modern shutters are likely to be more accurate than older types.

The efficiency of an everset shutter is usually in the 60–70 per cent range for shutter speeds from 1/25 to 1/100 second, which is as far as such shutters usually go.

The efficiency of pre-set shutters is higher, and is generally about 90 per cent at 1/25 second, 80 per cent at 1/100 second, and about 70 per cent for higher speeds, falling to 65 per cent at 1/500 second. These figures are for the smaller shutters, and are usually slightly lower for large ones. The calibration of these shutters is usually more accurate than with the everset type.

Higher effective shutter speeds can be achieved with focal plane shutters, because exposure can be shortened by simply narrowing the slit instead of speeding up the movement of the blind. Although the efficiency falls as the speed is increased, a precision focal plane shutter is usually more efficient than a precision diaphragm shutter at the same speed.

Efficiency and Movement Blur. The time for which a shutter is fully open is less than the total time from the beginning to the end of the exposure. This is of considerable practical importance in photographing moving objects. If the shutter is of low efficiency and takes an appreciable time to open and close, the brighter parts of the moving object will be recorded both before and after the shutter is fully open, and will appear more blurred than darker parts which are only recorded at the maximum shutter opening.

Efficiency and Calibration. As the efficiency of the shutter drops at the highest shutter speeds, this should be allowed for in the calibration of the shutter. Modern precision shutters are in fact calibrated in such a way that the shutter speed represents the exposure that the shutter would give if it were operating at the indicated speed with 100 per cent efficiency, rather than the actual open time of the shutter. Thus the light passed through the shutter at 1/500 second is adjusted to be one-half of the light passed at 1/250 second, one-quarter of the light at 1/125 second, etc. This means that the 1/500 second setting may yield a total exposure time from the beginning of the opening phase to the end of the closing phase of, say, 1/300 second.

Such photometric, as distinct from purely time calibration is important with cameras

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

using a coupled or automatic exposure meter. If the camera itself selects the shutter speed setting, the photographer may have no indication of the actual speed in use and his exposures may be open to unpredictable errors. Photometric calibration of the shutter largely avoids this. It cannot do so completely where shutter speeds are separately adjustable, because the efficiency (and hence the light passed) depends also on the lens aperture used. In fully automatic cameras with a programmed shutter the effect of the lens aperture can however also be allowed for in calibration. A.S.C.

SHUTTER MANUFACTURE

The rôle of the camera shutter is to regulate the time during which light is allowed to act on the sensitive material. With simple cameras the action of the shutter merely consists of uncovering and covering the lens opening in an instant, lasting usually approximately 1/20 to 1/40 second. For ordinary snapshooting this is quite adequate, and variations in the effective exposure time from shutter to shutter are usually taken care of by the latitude of the negative material.

Better cameras have more complicated shutters with a range of exposure times which are more accurately determined. To achieve this degree of accuracy, within the small space available for the shutter mechanism in the camera, requires manufacturing methods of appreciable precision. High class shutters are therefore generally made by a small number of specialist firms who supply them to the various camera manufacturers.

There are two fundamental types of shutter: diaphragm shutters which are generally mounted between or just behind the lens elements, and focal plane shutters which work just in front of the sensitive emulsion. The construction and to some extent the materials required for the two types of shutter differ, but the same skill and precision in manufacture are required in each case.

DIAPHRAGM SHUTTERS

The modern diaphragm shutter has to satisfy certain basic requirements relating to the time of action, the control of the speeds, the shape of the sectors and the movement, as well as the subsidiary gear mechanisms which control such items as self-timer and flash synchronization.

The exposure with a diaphragm shutter is spread over three intervals:

(1) The interval during which the blades are opening.

(2) The interval during which the blades remain open.

(3) The period during which the blades are closing.

The first and the third of these intervals must be as short as possible to obtain a maximum effective open interval. The shutter mechanism therefore has to work under much more difficult conditions than, for instance, a watch. The above requirements call for a sudden acceleration, and then a final braking of the shutter blades and the driving elements. The degree of wear and tear is therefore far greater than with a watch where the movement is more or less uniform.

The basic speed of the best diaphragm shutters is 1/500 second; some models may have a basic speed of 1/400 or 1/300 second, and certain special ones up to 1/1000 or even 1/2000 second. Longer exposure times (slower shutter speeds) are obtained by means of a delay mechanism, usually an escapement. This is linked to, but otherwise independent of, the main opening and closing drive.

Other subsidiary mechanisms include the delayed action release or self-timer which is another escapement mechanism to retard the release of the shutter itself. In addition the shutter contains built-in flash contacts coupled in many cases with the delayed action mechanism to time the firing of flash bulbs. The contacts have to be insulated and big enough to carry the firing current.

The shutter blades must exclude all light when closed. To do this the blades have to overlap each other in a fan-like fashion, yet move with the minimum possible friction to permit the short exposure time required.

Owing to the ease of synchronization of electronic flash at all shutter speeds, diaphragm shutters have also been designed for use with interchangeable lenses. This raises special design problems where the shutter is permanently mounted on the camera and the lens units fit into the front of the shutter. (On some cameras the lenses are interchangeable together with the shutter; that only requires an auxiliary shutter in the back of the camera to protect the film against the light during lens changing.) As the interchangeable lenses usually have their own iris diaphragm, the changing system must also incorporate suitable features for coupling and uncoupling the aperture setting.

The design becomes still more complex with diaphragm shutters built into single lens reflex cameras and with automatic exposure control systems. In the first case the shutter tensioning (linked to the film transport) movement must open the shutter and iris diaphragm at the end of the tensioning cycle to permit viewing of the

SHUTTER MANUFACTURE. The stages illustrated symbolize rather than attempt to show in detail the production of a between-lens shutter. They are, however, typical in a simplified form for a modern unit. Top: *The base plate is stamped by special presses and machined and drilled for the various cut-outs, apertures, and screw holes.* Upper left: *Most of the levers and rings are cut out from sheet metal, drilled and machined.* Upper right: *Suitable stamping machines cut the shutter blades from continuous bands of very thin spring steel.* Centre left: *Screws, shafts, and pins, as well as mechanical components like gear wheels are mass turned on automatic lathes and finished on precision milling machines.* Centre right: *Iris leaves are stamped from thin steel bands in the same way as the shutter blades. The leaves are assembled inside the main housing together with the rest of the mechanism.* Lower left: *The cover plate, speed setting ring, etc., are stamped in hydraulic presses and machined. The various assemblies and sub-assemblies are checked at different stages throughout production.* Lower right: *Speed rings and other scales are engraved after calibration, the synchronizing contacts are set with the aid of a testing circuit.* Bottom: *Finally the complete shutter undergoes a thorough test for accuracy, consistency, synchronization, etc., before being built with a lens into a camera.*

image on the ground glass screen. This also makes the release cycle more involved: the shutter has to close while the iris stops down to its pre-set aperture and the mirror moves out of the way. Then the shutter opens again for the exposure and—after closing—may be further linked with a mechanism to bring the mirror back into the viewing position and to open the shutter once more (instant return mirror).

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Automatic exposure controls systems require the shutter speed (and usually also aperture) settings to be linked with a pre-selector system actuated by the shutter release, but controlled by the position of an exposure meter needle in the camera. Systems of this nature have to be developed in conjunction with the exposure meter design and the camera to shutter linkages. In some cases the primary development work is carried out by a camera manufacturer who patents the design, or new shutter systems evolve as the result of co-operative research programmes between camera and shutter manufacturers. In that case the camera manufacturer generally has a priority claim on that particular design, which however may at a later stage be offered to other camera manufacturers as well.

Planning and Tooling Up. The initial design is based on previous experience and much experimental work on prototypes. Solving the various problems of making the comparatively small shutter is the work of a staff of skilled engineers.

Once the finalized design blueprints are released by the drawing office, the pre-production planning begins. This involves decisions on the methods of manufacture, the sequence of stages, and the machine tools required. Most parts of a shutter consist of metal stampings. These call for the production of a large number of different stamping presses, drills and jigs, measuring and test instruments, as well as special machine tools. All that plant must be developed at this stage.

The machine tools are sometimes made and serviced by special engineering works, and sometimes by the manufacturer himself. All the required stamping and embossing tools, dies, and finishing instruments call for an extremely high standard of precision. It must be remembered that the tolerance of shutter components is of the order of plus or minus 0·0004 in., and the tool must be even more accurate than the components it produces.

Raw Materials. As the various parts inside the shutter often have to stand quite high strains and stresses, raw materials have to be carefully selected. This involves physical and metallurgical tests in a special laboratory which checks incoming deliveries of raw materials.

The materials consist mainly of sheets and rods of various light metal alloys, brass and steel, spring steels for the various springs, and special thin steel plates for the shutter blades.

The moving parts of a shutter also need suitable lubrication. Since the viscosity of normal lubricating oils depends on the temperature and could thus appreciably affect the working of the shutter in cold weather, special lubricants like molybdenum disulphide are used. In some more recent shutters synthetic plastic components are also used. Those are not only corrosion-proof but also need no lubricant since they move with negligible friction at all temperatures.

Stamping. Such parts as levers, rings, cover and base plates, are stamped out of strips of metal in dozens of stamping presses from small table models to large 60-ton eccentric presses. Other presses stamp out large numbers of blanks for gear wheels. These are collected in packets for subsequent milling of the gear teeth.

Machining. Stamped parts are passed on to another department for machining. Automatic lathes machine and shape the various screws, bolts, and complicated shafts that go to make a modern camera. The whole operation is automatic, and human attention is only required to keep the machines running and supplied with the different sizes and types of metal rod.

The shutter casings are generally machined from die castings. Here again automatic machines work on dozens of parts of the casing at once; the job of the attendant is confined to inserting the castings and removing the finished casing.

Certain parts of the shutter have to carry exceptional stresses and strains and the components have to be specially treated by suitable heating and tempering. In some cases the extreme tip of a tiny shaft is hardened in a special machine using a high frequency alternating current to heat up the parts locally.

Checking. Economical mass production of precision components of this type calls for highly efficient checking at each stage in the production. Many of the parts are checked individually by the operator at the machine, and extensively rechecked at the end of each production stage. In some cases a production stage may include as many as fifty to seventy individual operations and involve a considerable amount of careful testing.

In modern production technique the checking of all components by human operators is however uneconomical, since such components are produced faster than they can be examined. Frequently such parts are therefore checked by electronic machines which reject all components falling outside the prescribed tolerances, and at the same time keep a constant tally of the number of items checked as well as the rejection rate.

All measurements boil down to a comparison of the part with an accurate standard. The comparison may be optical or mechanical. Optical checking is carried out by projecting the outlines of the component—e.g., the pro-

file of a tiny screw thread by means of profile projectors. Some of these permit simultaneous measurements of up to ten different components. By comparing the outline of a component with the outline of the appropriate standard projection slide, the tester can see whether the accuracy of machining falls within the permissible tolerances.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

Such an instrument—of which there are many in a shutter factory—permits the speedy checking of distances, outlines, angles, etc., with an accuracy of up to 0·0004 in.

Mechanical checking is carried out with gauges linked to suitably calibrated indicators which show instantly if the dimension being measured is correct. Again these gauges operate automatically, controlled by a programming unit, which passes several thousand components through the checking machines.

Finishing. The shutter-speed scales are engraved by hand with the aid of suitable stencils.

To protect the metal surfaces from wear and corrosion and give them an attractive appearance, they are treated by various plating or anodizing processes or by lacquering.

Assembly. The various parts converge first into pre-assembly groups—e.g., escapements and delay mechanisms—and next to the final assembly line.

In modern shutter production even sub-assemblies are put together by automatic machinery. Vibrators and other feeding units supply the individual components in their correct orientation and proper order, while the machine joins them up, rivets pivots etc. Automatic cut-outs stop the machine if any part supplied to the sub-assembly is faulty or if any assembly operation goes wrong.

With a precision mechanism like a shutter, strict cleanliness is essential. The assembly room therefore has to be kept completely free from dust, and at an even temperature and humidity. The most modern assembly departments are air-conditioned and work with closed windows in summer and winter.

The assembly department operates on the principle of the continuous production line. The various parts and various groups are assembled step by step while the shutters move continuously forward towards the finished product. Each worker carries out one operation, often doing no more than adjust a single shutter speed.

Final testing. The shutter speeds are checked by a photocell which measures the light transmitted by the shutter while it is open. An electronic circuit converts the output of the photocell into a direct indication of the shutter speed.

The delay time of the flash contact is measured by a similar device. Built-in calibrating instruments keep a constant check on the speed testing equipment itself.

Final Stages. One of the last production stages is the cutting of the two threads which take the lens components. This operation has to be specially precise to ensure that the axes of the front and rear lens elements exactly coincide. The discrepancy between the two axes must not exceed 0·0006 in., while the deviations of the thread itself must be within a tolerance of the order of 0·0004 in. A special screw-cutting lathe cuts the two threads simultaneously on the finished shutter. W.A.B.

FOCAL PLANE SHUTTERS

The focal plane shutter is not a self-contained unit made separately from the camera. It is built into the camera body and its manufacture is inseparable from that of the rest of the camera. Whereas a diaphragm shutter, perhaps complete with lens, can be obtained ready-made by the camera manufacturer, this is not so with the focal plane shutter.

The main mechanism is built on a scale larger than that of the diaphragm shutter, and the work involved is medium-fine engineering rather than extra-fine. This applies to small camera shutters; the standard can be lower still for larger cameras.

If the shutter has associated mechanisms, such as escapements for slow speeds and delayed action, these are usually similar in quality to the corresponding components of the diaphragm shutter and require a similar standard of workmanship.

Large Cameras. Shutters in current use are of two types—coupled-blind, or independent-blind. The first is used for cameras of large negative size, such as press cameras. Each blind runs between separate pairs of rollers, one at each side of the camera. The two take-up rollers are driven by coil springs, and the winding spools are connected by gears engaged in the position necessary to give the desired slit width. When the shutter is released, the blinds therefore travel across together at constant slit width.

The basic mechanism is simple and presents few manufacturing problems. The design is complicated by the self-capping arrangement, but this does not add any particular difficulties.

Speed calibration is based on slit width. The driving springs are then tensioned until the speeds are correct. Some cameras are provided with a tension control to vary the speeds.

Small cameras. The precision miniature camera shutter is a different proposition. The two blinds operate independently and are not coupled to maintain a constant slit width. Depressing the shutter button releases the first blind, and when this has travelled a certain distance the second blind is automatically released. The exposure time is the time interval between the release of the blinds, and this remains constant providing the travel characteristics of the two blinds are identical—that is, providing the inertia and acceleration are the same. The slit width is not constant, but it becomes wider as

the velocities of the blinds increase, which is necessary for even exposure.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Good consistency in performance therefore depends on good design and high accuracy in manufacture; friction losses must be kept to a minimum and the design be such that further friction cannot readily develop. Any differences in the movement of the blinds will result in uneven exposure across the frame; the higher the speed setting the more evident this becomes. The blind fabric in particular should not vary in flexibility over the normal range of temperatures, nor vary greatly with use.

Traditionally focal plane shutters used to be produced to individual designs to suit particular camera models. But such shutter types are also appearing as completely independent assemblies suitable for fitting into appropriate camera models. The assembly and production of such individual focal plane shutters then follows the same principles as with diaphragm shutters, subject to the modifications of design involved.

Usually separate focal plane shutters are all-metal types using sliding blades that move in front of the film, rather than cloth blinds. Some focal plane shutters employ very thin flexible steel blinds covered with black plastic instead of cloth.

Production. In general the production outline for the focal plane shutter of a small precision camera is similar to that for the diaphragm shutter. The methods of making the components depend on the scale of production since this determines the size of the plant available; but the same principles apply as described in detail above.

Assembly and Testing. In assembly the total camera mechanism has to be considered as a whole. The shutter of a small precision class camera is coupled to the film transport; there are the winding, metering and exposure counting arrangements for this, and usually a double-exposure lock. The combined mechanism may therefore be quite complex, and assembly of the shutter becomes part of the general camera assembly. This calls for a team of skilled technicians, each dealing with different stages of the work and each capable of making any adjustments to ensure perfect operation.

The complete assembly is then checked and final adjustments made if necessary to ensure smooth working. The tensions of the driving springs for the blinds are also adjusted at this stage. The usual procedure is to set the shutter to one of the higher speeds, such as 1/200 second, and measure the speed given at each side of the film opening and in the centre. The blind springs are adjusted so that the speed recorded at each point is the same, or as nearly so as it is possible to get it, and so that this speed agrees with the shutter setting. All other speed settings should then be automatically correct, but it is nevertheless usual to check throughout the range. H.H.

SHUTTER RELEASE

The normal shutter release is a press button or lever which is ideally mounted in such a position that it can be depressed naturally by the forefinger while the other fingers have a comfortable grip on the camera body.

In practice its position varies; it is usually mounted on the lens-shutter assembly for a between-lens shutter, and on the camera body for a focal plane shutter.

Nowadays many cameras with between-lens shutters have the release button mounted on the body and connected to the shutter by a mechanical link. This is because it is easier to hold the camera steady when pressing a button on the body than one near the lens.

PNEUMATIC BULB RELEASE. 1. Rubber bulb connected by flexible tube to collapsed bulb under shutter release. 2. Pressure on bulb inflates the small bulb and trips shutter.

Some form of supplementary release with a flexible connexion to the camera is always an advantage when making time exposures with the camera mounted on a tripod. At such times direct pressure on the release button on the camera tends to shake it.

Pneumatic Release. The early form of flexible remote release consisted of an india rubber tube which was connected to a cylinder and plunger, or a simple inflatable bag mounted in contact with the shutter release. At the other end of the tube there was a rubber ball which, when squeezed by the operator, caused the plunger or bag to exert pressure on the release.

This type of release is still used on some studio cameras. It has the advantage of being silent, frictionless, and easy to renew.

Flexible Wire Release. The flexible wire (or cable) release is the one in general use for extending the existing shutter control. It consists of a thin stranded steel cable sheathed in a flexible tubular casing made of coiled or braided steel wire.

At one end the outer casing terminates in a

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

CABLE RELEASE. 1. Stiff cable with plunger at one end and solid pin at other inside a flexible sheath. 2. Pressure on plunger pushes out pin to trip shutter. Bottom: Locking screw for keeping release depressed for long time exposures.

conical screwed nipple through which projects a pin, sweated to the end of the inner cable. This nipple screws into the standard screwed socket which is fitted to most shutters, and the pin engages with the shutter release mechanism.

The other end of the flexible casing is fitted with a collar which acts as a guide for a plunger connected to the inner cable. An internal spring keeps the plunger raised. Pressure on the plunger operates the release.

A short wire release is used when the existing release is not conveniently placed for operating with both hands gripping the camera body.

A flexible release is also used when the camera is mounted on a tripod. In this case it is designed to prevent the operator's hand from shaking the camera when opening the shutter. For this purpose a long release—8 to 12 ins.—must be used; anything shorter than this is likely to transmit movement to the camera and so defeat the whole purpose of the tripod of keeping the camera steady.

This type of remote release is far from being perfect. Its great drawback is the serious amount of friction and lost motion that takes place between the cable and the casing. The result of this is that a short length tends to transmit shakes and vibration while long lengths call for relatively heavy pressure on the plunger and a considerable amount of travel to allow for the large amount of unavoidable slack in the cable.

Where a flexible release is to operate over a distance of more than 3 or 4 feet, this type of cable is unsatisfactory. A more positive action is given by a Bowden type of cable, where the inner cable is under tension and the slack can be taken up by a screw adjustment. This type of release needs a special fitting at the camera end to convert the pull in the cable into the push needed to operate the shutter.

Locking Release. Many modern camera shutters have no T-setting for long time exposures (i.e., where one pressure on the release opens the shutter and a second pressure closes it). This is largely to permit the inclusion of double exposure locks with which two successive pressures on the release—without winding on the film—are impossible. As it is inconvenient to keep the plunger of a cable release pressed down for long periods by hand, many such releases incorporate a lock.

The lock usually takes the form of a small clamping screw fitted in the collar of the plunger. To make a time exposure with such a release, the plunger is depressed to open the shutter (set to B) and the screw tightened to keep the plunger pressed down. Slacking off the screw allows the plunger to return to its original position, thus letting the shutter close.

On some models a second movable collar, arranged concentrically with the plunger, serves as the lock. Depressing the plunger also locks it, depressing the movable collar frees it.

Air-Pressure Release. One type of remote release consists of a long tube with a rubber ball at one end, and a cable release holder at the other. Pressure on the rubber ball actuates the cable release by air pressure. This system can work over appreciable distances (30 feet or more).

Electrical Release. Mechanical remote control of the shutter at distances greater than 10 feet is inconvenient and uncertain. At such distances electrical control is more satisfactory. The shutter is electrically controlled by having some form of electromagnet or solenoid attached to the camera so that it works directly on the shutter release or on the plunger of a cable release screwed into the shutter. A length of twin flex connects the solenoid to a press-button switch at the operating position, and the battery supplying the current may be at either end.

With this method of operation, the full working current required by the solenoid has to flow in the control wires. The control wires have therefore to be fairly thick because a suitable solenoid will require a current of at least 3 amps at 12 volts. So direct operation is only convenient over fairly short distances—not more than 20–30 feet.

A more flexible arrangement is to house the battery close to the camera to keep all the heavy current wires as short as possible. The switching in the solenoid circuit is then done by a relay, operating from the same battery, but consuming a much smaller current. This system makes it unnecessary to run heavy wires between the camera and the shutter release position. Bell-wire or clock flex will carry the small operating current over considerable distances.

Another system uses a spring loaded bar which bears directly on the cable release plunger. The bar is held against the tensioned spring by a catch. A magnetic relay operates the catch so that when the circuit to the relay is closed the bar is released and the cable release plunger operated.

In any system where the camera shutter release is pressed by a remotely controlled mechanical or electrical device, the pressure

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh.

ELECTRIC RELEASE. Design of an electrically operated remote control release. A spring loaded bar is released by the electromagnetic relay, depressing the cable release plunger. A, re-setting bar (engages relay arm). B, spring. C, plunger. D, relay arm. E, electromagnetic relay operated from suitable point. F, cable release to camera.

must not be applied with a sudden jerk. Unless the action is similar to the relatively gradual application of pressure by the fingers, the shutter mechanism may be damaged and there will be a risk of camera shake.

The methods described above provide only for the remote release of the shutter, so the camera must be visited after every exposure to re-set the shutter and change the film or plate.

If the entire sequence of operations is to be carried out from a distance then there must be an independent device for re-setting the shutter and changing the negative material. The most satisfactory way of dealing with complete remote operation is to use a clockwork mechanism arranged to carry out the cycle of operations on the receipt of a single signal from the distant end of the circuit.

When the operator presses the remote release, an electric relay at the camera end operates a solenoid; the solenoid lifts a catch on the clockwork unit; the clockwork mechanism then depresses the camera shutter release, winds on the film, and re-sets the shutter, finally coming to rest against the catch ready to repeat the cycle of operations. One winding of the clockwork spring is enough to expose a whole length of film without further attention.

The above release systems are used in nature photography and in scientific work for photographing events in which the operator would be exposed to risk if he remained with the camera.

Synchronized Release. A special type of release is used for synchronizing the opening of the shutter with the most useful part of the light output of a flash bulb. The flash bulb takes some milliseconds to reach peak brilliance. So if the shutter is to open and close while the bulb is at its brightest, the flash bulb circuit must be closed first, and then after a definite period of time, the shutter must be released. The synchronized release performs both these operations in the correct sequence and with the required delay, on a single pressure of the control plunger. It is possible to adjust the delay between the closing of the flash contacts and the operation of the shutter to allow for differences in the burning rate between the various types of bulb. There are several methods of obtaining the delay, mechanical and electromagnetic; some types must be attached to the camera baseboard and others simply screw into the shutter release socket.

Automatic Release. The commonest form of automatic release is the delayed action device by which the photographer can include himself in the picture. Some shutters incorporate a delayed release which can be brought into action when the shutter is set.

With the device in action, when the release is pressed in the usual way, exposure does not take place immediately, but is delayed for 15–20 seconds—long enough for the photographer to take his position in the picture. The delay is usually achieved by allowing a spring to unwind slowly under the retarding action of a train of gears.

Supplementary devices are available for converting ordinary shutters to delayed action. These usually consist of a unit which screws into the ordinary cable release socket and has a plunger which is depressed instead of the normal camera shutter release. A train of gears or a spring-loaded dashpot device holds up the final pressure on the shutter release for the required number of seconds.

Subject-Operated Release. It is often desirable to arrange for the shutter to be operated by the subject—with or without his knowledge. This can be done by making use of one of the

DELAYED ACTION RELEASE. On winding the lever and releasing the catch, the arm is slowly drawn into the body, and presses the plunger of the cable release until it trips the shutter.

remote release devices described above.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

In big game photography a thread may be stretched across the path of the game and connected to a pin or trigger which when pulled allows a spring to depress the shutter release. The camera is focused on the spot where the game will walk into the thread. For pictures at night, the shutter is synchronized with some form of flash lighting.

Electrical release lends itself to a number of ways of obtaining subject-operated photographs.

One is by pressure operated release. If it is known that the subject will touch or pass over any object, a pair of contacts may be concealed below the object and connected to the remote control wires of the electrical release. This method is particularly suitable for nature photography because it consumes no current when it is waiting to make the exposure and so can be left for long periods after being set, until actuated by the subject.

Another method is by light-operated release. The electrical release may be triggered by a photocell connected to a valve amplifier in the relay circuit of the shutter operating solenoid. The photocell is placed so that when the subject occupies a particular spot (on which the camera is focused) the light is cut off from the cell. This changes its electrical potential and makes an energizing current flow in the relay circuit of the shutter operating solenoid.

The same effect may be produced by directing a beam of invisible infra-red light at the photocell so that when the subject passes through the beam the shutter operating circuit is completed.

This system has many applications in the detection of criminals and in industrial and scientific research. A disadvantage is that the amplifier must be permanently switched on, and a failure of the power supply puts it out of action.

Where absolute reliability is essential, the photo-emissive type of photocell circuit can be replaced by one incorporating a photo-transistor which operates from a 12-volt dry battery and has an extremely low dark current.

Radio Release. The relay of the electrical shutter release can be triggered off by various methods, including a radio signal. This method has been employed in photographing birds and animals from a distance. The quarry is followed through binoculars or a telescope and when it is seen to be within range of a concealed camera, a pulse sent out from a radio transmitter either releases the shutter or switches on a photocell circuit which operates an automatic release mechanism. Radio release is also employed for operating photographic equipment on space rockets or earth satellites.

Acoustic Release. If a microphone is substituted for a photocell, the shutter may be released by sounds. The amplifier circuit can be adjusted to respond to a sound of any given volume or pitch. This system also is used in crime detection and some photographic studios are equipped with it so that the operator can work the shutter release from any part of the room by simply clapping his hands. F.P.

SHUTTER TESTING

The purpose of a photographic shutter is to allow the light forming the image in a camera to act upon the sensitive emulsion for a definite time and at a definite moment.

Ideally the shutter should open and close very quickly, but most shutters fall short of this ideal, and there may be wide differences between shutters in this respect. Thus the more detailed tests are concerned not only with determining the period of opening of the shutter, but also with investigating the way in which the shutter opens and closes and how much light it passes during this phase.

Better-quality shutters are surprisingly reliable and consistent in their performance, and individual shutters conform well to type. Consequently, there is little to be gained from attempting to test such a shutter for oneself, unless some fault is suspected, or a precise knowledge of some characteristic is wanted for a special purpose. Some simple tests are possible, however, and examples are given below.

In general, the complete testing of a shutter is rather difficult, and is usually only carried out in the development of new designs or for checking standards in production.

Shutter Characteristics. Important properties of shutters are specified by quantities which now have accepted definitions.

(1) The property of apparently stopping the motion of a moving object is dependent on the time interval during which the shutter is open, or partly open. This is the total open time.

(2) While the shutter is opening and closing it is not passing as much light as when it is fully open. The first and last parts of the exposure are not fully effective. The total amount of light passed is proportional to the effective exposure time, which may be regarded as the period for which the shutter would have had to be fully open to pass the same total amount of light.

(3) The effective exposure time is evidently less than the total open time, but the more effective the opening and closing parts of the cycle can be made, the more nearly equal these quantities become. The ratio of the effective exposure time to the total open time is the efficiency, and is expressed numerically as a percentage.

The time the shutter takes to open is greater, the farther it has to open. With a given indivi-

CC-0. Agamnigal Digital Preservation Foundation, Chandigarh

dual shutter, the shutter is affected much sooner when the lens is used at a small aperture. Then part of the opening time no longer leads to an increased amount of light transmission. Accordingly the shutter efficiency at small lens stops is increased and the effective exposure time becomes more nearly equal to the total open time.

By agreement in international standards the shutter speeds marked on a shutter refer to the effective exposure time at the maximum lens opening. From this follows the slightly paradoxical state of affairs that at small lens apertures the effective exposure time of the same shutter becomes longer.

Simple Tests. It is possible to measure the total open time of a shutter quite accurately by photographic methods using the shutter in the camera in the ordinary way; this technique, incidentally, fulfils the requirement, mentioned above, of simulating actual conditions of use.

ROTATING MIRROR SHUTTER TEST. A, vertical fluorescent tube. B, screens with slits. C, mirror on motor driven turntable. D, flash bulb (when testing synchronization). E, torch bulb supplying steady light, arranged above or below flash bulb. F, shutter. The film is exposed once to the light from the steady lamp and the flash (if used) at shutter setting to be tested, and then again to the fluorescent tube with the shutter open on time while the light reflected from the mirror sweeps once across the film. When testing a focal plane shutter, the blind must travel parallel to the direction of the fluorescent tube. The flashes from the latter are separated by 10 milliseconds on the film if powered by 50 cycle A.C. mains. Speed of mirror adjusted to give adequate separation of tube images.

In the simplest test, all that is required is some small bright object which can be made to move at a constant known speed s, and which can be photographed, using the shutter to be tested, at a known magnification m. The length of the trace of the moving point on the developed film. l, is measured. Then the total open time, t_o, is given by the relation

$$l/ms = t_o.$$

Thus, for example, if a small lamp is carried by a vehicle moving at 30 m.p.h. (528 ins. per second) across the line of sight of the camera, and is photographed from 50 feet away, by a camera with a 2 ins. lens, the calculation is as follows. The magnification is $2/(50 \times 12) = 1/300$. If the streak on the film is 0·10 in. long, the total open time is:

$$t_o = \frac{0{\cdot}10}{1/300 \times 528} \text{ second}$$
$$= 0{\cdot}057 \text{ second.}$$

If the lamp or brightly illuminated object can be arranged to move in a circle with a known angular velocity, and the angle subtended by the arc on the film is measured, it is not necessary to know the magnification. Thus, if a bright source is mounted near the edge of a gramophone turntable rotating at 78 r.p.m. (468 degrees per second) and is photographed from immediately above the centre of the turntable, the record on the film will appear in the form of a circular arc. The angle subtended at the centre of the turntable by the ends of this arc can be measured with a protractor. It helps if the centre of the turntable is made to show up clearly on the film. A convenient point source can be provided by fixing a small pocket or pen torch on to the turntable, first removing the glass and reflector. Suppose the arc measures 40°; then the total open time is:

$$t_o = \frac{40}{468} \text{ second} = 0{\cdot}087 \text{ second.}$$

Several measurements may be made on one frame if the camera is shifted slightly between exposures. The repeatability of the shutter can be quickly checked in this way, or different shutter speeds can be easily compared on the one single frame.

In the case of focal plane shutters, repeating the measurements at a number of places along the direction of travel of the blind will give a measure of the variation of exposure caused by blind acceleration. The investigation of this point may be made difficult if the performance of the shutter is not repeated exactly, and in any case the trace may be shortened or lengthened if the image of the gyrating source is moving towards or away from the direction of travel of the blind at the time of exposure.

Flashing Light Source. The procedure can be improved if the light which illuminates the moving object can be modulated at a known frequency—e.g., by employing a stroboscopic

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

ROTATING MIRROR TEST RESULT. A, direction of focal plane blind (if used). B, streak from steady light. C, flash from bulb. D, interval of tube images (10 milliseconds on 50 cycle mains). Total open time = B/D × 10 milliseconds. Flash occurs C/D × 10 milliseconds after shutter begins to open.

lamp as the source, or by using a discharge lamp run from alternating mains. On 50 cycle supplies, for example, an ordinary fluorescent lighting lamp produces a flash every 1/100 second.

The exposure could then be determined by counting the number of flashes recorded on the film, and it would no longer be necessary to be sure of the constancy of the speed of movement.

The counting method is obviously useless for times less than 1/100 second, but a simple modification enables the whole range of shutter speeds to be tested. A horizontal turntable driven at a constant speed is required, but the speed of rotation need not be known. A speed of about 1 r.p.m. is suitable for times up to 1 second, and about 10 r.p.m. for times less than 1/10 second.

A good quality mirror is mounted vertically along a diameter of the turntable, and the camera is arranged as close as possible, looking into the rotating mirror. The mirror should be large enough to cover the whole field of the camera, if possible.

A fluorescent tube, or other discharge lamp, is set up vertically some distance away, and the width of the tube is masked down to a long narrow slit formed by the edges of two long strips of card, or other opaque material. Near the tube is set up a torch bulb supplied from a battery. The camera is focused on the slit and torch bulb via the rotating mirror, and the shutter and aperture are set to the combination to be tested. Exposures are now made with the steady light from the torch bulb only. Successive exposures on the same frame can be obtained if the lamp is moved vertically between exposures.

Then while the mirror continues to rotate at the same speed, the steady light source is switched off and the discharge lamp is switched on. An exposure is then made to the light from this lamp, using the T or B setting of the shutter and opening the shutter while the mirror causes the image of the illuminated slit to sweep once across the focal plane of the camera.

A series of images of the slit are formed which are somewhat blurred, but whose separation on the film can be measured quite accurately. The separation between adjacent images represents the interval between successive flashes of the lamp.

The exposures made via the shutter to the light from the steady source will give a series of streaks. These represent the movement of the spot of light on the film during the exposure interval, and since the spot was moving at the same rate as the flashing source, a comparison of the length of the trace with the interval between successive images of the flashing lamp gives the total open time, even if this time is less than the interval between successive flashes of the discharge lamp.

Testing Synchronization. This arrangement can be elaborated slightly to test the timing of the synchronizer and the operation of flash equipment.

All that is needed is to set up the flash bulb just behind a slit arranged vertically above the torch bulb in the apparatus just described. The flash is fired by the shutter when the exposure to the steady source is made, and an image of the slit in front of the flash bulb will be recorded in the exact time relation to the opening of the shutter.

This procedure could become rather expensive in flash bulbs if many tests are needed. One possibility is to use another torch type bulb with a thin filament which lights up quickly, operated through the flash contacts, instead of the actual flash bulb used with the camera.

A low wattage, high voltage lamp is suitable, and in cases where the flash contacts make for only a brief time, the lamp can be run with a great deal more than the nominal voltage applied to it. This shortens the delay between the making of the contacts and the instant when the light from the lamp first begins to be recorded on the film. There will, however, still be an appreciable lag, which must be found by a parallel experiment with the proper flash bulb. The method described can then be used to check the operation and timing of the synchronizer.

Cathode-Ray Traces. When a cathode ray oscilloscope fitted with a short-persistence tube is available, the trace on the screen can be used instead of the moving objects described. It is usually possible to modulate the movement in some way to provide a time scale. This can be done by using the mains frequency to deflect the spot vertically, or by arranging a circular trace deflected radially. The scanning raster of interlaced lines as produced on the screen of the domestic television receiver would form an ideal test object for shutter

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

SHUTTER TESTING BY OSCILLOSCOPE. Top: *Layout of apparatus. A light beam passes through the shutter to a photocell, and the output is fed to a cathode ray oscilloscope. It is also utilized to trigger off a time base and to control spot brilliance. A timing mark generator provides pips on a base line of a second sweep or interrupts the previous curve at regular intervals.* A, *photocell.* B, *compensating grey wedge.* C, *shutter.* D, *condenser.* E, *lamp.* F, *amplifier.* G, *single stroke time base.* H, *automatic brilliancy control.* I, *timing mark circuit.* J, *cathode ray oscilloscope.* Bottom: *Characteristic shutter curves.* K, *curve with vertical timing marks at pre-set intervals. With a known interval between the marks, the opening, total open, and closing times can therefore be read off directly.* L, *curve with interrupted trace at pre-set intervals.* M, *curve indicating shutter bounce; i.e., the blades open again slightly for an instant after the exposure.*

testing of times up to 1/25 second, but unfortunately some television tubes have rather a long afterglow period. However, the technique may offer a rapid way of comparing speeds of about 1/50 second.

Effective Exposure and Efficiency. The measurement of the effective exposure time and the efficiency of shutters is rather more difficult than the measurement of total open time. Some idea can be obtained of the time the shutter is taking to open and close, however, by examining the blackening produced on the negative at different points on the streaks. Variations in the blackening are more easily seen if care is taken not to over-expose.

A series of streaks made with the same shutter setting, or, preferably a number made all at the same time, in which there is a progressive increase of density from one streak to the next, gives the best chance of estimating the time for which the shutter was fully open. It will also yield an approximate value for the effective exposure time.

Such a series of exposures can be obtained from a line source screened by a series of graded densities, or by using a row of small lamps of different candle power. If the time for which the blackening is constant at its maximum value can be judged, the effective exposure is not likely to differ much from the mean of this time and the total open time.

Laboratory Methods. In the development of new designs of shutter, and for diagnosing faults in operation, it is necessary to examine the behaviour of the shutter at each stage in the cycle. The more refined methods of testing are therefore aimed at obtaining a record of the light passed by the shutter at each moment in the cycle. Considerably more information is then available for calculating the effective exposure time, but the measurement of the total open time may not be any more accurate than is possible by the simple photographic methods described above.

One technique is, in fact, a refined version of the method described. A light source is modulated mechanically, by a sector disc or by reflection by the mirror of a vibration galvanometer. The light trace is drawn out on the film by some means, and the analysis is carried out in a similar way to that already described.

Another method which is particularly useful for the study of the motion of the shutter blades in inter-lens shutters, makes use of an arrangement which is virtually a high-speed cine camera to photograph the shutter aperture. The transmission of the shutter can be found by measuring the open area in each picture. A graph of shutter opening against time can then

TYPICAL DIAPHRAGM SHUTTER CURVE: A, *time of full shutter opening.* B, *maximum shutter opening.* C, *effective exposure time set on shutter (corresponds to actual total amount of light passed by an ideal shutter during the effective exposure time).* D, *total exposure time, taking into account the opening and closing times. If the opening and closing phases of the shutter are equal in length, the effective exposure time can be taken as the distance from the half-open to the half-closed stage of the shutter at full aperture. In practice the effective exposure time is more reliably obtained by integrating the area underneath the curve or by determining the light transmission during the shutter opening photometrically.*

be drawn, if the interval between successive pictures is known.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Non-Photographic Methods. For routine testing of shutters in the course of camera manufacture or maintenance, photographic methods are too slow and too expensive. So non-photographic procedures are almost invariably used. Chief of these is the photo-electric method, specified in various forms as a standard test method by standards institutions and associations.

In this kind of test, a broad light source is focused on a photocell by a lens system near the shutter under test. In the case of focal plane shutters, it is necessary in addition to place an opaque screen with a narrow slit near the shutter, in the position normally occupied by the plate. When all precautions have been taken to ensure that the arrangement is optically similar to that of the camera, the illumination on the photocell at any instant is proportional to the transmission of the shutter. The output from the photocell is amplified and applied to a cathode ray tube so as to cause a vertical deflexion of the spot. The horizontal deflexion is obtained from a time base, and a second simultaneous trace is usually provided, with a modulation at a known frequency, for accurate timing.

This method makes visible the transmission-time graph of the shutter, and makes it possible to diagnose instantly such troubles as bounce of the shutter blades after closing. For more detailed examination, and for record purposes, the trace may be photographed.

The method can be made very elegant, but brings additional troubles. For example, tests must be made of the linearity of the amplifier and cathode ray tube. Often it is convenient to have the horizontal deflexion of the spot initiated by the signal from the photocell, but by the time the spot begins to move horizontally the beginning of the upward deflexion may have been lost. This can be overcome by delaying the light signal applied to the vertical deflexion until the trace has begun to move horizontally, but once again this refinement may give rise to non-linearity.

Flash contacts can easily be timed by this method. A simple circuit can be made to brighten the trace when the contacts close, and the relation in time to the opening of the shutter is easily found by measurement.

Digital Readout. Normally the photo-electric testing set-up also uses a diffuser in front of the photo-cell to ensure that the latter takes in the total light passing through the shutter. Alternatively a small aperture of about 0·5 mm. diameter can be placed so that it is uncovered just when the shutter is half open, and covered again as the shutter half closes. With this arrangement the oscilloscope records a more or less square waveform which corresponds in its length to the effective exposure time. If the small opening is placed in the axis of the shutter it measures the total open time.

For focal plane shutters the opening is best a slit placed parallel to the shutter opening slit. The measuring slit can then be positioned in various parts of the picture area and measure varying exposure times over the image width.

Another way of obtaining a square wave form is to connect the photo-cell, reading the total light from the shutter through a diffuser, with a capacitor discharge circuit. With the shutter fully open, a neutral-density filter with a 49 per cent transmission is then placed in the light path. The capacitor circuit is adjusted so that it just fails to trigger the discharge. The neutral density filter is then replaced by one of 51 per cent transmission and the circuit adjusted so that it just triggers the capacitor. In this way the triggering circuit in effect reacts to a light transmission of 50 per cent.

When the shutter is now tested with a diffuser in front of a photo-cell, the triggering of the circuit indicates a light transmission of 50 per cent of the full shutter opening, in other words the moment when the shutter is half open.

During the shutter opening cycle the circuit thus produces two such signals at the half open and half closed stage. These signals again can be displayed on the oscilloscope screen as a square wave, the length of which corresponds to the effective exposure time.

Apart from giving a direct indication of the effective exposure time, such a square wave signal can also be used for digital readout systems. The beginning of the square wave impulse opens a gate circuit which connects an oscillator of for instance 100,000 cycles per second with a counting circuit. This counts the individual impulses from the oscillator during the period that the gate is opened—i.e., the effective exposure time. The counting system then displays the actual exposure time—in multiples of ten microseconds—as a digital readout. (According to the counting circuit used, the initial signal may be a binary number which is then reconverted into the usual decade system.)

Thus when the digital readout shows the figure 800, this corresponds to 8,000 microseconds, or 1/125 second. The precision of this system is plus or minus one step—in this case plus or minus 10 microseconds. For less exacting requirements the counting frequency may be lower, for instance 10,000 cycles per second in which case exposure times are measured to the nearest hundred microseconds (1/10,000 second).

Performance Requirements. Various international standards lay down the required accuracy and performance of camera shutters. The most important of these standards are the British Standard BS 1592: 1958, the German standard DIN 19015 of 1961 and the American standards ASA PH 3·3 and 3·5. They specify the shutter speed calibrations, the tolerances in effective exposure time, the efficiency, the consistency of readings and the delay times and

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

contact times for flash synchronization.

The scale marked on the shutter should be the reciprocal of the effective exposure time in seconds, markings being chosen from the series 1, 2, 4, 8, 15, 30, 60, 125, 250, 500, 1,000, 2,000 etc. This applies to both diaphragm and focal plane shutters.

The tolerance in effective exposure time for diaphragm shutters is ± 20 per cent for exposure times longer than 1/125 second and ± 30 per cent for exposure times shorter than 1/125 second. At full aperture the shutter must have an efficiency of at least 60 per cent.

A focal plane shutter must be accurate within ± 25 per cent at exposure times longer than 1/250 second, or ± 33 per cent at exposure times shorter than 1/250 second. The efficiency with the lens at maximum aperture must be not less than 60 per cent at all exposure settings and on all points of the image plane. With focal plane shutters it is also specified that the maximum effective exposure and minimum effective exposure over the whole frame area should not exceed a ratio of 3·2. In addition errors in measurement of up to 5 per cent are tolerated.

From these limits it is possible to calculate the ratio of the total open time to the marked normal effective exposure time. Even with a shutter which satisfies standard requirements, the total open time may be up to twice as long as the effective exposure time in the worst case. It is easy therefore to over-estimate the power of a high-speed shutter to stop movement.

For flash synchronization with diaphragm shutters the firing contact for X synchronization should close within 1 millisecond of the shutter being 80 per cent open. (The German standard specifies the contact to close between the instants when the shutter is 85 per cent and 100 per cent open.) The firing contact should close for at least 2·5 milliseconds at shutter speeds slower than 1/125 second.

When set for M-synchronization the delay time between the closing of the firing contact and the shutter first being fully opened is laid down as 15 ± 2 milliseconds (16·5 ± 1·7 milliseconds in the German standard). For focal plane shutters the delay from the commencement of firing contact to the moment when the leading edge of the shutter blind begins to uncover the picture area should be 17 ± 2 milliseconds.

For all shutters the firing contact duration should be at least 2·5 milliseconds and the contact sufficiently robust to withstand a current of 2 amps. J.W.G.

SHUTTER, VARIABLE. Rotating shutter (in a cine camera) with adjustable opening. Normally the shutter has a 180° opening, in other words it lets light through to the film during one half of its revolution and obscures the light during the other half while the film is advanced in the camera. In a variable shutter this opening can be reduced to a smaller angle or even closed down altogether. Smaller shutter openings means shorter exposure of the individual frames (leading to sharper individual images). A variable shutter provides an additional means of exposure control in a cine camera, and can also be used for fading in and out.

In a projector designed for running at slow speeds a variable shutter may increase the number of interruptions of the light beam during projection, to eliminate flicker.

SILHOUETTE. Black-and-white picture consisting of the subject in solid black seen against a white background. Named after a French minister, Étienne de Silhouette, who practised portraiture with paper and scissors as a hobby. The effect is easy to reproduce photographically. Portraits with the subject seen in profile are the most popular subject for silhouette treatment.

There are several ways of making silhouettes photographically, but the same principle is common to all. The subject is posed some distance in front of a brightly illuminated surface and all other light is taken away. This shows the subject as a black shape on a white ground. The farther the subject can be from the surface the better, because all the illumination should come from behind—any rays falling on the edges of the subject weaken the silhouette effect.

For the same reason it is better to use a background just big enough to surround the subject and block out the remainder of the negative rather than to use a background that fills the whole picture area and throws unwanted light on to the sides of the subject.

The camera is focused sharply on the profile of the sitter and the shortest exposure given that will cause the background to print out pure white. There are three ways of providing an illuminated background:

(1) A thin white sheet may be stretched across the doorway of a room and illuminated from behind by one or two Photoflood bulbs. With this type of background an exposure of the order of 1/25 second at *f* 8 on fast panchromatic film would be about normal.

(2) A light wall surface—or a white sheet—may be lighted from the front by Photofloods screened to prevent any light from falling directly on the subject. Exposures with this method would be about four times as long as above.

(3) The Photoflood lighting in either of the

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

SILHOUETTE LIGHTING. Top: *Subject set up in front of a white sheet or other translucent screen stretched across a doorway. This is illuminated from the rear only, while the camera room remains dark.* Bottom: *Subject set up in front of a white background which is evenly illuminated by two lamps. The lamp reflectors carry snoots to avoid spilling any light on to the subject which would illuminate shadows.*

above methods can be replaced by flash. In this case the room lights are switched off after focusing the subject, and the exposure is made either by open flash technique or with synchronized flash.

Still life subjects may also be photographed as silhouettes provided that they have a suitable profile. The most usual method is to employ a special baseboard consisting of a deep wooden frame with a sheet of clear glass on top, a sheet of opal or ground glass set halfway down the depth of the frame, and four strip lights fitted at the bottom of the frame underneath the glass diffuser. The subject is placed on the clear glass, and the camera is mounted pointing vertically downwards above this. When much work has to be done, the set-up can be constructed on the lines of a vertical enlarger with a camera in place of the enlarger head used in filming animated cartoons.

STILL-LIFE SILHOUETTES. Background is opal glass illuminated by strip lights. Subject is set up in front of opal glass; foreground shapes can be stuck to plain glass front of box.

This same equipment can be used to make silhouettes from cut-out figures. By using tissue paper for the figures, in multiple layers, it is possible to vary the tone of some objects in relation to others. For example, with a plain sheet of single tissue for the sky, single sheets cut out for trees and laid over the sky will appear a tone darker; foreground objects of extra thicknesses appear even darker.

An ordinary photograph can also be turned into a silhouette by painting the subject out in indian ink and then bleaching away the rest of the picture as in the bleach-out process for making sketches from photographs. In this case the photographic image should be soft and faint. F.P.

See also: *Abstract photography; Lighting the subject; Photograms; Tricks and effects.*

SILK PRINT. Silk and similar fabrics can be treated so that they can be printed with a photographic image.

The methods available are:

(1) Diazotype printing which leaves a dye image on the material in black or a colour.

(2) Iron-silver printing which gives a black silver image.

(3) Photo-mordant dye printing in which a silver image is first printed on the material. This forms the basis of the final dye image.

See also: *Fabric printing.*

SILK SCREEN PRINTING. Silk screen (retigraphy) is a remarkably versatile printing process by which almost any liquid medium can be printed upon any material with a flat surface or on cylindrical curves, such as bottles. Such media include dye and water colour, paint, printing ink, cellulose, fluorescent pigments, chlorinated rubber, etc., and even semi-conductors of electricity for electronics apparatus. The process is used for the commercial printing of everything from leaflets to posters, for printing on plastics and textiles, and for applying decoration, trade marks, and instructions to all manner of manufactured goods. Printing can be done by hand or by machine. Silk screen is also used extensively for the production of printed circuits for electronics in which lines of electrical conducting material are printed direct on to an insulating surface, or a resist is printed on a copper or other metallic layer and the unprinted areas subsequently etched away to leave only the circuit pattern.

The basic principle of the method is that silk, chiffon, or any other suitable woven material is stretched tightly across a frame and the parts required not to print are filled in with shellac, glue, gum, gelatin, cellulose,

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

paper, or any other suitable substance. The screen is then laid upon whatever material is to receive the image and the "paint" (the general silk screen term for any printing medium) is squeegeed across the screen from the other side, forcing the paint through the open areas of the mesh of the screen on to the material beneath.

Hand-cut Stencils. Stencils can be hand cut out of paper but it is easier to cut them from the special stencil material consisting of a plasticized shellac coating on a translucent paper temporary support. The design is cut with a sharp knife through the shellac film only, and the areas required to print are peeled off. The material is then applied to the screen with a hot flatiron, after which the paper support is removed, leaving the shellac stencil firmly adhering to the screen.

Photo-stencils. The screen itself can be coated with a light-sensitive colloid such as dichromated glue, gum or gelatin, or a gelatino-bromide or chloride photographic emulsion. This is exposed under the positive and leaves a light-hardened stencil after the unaffected areas are washed away on development.

The most common form of photo-stencil is produced by a variation of the carbon process. The carbon tissue may be dichromate sensitized and printed while still wet; or it may be replaced by a special type of pigment paper ready sensitized and mounted on its temporary support.

Photographic stencils may also be made on a special type of permeable membrane which is rendered less permeable by the action of light and so can be used for printing continuous tone images in coloured dyes.

Serigraphy. There is also a fine art process, serigraphy, in which the artist draws directly on the screen using a separate screen for each colour. After filling in the screens with a suitable colloid, the drawn parts are washed-out so that they will print.

Copies of limited editions by this process sell at prices comparable with lithographs, engravings or etchings. F.H.S.

See also: *Photomechanical reproduction.*

SILVER. Used for the production of silver bromide, chloride, and iodide, the halogen salts used in the principal light sensitive photographic emulsions.

Formula and atomic weight: Ag; 107·88.

Characteristics: A lustrous white metal.

Solubility: Insoluble in water and acids, but forms amalgams with many other metals—e.g., mercury.

The photographic image formed in conventional negative and positive black-and-white materials is very finely divided metallic silver in the form of microscopic crystalline ribbons. The usual image colour is black, but may vary through shades of brown according to the fineness of the silver produced.

SILVER HALIDE. Collective term for compounds of silver with the halogens (fluorine, chlorine, bromine, and iodine). Of these compounds silver chloride, silver bromide and silver iodide are of importance in photography, as they are all sensitive to light. On comparatively short exposure to light they yield latent images which can be reduced to a visible silver image by suitable developers. On prolonged exposure to light the halides become visibly discoloured.

The halides are very slightly soluble (chloride) to practically insoluble (iodide) in water, but are soluble in sodium thiosulphate and certain other solutions in which they form complex salts. The solubility in sodium thiosulphate (i.e., fixing baths) is greatest with silver chloride, less with silver bromide, and least with silver iodide.

Emulsions containing appreciable amounts of silver iodide, therefore take a very long time to fix after development.

Silver chloride (AgCl) is white, and comparatively rapidly turns blue on exposure to light. It is used in the preparation of positive emulsions for contact printing (contact papers and lantern plates) where it is usually the main or only sensitive ingredient. Most of these emulsions are rather slow. Silver chloride is also the main sensitive salt in printing-out (daylight) papers.

Silver bromide (AgBr) is yellow and slowly darkens on exposure to light. It is the main light-sensitive salt in negative materials and enlarging papers (to which it gives the name, bromide paper) and yields comparatively fast emulsions.

Warm-tone printing materials contain both silver bromide and chloride.

Silver iodide (AgI) is pale yellow, and darkens only very slowly on exposure to light. It is used in small proportions as an addition to fast negative emulsions and certain specialized materials.

See also: *Sensitizer.*

SILVER NITRATE. Lunar caustic. Used in silver intensifiers, physical developers, and many sensitizers.

Formula and molecular weight: $AgNO_3$; 170.

Characteristics: Colourless crystals.

Solubility: Highly soluble in water at room temperature.

SILVER RECLAMATION. When a negative or print is fixed, the unexposed silver salts are dissolved by the fixer. It is a fairly simple matter to reclaim this silver from exhausted fixing baths.

In big commercial D. & P. establishments where the silver is recovered, the spent fixer is treated with potassium sulphide. This precipitates the dissolved silver salts as silver sulphide which is collected and sold to refiners, who extract the metallic silver by fusing the

CC-0. Agamnigam Digital Preservation Foundation Chennai

precipitate in the presence of a reducing agent. In this way it is possible to recover silver to the value of one per cent of the total value of the materials handled.

The silver in a fixing bath may also be recovered electrolytically. This produces very pure silver and is ideal when dealing with large volumes of solution. The principle involved is that when electrodes are immersed in the fixer and a current is passed through it, silver will be deposited. The electrodes are made of special materials such as carbon or silver, the actual choice depending on the composition of the bath.

Similar methods are also employed to regenerate exhausted fixing baths.

In practice, some firms will install silver recovery plant free of any charge (where the quantities used justify it), claiming as profit a proportion of the silver recovered.

See also: *Regeneration of fixing baths.*

SILVERWARE. What applies to photographing silverware applies to other highly polished surfaces like gold, chromium, brass or steel. Articles finished in this way are difficult to photograph.

Squat Subjects. Flat subjects, such as cutlery, trays, coins, etc., are the easiest to photograph. These are best illuminated by one low modelling light to the side or rear and another light directed on to a large sheet of white card behind the subject and leaning forward over it. Light is reflected from this card to illuminate the polished surfaces; the card is adjusted to reflect the maximum amount of light on the subject when viewed from the camera.

For flat objects the camera needs to be fairly high. The tone and texture of the background are chosen to suit the subject. The background is normally darker in tone so that the subject stands out from it.

Tall Subjects. Tall articles are more difficult as the sides reflect everything around them including the background. A kettle or teapot which is smooth and undecorated, for instance, will mirror everything in the room including the camera.

Straight-sided objects, like jugs or tankards, need to be placed in the centre of a large piece of plain white cardboard curved up behind to form a background. The card should extend at least 3 feet each side and to the front of the subject. This arrangement eliminates all reflections provided that the camera viewpoint is not too low. If the sides of the subject taper into the base they reflect a smaller area and call for a smaller surround. This applies to things like bowls or dishes. But if the sides converge towards the top, as might occur with a coffee-pot, the surround often has to be extended to a great distance behind the subject, and be curved upwards towards the edges to avoid reflections.

Round Subjects. With rounded objects it is impossible to avoid all reflections. Even if the object is completely surrounded with white card or sheet, the surface reflects joins or folds and the image of the lens always appears on the front of the subject.

In such cases the reflections can be greatly reduced by using suitable lighting. One almost frontal spotlight directed on to the subject produces a highlight which brings out the sheen of the metal and helps to destroy reflections of the camera. The rest of the illumination is indirect; it is directed on to the background or on to reflectors so that highlights are reflected back on to the subject where required.

Reflections and glare spots which persist even with the most careful lighting can be toned down by dabs from a ball of putty.

The number and position of the light sources vary with different types of subject. A second spotlight is sometimes directed on to the back-

LIGHTING CUTLERY. One spotlamp directly illuminates the subject, while a second spot is reflected by a white card on the far side of the set-up to provide general lighting.

SOLID SILVERWARE. The background is a roll of white paper, lit up by one spot lamp. A second spot, coming from low down illuminates the subject directly.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

ground immediately behind the subject to help to outline its shape so that it is not lost in the background.

Equipment. Panchromatic material is not strictly necessary for silver, but it usually gives better quality. It should always be used for coloured metals like gold, brass and copper.

Really high class work for catalogue and "glossy" magazine reproduction is almost always done with a large format plate camera using a long focus lens stopped right down to give the necessary depth of field.

As with most commercial photography, a lens with a long focal length is generally chosen to avoid close-up distortion.

Exposure and Processing. If the subject is being treated purely on its pictorial merits, then a soft, high key treatment will do it most justice. The exposure should be on the long side and the negative given the minimum development time in a soft-working developer.

If the interest is in ornamentation, chasing or engraving on the surface of the silverware, then lighting, exposure and development should tend to produce a fair amount of contrast—e.g., side lighting, minimum exposure and slightly extended development. These expedients need to be employed with great restraint or the subject will lose its characteristic appearance of delicacy and brilliance.

In practice, with this type of subject, the amateur has a chance to arrive at the desired result by trial and error—only a specialist or a professional worker can hope to make a perfect photograph first time. D.L.H.

SILVY, CAMILLE. Dates unknown. French diplomat, from 1859 professional portrait photographer in London. His cartes-de-visite of royalty and society earned him an international reputation as "the Winterhalter of photography". About 1868–9 Silvy sold his business and retired to his ancestral chateau. After the Franco-Prussian War, in which he was wounded, Silvy opened another portrait studio in the outskirts of Paris.

SIMPSON, GEORGE WHARTON, 1825–80. English photographer; editor of the *Photographic News* (1860–80) and the *Year Book of Photography* (1860–80). Did valuable work on development (1861), collodion silver chloride emulsions for printing-out papers (1864–5) which formed the basis for the manufacture of Celloidin paper by Obernetter, 1868; on the "photochromy" of collodion silver chloride papers (1866), and on Swan's pigment print (carbon) process.

SINE WAVE. Wave form of a shape based on the variation of the value of the sine of an angle with the angle itself.

The sine of an angle of 0° is 0, and rises to a maximum of 1 for an angle of 90°. It then drops again to 0 at 180° and to — 1 at 270°, returning to 0 at 360°.

THE SINE WAVE. This is mathematically a plot of the sine of an angle against its size (for example, in the circle top right, the angle a). Since the sine value can never be more than + 1 and never less than — 1, the curve runs regularly up and down between these values.

This wave form is characteristic for many simple oscillating movements, for example, the movement of a simple pendulum, but also including the wave propagation of light and other radiation. It is significant for two reasons.

The first is that even complex wave forms can be analyzed and evaluated mathematically in terms of sine waves (Fourier analysis). This includes mathematical functions used in evaluating optical performance, such as the spread function of an image forming system.

Secondly, following from this, the use of test objects or targets (e.g. as a regular pattern of lines) with a brightness distribution based on a sine wave has been found particularly useful for testing image reproduction systems (including lens and sensitive material) to establish their transfer function. In such a test pattern the brightness varies continuously from 0 to a maximum and back to 0 again; this appears as a series of blurred bars rather than sharply

SINUSOIDAL TARGET. When the density of the regularly spaced line image fluctuates in a manner corresponding to a sine wave, that line pattern constitutes a sinusoidal target. This is used for lens performance tests in place of the classical resolution line charts.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

SINE WAVE AND REGULAR WAVE FUNCTIONS. All wave patterns—even a square wave (heavy solid line) can be considered as made up of sine waves of a fundamental frequency (heavy broken line) together with its associated harmonics. This involves a mathematical transformation known as Fourier analysis.

defined lines. Such a brightness distribution is known as sinusoidal.

When a sinusoidal test target is reproduced by a photographic recording, the brightness distribution of the latter remains sinusoidal irrespective of reproduction contrast. This can be measured by a scanning densitometer.

SINGLE-8 mm. Designation of 8 mm. cine film packed in single width for camera use—in contrast to double-8 mm. film. Also a Super-8 mm. type of cassette adopted by a group of manufacturers.

See also: *Cine camera; Cine film; Super-8 mm.*

SIZES AND PACKINGS

Sensitized materials for sale to the public must be packed in such a way that they will be protected from both physical and chemical injury in transit and store, and they must be supplied in certain standard sizes. The method of packing depends to some extent on climatic and other conditions under which the material is to be kept and used—e.g., most materials can be obtained in special tropical packing.

Plates. Plates are usually packed in boxes of twelve in a range of sizes based on either British or metric (for Continental cameras) units. The plates in each box of twelve are generally split up into three separate wrappings of four plates each, packed emulsion to emulsion. Thin strips of folded card (called separators) are inserted along two edges of each pair of plates to prevent the emulsions from rubbing or sticking.

BRITISH PLATE SIZES

Ins.	*Nominal cm. Equivalent*	*Ins.*	*Nominal cm. Equivalent*
2½ × 3½	6·5 × 9	10 × 12	25·4 × 30·5
3¼ × 4¼	8·2 × 10·8	11 × 14	28 × 35·5
(¼-plate)		12 × 15	30·5 × 38·1
3½ × 5½	9 × 14	16 × 18	40·6 × 45·7
(post card)		16 × 20	40·6 × 50·8
4 × 5	10·2 × 12·7	20 × 24	50·8 × 61
4¾ × 6½	12 × 16·5	20 × 30	50·8 × 76·2
(½-plate)		24 × 30	61 × 76·2
6½ × 8½	16·5 × 21·6		
(1/1-plate)		24 × 36	61 × 91·4
8 × 10	20·3 × 25·4	30 × 40	76·2 × 101·6

Usually only photomechanical plates are made in the larger sizes (above 12 × 15 ins.).

NOMINAL METRIC PLATE SIZES

Centimetres	*Nominal In. Equivalent*	*Centimetres*	*Nominal In. Equivalent*
4·5 × 6	1¾ × 2⅜	18 × 24	7⅛ × 9½
6 × 9	2⅜ × 3½	24 × 30	9½ × 11¾
9 × 12	3½ × 4¾	30 × 40	11¾ × 15¾
10 × 15	4 × 6	40 × 50	15¾ × 19¾
13 × 18	5⅛ × 7⅛	50 × 60	19¾ × 23½

The actual cutting sizes are laid down in the British Standard No. 1406 of 1947. They are slightly smaller than the nominal sizes:

CUTTING SIZES OF PLATES

British Dimensions		*Metric Dimensions*	
2½ to 5½ ins.	1/32 in. smaller	4·5 to 15 cm.	0·1 cm. smaller
Above 6½ ins.	1/16 in. smaller	Above 15 cm.	0·15 cm. smaller

Film. Film negative material is available in the form of sheet film (cut, or flat film), film packs, roll film, and perforated 35 mm. miniature film. Sheet films are usually packed in boxes of 25 sheets (10 in very large sizes). Nominal sizes are laid down in the British Standard B.S. 1772: 1951:

BRITISH AND AMERICAN SHEET FILM SIZES

Ins.	*Nominal cm. Equivalent*	*Ins.*	*Nominal cm. Equivalent*
2¼ × 2¼	5·9 × 8·2	6½ × 8½	16·5 × 21·6
2½ × 3½	6·5 × 9	8 × 10	20·3 × 25·4

4¾ × 6½	12 × 16·5	16 × 20	40·6 × 50·8
5 × 7	12·7 × 17·8		

A number of odd sizes—usually panel-shaped—are also made for stereoscopic photography, spectrography, and other scientific fields.

NOMINAL METRIC SHEET FILM SIZES

Centimetres	*Nominal In. Equivalent*	*Centimetres*	*Nominal In. Equivalent*
4·5 × 6	1¾ × 2⅜	18 × 24	7⅛ × 9½
6·5 × 9	2½ × 3½	24 × 30	9½ × 11¾
9 × 12	3½ × 4¾	30 × 40	11¾ × 15¾
10 × 15	4 × 6	40 × 50	15¾ × 19¾
13 × 18	5⅛ × 7⅛	50 × 60	19¾ × 23½

Certain sensitized materials with specialized uses are made in a number of other sizes—e.g., for document photography, microfilming, stereoscopy, and photomechanical reproduction.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

PACKING PLATES AND SHEET FILMS. Top: Plates are packed back to back in pairs, with paper separators keeping emulsion faces apart. Bottom: Notching indicates position of emulsion of sheet films; as shown, emulsion faces observer.

Sheet films can be loaded into ordinary plate holders by first fitting them into special metal sheaths to hold them flat and compensate for the difference in thickness between the film and the glass plate. Special sheet film holders are also made.

Most sheet films are notched so that the emulsion side can be identified in the dark. When the sheet is held so that the notch is at the top edge in the right-hand corner, the emulsion side is facing the observer. Sizes above $3\frac{1}{4} \times 4\frac{1}{4}$ ins. may also carry extra notches to indicate the type of film.

The notches may be triangular, square, round, etc. Their shape and number indicates the colour sensitivity and speed of the film. The notching codes vary from make to make.

Film packs contain twelve sheets of film in a stiff cardboard carton. Each sheet of film is attached to a backing paper which has a long tab. The films lie one on top of the other in the carton and the outermost film is covered by a blank sheet of paper, also carrying a tab. All the paper tabs are folded under the edge of a stiff card which just fits the carton and separates it into two shallow boxes. The numbered ends of the paper tabs project from the top of the rear box.

Film packs are more convenient to use than plates, but their relatively complicated construction makes them costly. Packs holding twelve films are manufactured in a limited range of sizes, usually $2\frac{1}{4} \times 3\frac{1}{4}$ ins., $3\frac{1}{4} \times 4\frac{1}{4}$ ins., 9×12 cm., etc.

Roll films consist of a length of film attached to a backing paper and wound on to a wood or metal spool.

The backing paper is generally black on the inside, and red, green or even yellow or brown on the outside. The leading end of the film is stuck to the inside (black side) of the backing paper, leaving enough spare paper to reach across the picture aperture to the wind-on spool upon loading in the camera.

The back of the backing paper is printed with numbers which indicate the successive frames of the film as they are brought opposite the picture aperture. The number of frames varies with the format of the picture area and most films carry three sets of numbers—1 to 8 for the normal oblong format; 1 to 16 for cameras taking a half-size picture, and 1 to 12 for cameras taking a square picture.

One row of numbers is printed along each edge of the backing paper and the third is printed down the centre. The numbers are read through a red or green window in the back of the camera, the position of the window being fixed to read the right, left, or centre row of numbers in accordance with the format of the picture area.

When the whole roll has been exposed, it is wound on to the take-up spool, and it can then be removed from the camera in daylight. The backing paper is longer than the film at the trailing end so that the surplus shields the end of the film from the light.

Certain types of roll film are available with only a short length of backing paper overlapping the beginning of the film and another length attached to the film end. In the middle the

film is unprotected. As much less paper is spooled up there is room for more actual film on the spool—usually double the normal film length (e.g. 24 exposures $2\frac{1}{4} \times 2\frac{1}{4}$ ins. instead of 12).

Such double-elength roll films can only be used in cameras with automatic film counting devices and without a red window; this would fog the unprotected film and can only be used to get the first exposure into place (where the film is still backed by paper).

Camerax with automatic counters must be suitable—or adapted—for counting the double number of exposures.

Aerial films are supplied in rolls $5\frac{1}{4}$, $5\frac{1}{2}$ or $9\frac{1}{2}$ ins. wide and in lengths from 8 to 200 feet. They are usually unperforated or perforated along one edge. The most common standard packings are $5\frac{1}{2}$ ins. × 47 feet and $9\frac{1}{2}$ ins. × 165 feet.

Metric aerial films come in widths of 80 and 190 mm., and length of 5 to 16 meters. Various special lengths and spool types are available to fit specific aerial cameras.

Aerial film is also supplied in perforated 70 mm. widths (see below).

Perforated miniature film is generally packed for use without a backing paper. The film is 35 mm. wide, and is coated on either cellulose nitrate or cellulose acetate base. It is perforated along both edges in the same way as professional motion picture film, with the perforation centres 5 mm. apart. The picture width available between sprocket holes is 24 mm. (approximately one inch).

This type of film is used in miniature cameras for three principal negative sizes: 24 × 36 mm. (just under 1 × $1\frac{1}{2}$ ins.), 24 × 24 mm. (1 × 1 in.), and 24 × 18 mm. (1 × $\frac{3}{4}$ in.).

35 mm. miniature film is sold in several different packs:

(1) Daylight loading cassettes to give thirty-six exposures, 24 × 36 mm. Some extra film is always allowed for threading. Special daylight loading cassettes holding only twelve or twenty exposures are also made for individual makes of camera. 35 mm. colour film is usually supplied in daylight loading cassettes to give twenty exposures.

(2) Daylight loading spools holding thirty-six (or twelve or twenty) exposures as above, but with a paper leader and trailer for insertion into a daylight cassette.

(3) Darkroom loading refills for reloadable cassettes. These are simply lengths of film wrapped in black paper or rolled in a light-tight tube of black card. The length is usually about 65 ins. or 1·6 metres, which is sufficient for the normal thirty-six exposures in the popular miniature format (24 × 36 mm.) and carries a trimmed leader and trailer.

(4) Unspooled bulk lengths of 25, 50 or 100 feet, or of 5, 10, 17, 25 or 30 metres. For certain purposes bulk lengths are also supplied without perforations.

Perforated 70 mm. film is available for various aerial and also professional cameras in lengths of 30 and 60 meters (100 and 200 feet) and may be loaded into special cassettes for 70 mm. cameras or adaptors.

A variety of packings of 16, 35 and 70 mm. film—both perforated and unperforated—is available for microfilming, recording, fluorographic and other purposes.

Transparency Materials. Lantern plates are made in the following sizes. In each case the first figures give the British or metric units in which the standard is laid down, followed by the equivalent British or metric units in brackets.

LANTERN PLATE SIZES

Lantern Plate	*Sizes*	
Standard British:	$3\frac{1}{4} \times 3\frac{1}{4}$ ins.	(8·2 × 8·2 cm.)
Standard U.S.A.:	$3\frac{1}{4} \times 4$ ins.	(8·2 × 10 cm.)
Standard Continental:	8·5 × 10 cm.	($3\frac{3}{4} \times 4$ ins.)
Standard Stereo:	6 × 13 cm.	($2\frac{3}{8} \times 5\frac{1}{8}$ ins.)
Miniature:	2 × 2 ins.	(5 × 5 cm.)
Miniature Stereo:	4·5 × 10·7 cm.	($1\frac{3}{4} \times 4\frac{1}{4}$ ins.)

Transparency sheet film is made in most paper or sheet film sizes.

35 mm. film strip material is made in continuous lengths (up to 100 feet or more on suitable spools), and may be imperforated or

perforated along both edges with standard cine perforations or along one edge with special perforations.

Single perforated film is used for 28 × 40 mm. size ($1\frac{1}{8}$ × $1\frac{5}{8}$ in.) pictures. The standard projector mask cuts this down to 26·5 × 38·1 mm. For camera use, this film is packed in 8 exposure rolls with backing paper.

Double perforated film is used for the following standard picture (frame) sizes in miniature film strips:

Double frame: 24 × 36 mm. (1 × $1\frac{1}{2}$ in.); projector mask 23 × 34 mm.

Single frame: 18 × 24 mm. ($\frac{3}{4}$ × 1 in.); projector mask 17·5 × 23 mm.

Square frame: 24 × 24 mm. (1 × 1 in.); projector mask 23 × 23 mm.

Double frame transparencies are often mounted singly between 2 × 2 ins. cover glasses or in special holders of the same size, and used as miniature slides.

Paper Sizes. Papers are usually cut to sheet sizes which correspond roughly to standard negative sizes. In addition there are several odd sizes available.

HALVABLE PAPER SIZES

		$1\frac{3}{4}$ × $2\frac{1}{2}$	4·5 × 6·5

Printing papers are sold in a standardized range of sizes and packings, which coincide broadly for the most popular sizes in various countries. Some non-standard sizes may be available in certain countries, as well as a few popular sizes not packed elsewhere.

The range of sizes offered nowadays is appreciably smaller than it used to be, when manufacturers produced many little used formats which made cutting and distribution comparatively uneconomical.

Another system proposed for rationalizing paper sizes and reducing the range is based on the principle of the halvable format. Around 1945 two such standard sizes were suggested: 10 × 14 and 12 × 17 ins. (25·4 × 36 cm. and 30·5 × 43 cm.). All other sizes could be derived from these by successive halving, and some were similar to existing standard paper sizes. For a time some manufacturers marketed these halvable formats. There is some more recent interest in this principle, using again the 10 × 14 in. range (based however on four times the area at 20 × 28 ins.) and $16\frac{1}{2}$ × $23\frac{1}{2}$ ins. (42 × 59·4 cm.) as the second range.

HALVABLE PAPER SIZES: If the sides of a paper format have the ratio of 1 : 1·4, halving the paper produces a smaller size with the same side ratio. This idea is the basis of the principle of halvable paper sizes. There a range of formats can be obtained by cutting down one standard large format—which then is the only one that has to be stocked. A basic format of 10 × 14 ins. as shown here has been proposed as one of the halvable sizes; usually a second basic format is also needed.

The latter series of sizes corresponding to the standard A range of stationery formats used in a number of countries on the Continent of Europe and elsewhere.

Though such a halvable range of sizes does not correspond to negative sizes at all, it has the advantage that the relative proportions, and thus the shape of a sheet of paper, is the same whatever the size.

The main opposition to halvable sizes comes from photographers who regard the sheet as too oblong in shape for pictorial presentation.

L.A.M.

SKETCH PHOTOGRAPH. Term applied to photographs which have the appearance of a pencil sketch. In practice, this may be achieved in a number of ways. A very light print can be made and the tones built up by careful shading with a pencil; this is only suitable for subjects consisting of a few basic tones—e.g., a portrait taken with almost shadowless lighting. Or it is possible to make sketches by drawing over a faintly printed photographic image and then bleaching it out to leave only the drawn outlines. Another method is to project a negative in the enlarger on to a piece of white paper; the light areas are then shaded in with a pencil until the whole paper assumes an even tone; when the enlarger is switched off, a positive picture built up in pencil is left on the paper.

The term is also sometimes used to describe extreme high key effects in which the subject is softly lighted from the front against a light background. The contours of the subject then appear in very faint tones as though sketched with an artist's pencil. The same remarks apply to bromoil prints which with certain types of subject frequently look like charcoal drawings.

SKIN AFFECTIONS. Photographers come in contact with a number of irritating chemicals in developing, fixing and printing. In many cases these chemicals can produce skin disorders on the hands and face.

Developers. Most developer solutions are alkaline and are the most common cause of dermatitis among photographers. The chief offenders are the bichromates used on blue prints which in either the dry or the dissolved state produce an irritating rash of small ulcers (chronic ulceration) on sensitive skins. Potassium dichromate and ammonium dichromate, which are used for sensitizing gelatin and also in blue printing, cause a greater percentage of dermatitis than any of the organic developers. Next to these, metol is the chief offender.

It is said that chemically pure metol is not a skin irritant and that dermatitis attributed to metol is really caused by traces of a poisonous compound (N.N.-dimethyl paraphenylenediamine) which can be eliminated if the metol is prepared by a special process. Metol poisoning affects some people and not others. It produces cracked, swollen fingertips and painful, spreading sores. Those who are susceptible to it should avoid it altogether. There are developing agents which are less likely to affect the skin and are as good as metol in other respects.

Amidol (diaminophenol) is made by reducing dinitrophenol with hydrochloric acid in the presence of iron filings, and dermatitis has resulted from the process. If the acid vapours are allowed to contact the skin it assumes a yellow appearance. Cyanosis or "blue lip" results from exposure to the vapours of dinitrophenol.

Diaminophenol used in developers can cause dermatitis in hypersensitive individuals. Hydroquinone is another developing agent which has caused dermatitis.

Quinone is a skin irritant to sensitive people and quinone dichloro diamine is said to be even more irritating.

Para-aminophenol is the basis of developers of the Rodinal class. It can be used as the hydrochloride or combined with sodium hydroxide; in both forms it can cause dermatitis.

The phenylenediamines, or diamino benzenes, are used as developers in the form of the hydrochloride, which can prove highly irritant.

Paraformaldehyde used in a hardener or photo developer has been the cause of many cases of dermatitis on the face and hands of photographers.

Other photographic developers which can cause dermatitis are: Adurol or monochlorhydroquinone, Ortol, or ortho-methylamino phenol, and pyrogallol or 1:2:3: trihydroxybenzene.

Sensitizers. Certain chemicals are used to increase the sensitivity of photographic plates to various regions of the spectrum. Some of these are said to cause dermatitis by photosensitizing the skin. Others of themselves cause dermatitis. They are used only in minute quantities in the photographic emulsions, but nevertheless, should be handled cautiously by persons with sensitive skins.

The principal sensitizing dyes are the cyanines and isocyanines, which are green sensitizing; the di-cyanines, which are red sensitizing; and the pinacyanols. The dyes used in photography which have caused dermatitis are auramine, aurantia, chrysoidine, crystal violet, methyl violet, malachite green and rhodamine B. The latter is a photosensitizer of the skin.

Other Chemicals. Other skin irritants used in photography are: ammonium bifluoride, used to remove gelatin films from glass negatives; ammonium sulphide, used in toning and in mercurial intensifications; caustic soda, used in alkaline developing solutions; formalin, used in gelatin mixtures and pastes; mercuric chloride and mercuric iodide, used in mercurial intensifications; oxalic acid, used as a preservative of pyro; potassium chloroplatinite, used for plate toning; potassium cyanide, used for bromide prints; potassium sulphide, used as a super toner; sodium carbonate, used in alkaline developing baths; sodium hypochlorite, used as a bleacher and oxidizer, and sodium thiosulpahte as a modern fixing agent.

Solvents, such as turpentine, benzene, etc., can also cause a dermatitis by denuding the skin of its natural lubricants.

Methods of Prevention. The ideal method is to keep the skin out of contact with the chemical solutions by using mechanical handling techniques. This, however, is not always practicable, especially where large numbers of prints have to be made within a limited period (as in press photography). The next best thing is to give the skin some form of protection. This can be provided in two ways: by the use of impermeable gloves or by applying a protective cream which can reinforce the skin to help it resist the action of chemicals.

Gloves have one or two disadvantages. They induce excessive perspiration which can soften and macerate the skin and render it highly vulnerable should the chemical accidentally come into contact with the fingers through penetration or spillage. Gloves also impede dexterity in handling plates and films.

On the other hand, a properly formulated barrier cream can protect and reinforce the skin against the penetration of acids and alkalis, and prevent the development of dermatitis. Creams of this type are made specially for photographers; they are simple to use and very efficient if applied correctly. About half a teaspoonful of the cream is smoothed into the skin of the hands and arms until it disappears. The hands are then held under cold water to set the cream, and then dried. If this technique is practised, there is no danger of contaminating films, plates or paper while processing, and the skin will remain perfectly healthy even if in constant contact with irritant solutions. An application of barrier cream lasts for three

hours and the hands can be repeatedly washed without affecting the skin adversely.

CC-0. Argentine Digital Preservation Foundation Collection

These precautions may be elaborate for any one who only occasionally needs to touch processing solutions—e.g., the amateur who may in emergency want to use his fingers for lifting a print out of the developer. Such infrequent immersions can be rendered safe by dipping the fingers into clean water before putting them into the chemical. This ensures that any solution in actual contact with the skin will be too dilute to be dangerous. Immediately afterwards the fingers should again be thoroughly rinsed in clean water so that no traces of chemical will be left to dry on the skin. These precautions are in any event advisable for preventing marks and stains on prints caused by traces of chemical on the fingers. A.S.H.

SKLADANOWSKY, MAX, 1863–1939. German showman and pioneer of cinematography. Constructed a crude projection apparatus for short loop films and was the first to show in Germany film projection (1st November 1895) on two projectors running simultaneously at 8 frames per second.

SKY FILTER. Filter in which the depth of tint increases progressively from top to bottom. When placed over the lens with the dense edge on top, it filters the light from the sky but allows the light from the foreground to pass through unaffected. In this way it holds back the highly actinic light from the sky and allows it to print in its natural tone instead of as a white featureless area of paper. The sky is also often very much brighter than the foreground anyway, so the filter also tends to prevent over-exposure of the sky.

The effect of a sky filter becomes less localized—e.g., on the sky—when it is used closer to the camera lens.

Sky filters are no longer as popular as they were some years ago, mainly because most photographers now use panchromatic films which, even without a filter, will give a reasonable rendering of the sky tones. When orthochromatic films were more generally used, they were so disproportionately sensitive to blue that the sky generally reproduced as blank paper unless corrected.

Another reason is that it is necessary to mount a sky filter well in front of the lens to confine the filtering to the sky area. This means that it must also be appreciably larger than an ordinary lens-mount fitting. The problem was not so serious with larger cameras, but the size of the filter and the awkward mounting rule sky filters out for modern cameras.

SKYSCAPE. Scene in which all or the greater part is taken up with the sky and clouds. Many excellent pictorial studies have the sky as their principal feature.

See also: *Clouds; Sunrise and sunset.*

SKY SHADE. Any form of shield attached to the front of the camera body for protecting the lens from the direct rays of the sun or strong, reflected light from the sky. Sometimes (particularly in the U.S.A.) used as another name for a lens hood, especially for the scoop-shaped type designed to shield the lens from above only.

The name is also used for the hinged flap fitted over the lens of the older types of camera and sometimes attached to the mount of a lens. As the hinge was at the top, the flap could be set at a suitable angle to shield the lens from sun and sky light.

SLAVE UNIT. Photo-electric relay used in multiple flash photography, which makes use of the light of the main flash to fire one or more auxiliary flashes. The slave unit consists of (1), a light-collecting lens or mirror which is pointed at the main flash and focuses the light on (2) a photo cell or photo-transistor connected to (3), an amplifier which closes the contacts of (4) an electro-magnetic relay.

The triggering lead of the auxiliary flash is connected to the relay contacts by plugging it in to a socket on the slave unit.

A slave unit may work off the mains supply or off a small dry battery and consumes a negligible amount of current. It will fire either bulbs or electronic flash and helps to keep the studio floor clear of trailing leads.

SLIDE DIAGRAMS. There are three ways of making slides of line subjects—e.g., maps, engineers' drawings and documents: copying with a camera, contact printing, and drawing direct on to the slide.

Copying. Copying is particularly suitable for making slides of large diagrams which are too detailed to re-draw to a smaller scale for direct contact printing. It is the only satisfactory method for making miniature slides.

The subject is first copied to the size of the lantern plate to be used. For a 2 × 2 ins. slide it is necessary to confine the picture area to 1 × 1½ ins. or the area of a 35 mm. negative, if the printing is to be done by contact: 2¾ × 2¾ ins. or 3¼ × 3¼ ins. slides can also be used. The copy may also be made upon a larger size negative and a reduced image printed on the lantern plate by projection. (The enlarger must have sufficient extension for this purpose.) A 35 mm. camera with a copying attachment may be used for making the negatives.

The diagram should be evenly illuminated as in normal copying. The camera must be rigidly supported and focusing exact to ensure the sharpest possible image.

If the subject is black-and-white, the negative is made on a process plate which gives the necessary high contrast. If this type of negative material is not available, a slow fine-grain film is almost as good. For a coloured subject a

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

METHODS FOR DIAGRAM SLIDES. 1. Copying a drawing, title, etc., by means of a camera. The negative is then printed by contact or projection on a suitable lantern plate material. 2. Direct contact printing. The diagram or lettering is drawn on a sheet of thin grainless paper, and contact printed directly on to a lantern plate. 3. Drawing on blackened glass. A clear glass plate of the right size is blackened by soot and the diagram scratched on it. 4. Direct drawing. A special opaque ink for glass will yield a black image on a clean glass plate.

slow panchromatic material is used with the appropriate filter.

The exposure is best found by trial. A contrast developer should be used, or the normal time of development increased by 50 per cent. The negative should show all details clearly against an opaque background.

A slow black tone or gaslight lantern plate is best for the print, and a contrast developer is recommended. Plates should be backed to prevent degradation of the image by light scatter. Over-exposure must be avoided and development carried rather further than is necessary for ordinary lantern slides. After fixing, the slide should show the lines very black against a clear background. If the lines are slightly veiled, they can be cleared by a short immersion in a weak ferricyanide-hypo reducer for a few seconds. This will make the slide very clear and transparent.

If desired, the slides may be made on slow or positive 35 mm. film. Care must be taken to expose fully, and to develop for longer than may seem to be necessary if a normal developer is used, otherwise the positives may be thin.

In some cases the negative can be used for projection if there is no objection to showing white lines against a black background. Slight reduction may be necessary to clear the lines of the subject.

Another way is to photograph the original diagram directly on a reversal film to yield a positive transparency (after reversal processing) from the original positive drawing. Suitable reversal films are available as 35 mm. stock; for larger diagram slides many process films can be processed by reversal. Contrastly materials are best to yield a high image density in the black lines against a transparent background. Reversal colour films are suitable for making diagram slides in colour, though here the contrast obtained is more restricted.

Special diffusion transfer films also exist, for use in appropriate cameras, to yield an immediate positive transparency after exposure of the negative material in the camera.

Contact Printing. This method is satisfactory where the diagram is fairly bold and with no fine detail.

The drawing is copied by hand, or with a pantagraph, in black ink, on to a piece of white paper the size of the slide with as little grain or texture as possible. This drawing is then printed by contact on to an ordinary lantern plate which is processed to give plenty of contrast. The diagram when projected will appear as white lines on a black background. If the normal black on white presentation is preferred, the slide is printed again by contact on to a second plate.

This method is not suitable for miniature slides as it is not possible to draw the lines accurately on such a small scale.

Direct Drawing. In this case the diagram is drawn straight on to a specially prepared plain glass plate of the right size. There are several ways of preparing the plate, but the simplest is to blacken it by holding it over the flame of a candle.

The diagram is then scratched in the layer of soot with a needle. This method gives white lines on a black ground. It is the stock device for throwing an urgent announcement on to the screen in a cinema.

Any of the special opaque inks made for writing on glass may be used for drawing on a clear glass plate to give a black on white projected image. A suitable ink can be made by dissolving 1 drachm of borax in 1 ounce of water and stirring it slowly into a solution of 2 drachms of shellac in 1 ounce of methylated spirit. Any precipitate should be dissolved by heating the solution. Enough methylene blue is then added to make the ink reasonably opaque and the solution kept in a tightly stoppered bottle. It may be applied to a clear glass slide with a fine

brush or a mapping pen. It is quick-drying and permanent.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Diagrams may also be drawn in Indian ink with a pen on a sheet of finely ground glass. When the ink is dry, the surface is painted over with a solution of gum dammar in benzole. This obliterates the grain of the glass and leaves the diagram on a clear ground.

Some of the more modern plastic foils are also suitable for direct drawings of diagrams to give slides for projection. These are particularly suitable for large-size slide diagrams to be used in an overhead projector. For small transparencies it is more difficult to keep the art work really fine and neat, since projection enlarges the slightest roughness and inaccuracy.

SLIDE (TRANSPARENCY)

Positive transparency on glass support, or on film mounted in a card frame or between glass cover plates. Slides are usually viewed by projection and are invaluable to lecturers and demonstrators because the picture on the screen is visible to a considerable number of people, and can be both large and brilliant. It has distinct advantages over paper prints which can be seen by only a few people at a time: and over the cine picture which is not adapted for the detailed study of static subjects.

For these purposes, any negative that will make a good print will make an even better slide, and even any documents and maps photographed on an appropriate scale may be turned into satisfactory slides.

Many photographers, however, are attracted to slides because they can render a much greater tone range than any paper print. In fact, to reproduce the full beauty of subjects with a long contrast range, a slide may be essential.

Formerly slides were regarded mainly as a means of entertainment by projection in the then comparatively large projection lanterns. For that reason the transparencies projected in this way were commonly known as lantern slides.

The immense popularity of slides and slide projection nowadays is directly connected with the fact that many colour films yield their results in the form of miniature transparencies which are bound in appropriate mounts as slides. In many ways the slide projector has become the modern equivalent of the photo album.

Sizes. There are two commonly used international slide sizes with the outside dimensions of the slide laid down by standards:

Miniature—2 × 2 ins. (50·8 × 50·8 mm.);
Intermediate—70 × 70 mm. ($2\frac{3}{4}$ × $2\frac{3}{4}$ ins.).

In addition several other large sizes and a sub-miniature or ultra-miniature size are in limited use:

British large: $3\frac{1}{4}$ × $3\frac{1}{4}$ ins. (82·5 × 28·5 mm.);
American large: $3\frac{1}{4}$ × 4 ins. (82·5 × 101·5 mm.);
Continental large—85 × 100 mm. (about $3\frac{3}{8}$ × 4 ins.);
Ultra miniature—30 × 30 mm. (about $1\frac{1}{8}$ × $1\frac{1}{8}$ ins.).

The majority of slide projectors take the miniature 2 × 2 ins. slide; larger models take 70 × 70 mm. slides and sometimes both miniature and 70 × 70 mm. The large slide sizes require appropriate large projectors: most of the latter will take all three large sizes, sometimes with alternative slide carriers. Ultra-miniature slides require a special projector designed for them.

Miniature slides, are used for a variety of image sizes. The largest format which can be accommodated conveniently within the slide is about 40 × 40 mm. ($1\frac{5}{8}$ × $1\frac{5}{8}$ ins.), made either by printing monochrome negatives on to 2 × 2 ins. lantern plates, or by mounting colour transparencies up to $1\frac{5}{8}$ × $1\frac{5}{8}$ ins. large in 2 × 2 ins. card or plastic frames. Slides of this size derived from film transparencies are also known as "super slides", by comparison with the more common 24 × 36 mm. transparency.

The 24 × 36 mm. (strictly speaking 23 × 35 mm. if the masking by the slide frame is taken into account) format is the most widely used for 2 × 2 ins. slides. This is the picture size produced by most 35 mm. miniature cameras, and the colour transparencies for use in such cameras are mounted in slide frames for projection. Other transparency formats, mounted in 2 × 2 ins. slides are the 18 × 24 mm. half-frame, 24 × 24 mm., 26 × 26 mm. and 28 × 40 mm. transparency taken by cameras for these sizes. Ultra-miniature transparencies, usually 10 × 14 or 12 × 17 mm. in size, may also be mounted in 2 × 2 ins. frames.

If a miniature projector is designed to illuminate the largest (i.e. 40 × 40 mm.) image area on a 2 × 2 ins. slide, it can of course also be used for the smaller transparencies—though this entails an appreciable loss of light and a smaller image on the screen. Projectors for transparencies smaller than 24 × 36 mm. are therefore usually available with a modified optical system and a shorter focus projection lens.

The Continental intermediate size of $2\frac{3}{4}$ × $2\frac{3}{4}$ ins. is designed to take $2\frac{1}{4}$ × $2\frac{1}{4}$ ins. or $1\frac{5}{8}$ × $2\frac{1}{4}$ ins. colour transparencies made with roll film cameras. The $1\frac{5}{8}$ × $2\frac{1}{4}$ ins. format can, however, also be cut down for mounting as super slides.

The large sizes are falling into disuse.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

MAKING MONOCHROME SLIDES

The main ways of producing monochrome slides are by exposure in the camera, printing on 35 mm. (or larger) film for subsequent mounting in transparency frames, and printing on plates.

Exposure in the Camera. Miniature transparencies for mounting as 2 × 2 ins. slides can be made in the camera on reversal black-and-white film. This is exposed in the same way as a normal reversal colour film. Usually the film is processed by the manufacturer, but can also be processed by the photographer.

Negative films can also be processed by reversal, but the resulting transparencies have the inherent base tint of the negative film stock (reversal materials are coated on a clear base). Reversal processing of negative materials is the only way of producing larger transparencies directly in the camera. The film base of roll films is usually clear, and the backing dye virtually disappears during processing.

Special transparency materials are also available for instant picture cameras and produce black-and-white positives ready for mounting in special standard frames, within about a minute of exposure.

Printing on 35 mm. film. Miniature transparencies can be printed on 35 mm. positive film from 35 mm. or larger negatives. Where 35 mm. negatives are used, a film strip printer is the most suitable equipment; larger negatives require projection printing on a reduced scale. Any normal enlarger is suitable for this purpose. It is best used with a short-focus enlarging lens to keep the required lens-to-negative distance within the focusing range of the enlarger. At this increased distance even a short focus lens will adequately cover the larger negative size, and gets over the problem that most enlargers do not provide sufficient lens extension for reduction printing with the normal focal length.

The printing technique is largely the same as for making film strips, though in this case there is no need for pre-planning the orientation or sequence of the images.

Printing on Plates and Sheet Film. Slides can be made by contact or by projection in an enlarger on to glass plates or film. Contact printing gives the best definition, and contact material—i.e., chloride emulsions—give high contrast. Plates for projection printing are either bromide, giving normal black-and-white images, or chloro-bromide, giving warm black and brown tones. Plates for printing slides, are still widely known as lantern plates.

Black-and-white material is well suited to slides for lectures, etc., illustration, especially of documents, line drawings and maps.

Pictorial work is best done on chloro-bromide material. With suitable developers this material gives warm black or brown tones direct, and the addition of potassium or ammonium bromide, etc., increases warmth.

Toning processes include gold chloride, which gives a fine blue, dye-coupled redevelopment, which gives a wide range of colours, and a number of classic metallic toners.

The most suitable sheet films for slide making are slow non-colour sensitive types, such as process, commercial and soft gradation emulsions. The latter are useful for very contrasty negatives, while the other two types give more contrasty images. In general a transparency for projection should be denser and more contrasty than a print for viewing by reflected light, since the projected image can reproduce a much greater brightness range.

Contact Printing. Lantern plates are printed by contact in a special frame designed to hold the plate and a plate negative. The two plates are placed in position, emulsion to

emulsion, and adjusted to centre the part of the negative which is to occupy the masked-off picture area on the finished slide. The frame is designed to make this possible.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Film negatives are held in contact with the lantern plate by being covered with a glass pressure plate.

Since the lantern slide image is considerably magnified in projection, it is very necessary to keep all printing surfaces dust-free. This is particularly important when printing film negatives, because the cover glass introduces two further dust-collecting surfaces.

The springs of the printing frame must be strong enough to press the two emulsion surfaces into close contact to avoid loss of definition.

The exposure is made in the usual way either by a printing light or on the baseboard of an enlarger with the negative carrier removed. Some control of the final result can be exercised by shading or overprinting, as in normal contact printing technique.

Projection Printing. Lantern slides can also be made by projection in the enlarger. This method offers much more scope than contact printing and it is, in fact, the way that many people choose to make their slides, even when printing to the same scale. The principal advantage of this method is that the negative, or any selected part of it, can be enlarged or reduced to suit the size of the slide, and the photographer is free to trim and compose the picture to the best advantage, just as in making an enlargement.

Projection printing allows the photographer to make slides of any required size from a variety of types of negative—e.g., from plates, roll films and 35 mm. film. The technique is similar to enlarging except that the resulting "print" is smaller than usual and the enlarger must be equipped for making same-size and even reduced scale prints—e.g., miniature slides and film strips. This may call for some modification to the focusing range.

Focusing Range Adjustment. Enlargers that are to be used for reduction printing need much greater focusing extension than usual. This can be obtained in several ways:

(1) An enlarger lens of only half the normal focal length may be used. (With same-size or reduction printing, lenses cover much larger negative sizes than under normal conditions, because of the abnormally large lens-negative separation in relation to the focal length.)

(2) The distance between the lens and the negative can be increased by extension tubes or similar adapters. For same-size printing the lens-negative distance must be twice the focal length of the lens, and for reduction it must be greater.

(3) The focal length of the enlarger lens can be modified by using supplementary lenses. Usually, however, supplementary lenses tend to impair the definition and sharpness of the projected image, so they are not often used.

Plate Holders. Lantern slides are printed in a masking plate holder instead of a paper holder. The mask cuts the picture down to the standard size required for projection.

The lantern plate may also be laid on a sheet of black paper on the baseboard and printed without a mask.

In either case the image is focused on a special focusing plate covered with white paper giving a combined thickness equal to that of the lantern plate. This ensures that when the image is focused on the focusing plate, it will be sharp on the emulsion surface of the lantern plate.

There are various devices and methods for ensuring that the lantern plate occupies exactly the same position as the focusing plate on the enlarger easel. Some means of accurately registering the two is always necessary, because the slide cannot afterwards be trimmed like a paper print to correct errors. The simplest way is to fix the position of the two adjacent edges of the holder with push pins, or to mark it with white ink in the middle of a weighted black card, sliding the card about on the easel until the image occupies the required position.

Exposure. It is not easy to cut up lantern plates into test strips, and it is wasteful to use an entire plate for the purpose. A more practical way is to find a grade of bromide paper which matches the lantern plate in contrast. This is more practical even when the printing material is sheet film.

Testing can then be made with the paper to show the relation between the exposures needed to produce an acceptable bromide print and an acceptable lantern slide.

Once this relationship has been established, all exposure tests can be made on the bromide paper, and the correct exposure adjusted by multiplying or dividing by a fixed factor when printing the lantern plate. The factor must be checked each time a new batch or packet of either lantern plates or bromide paper is opened.

LANTERN PLATE FRAME. A simple jig or holder will locate a lantern plate always in the same place on the enlarger baseboard. A hinged white card (ruled to show loss of image space from binding) serves for focusing.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

MATCHING TEST STRIPS Test strips on lantern plates are inconvenient so they are best made on bromide paper. A relative speed factor established by a comparative test between paper and plate will then give the right exposure.

Judging. There is an appreciable difference between the appearance of a correctly exposed lantern slide and a correctly exposed bromide print when they are seen in the developer or fixer by the darkroom safelight.

During development, while the image still contains a great deal of turbid white silver chloride or silver bromide, its density is best judged by looking at it through the back of the glass support. This gives a fairly good impression of the final visual density to be expected.

When all the white silver salts have been dissolved away in the fixing bath, the slide is best judged by holding it in front of a brightly-lit white surface—e.g., a sheet of white paper. This corresponds most nearly to its appearance when it is projected on to a screen. It is misleading to look at the image directly against the light, because this makes both density and contrast appear to be lower than they really are.

Processing. There is no difference in principle between processing lantern slides and processing prints, but there are certain differences in handling.

The same developer and other processing solutions are used for lantern slides as for prints (either normal or warm-tone).

It is not normally necessary to use a hardener in the acid fixer for prints, but it is advisable for lantern slides, because they are more sensitive to injury than paper prints.

To avoid blistering and reticulation to which lantern plates are more prone than prints, the temperature of the solutions should not vary between developer and rinse, or between rinse and fixer. Developers should not be warmer than 70° F. (21° C.); hot water-bath methods of development are out of the question.

Generally, lantern plates are handled in the same way as plate negatives. Some sort of plate carrier is, however, desirable to immerse the plates in the solutions and lift them out without getting the fingers wet. Washing and drying technique is again similar to that employed for ordinary plates. C.D.M. (L.A.M.)

Transparencies made on sheet film are also handled in much the same way, but using an appropriate film holder or hangar. As with plates, the emulsion is very sensitive to physical injury while wet.

Since sheet films are not normally made as special positive emulsions, they are less suitable for warm tone and other special development methods.

Finishing. Before a slide is made ready for projection, any pinholes caused by dust between the slide and the negative during exposure must be spotted out. If these spots are not dealt with, they will show with distracting brilliance on the screen.

Spots on slides are dealt with in much the same manner as spots on a print, except that the work has to be done even more skilfully or the result will be worse than the original fault. Opaque pigment, water colour, or one of the special spotting preparations, is used. The work is done on a retouching desk on which the slide is illuminated from below and masked so that no light shows around.

A fine-pointed No. 0 brush is used for spotting out pinholes, the pigment being matched to the colour and depth of the surrounding image; just enough is applied to fill in the pinhole. Some photographers use a fine mapping pen instead of a brush because it is easier to manipulate.

Masking. The slide, after retouching, is protected from mechanical damage and from damp by a cover glass, and if necessary it is masked to show only the selected part of the picture and exclude unwanted material. Cover glasses for miniature slides should not exceed ·045 in. (1 mm.) thick, or about 25 to the inch, or the slide may jam in the carrier.

Masking a lantern slide or transparency corresponds to trimming a print. The standard size masks cover only the edges of the slide, leaving the maximum area for projection. There are ready-cut masks of various shapes and sizes, and the holders made for 2 × 2 ins. slides are supplied complete with masks. The mask also cuts off unwanted light from around the slide when it is projected.

Slides may be masked with the same black adhesive binding paper used for binding up the slide, making one lot of paper do two jobs. This is a very effective way provided that the binding paper is stuck down accurately so that all the corners are rectangular. Masks may also be cut from any opaque paper, and it is possible to buy blanks printed with white guide lines for cutting out any required size. Masks of this type can easily be cut out on a sheet of glass using a steel rule and a razor blade in a holder.

Spotting. The slide is clearly marked so that whoever has to project it will be able to see at a glance (even in near-darkness) if he is putting it into the projector the right way around. Few things are more irritating to an audience than having to wait for the projec-

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

BINDING LANTERN SLIDES. 1. Thoroughly clean cover glasses. 2. Use crossed strips of binding paper to make a mask; (cutting a mask in one piece in 24 × 36 mm. size is not easy). Masks can also be bought ready made. 3. Place spot (in bottom left hand corner) and also title strips on mask. After making sure that all components are completely dry, assemble the cover glasses with the film and the mask. When viewed from the side carrying the spot and title strips the image should be upright and the right way round. With lantern plates no film is used, and only one cover glass becomes necessary. 4. Bind round edges with lantern slide binding tape of correct length. 5. A slide mounting jig makes this easier. 6. Fold tape down on each side, and cut corners for neat finish.

tionist to find the right way of the slide by trial and error at the prompting of the lecturer. While there are eight possible ways of inserting the slide, only one of them is right.

The commonest way of marking a slide is to put a white spot on the mount (or on the mask inside the mount in the case of glass-bound slides). This spot should be in the bottom left hand corner when looking at the slide image upright and the right way round. The slide is then inserted in the projector so that the spot is in the top right hand corner, facing to the rear. This automatically ensures that the slide appears upright and the right way round on the screen.

With slides made by printing on positive materials, the emulsion side of the transparency will face the lamp in the projector. On slides made by exposure in the camera the emulsion side faces the lens.

A titling strip can also be added above or below the mask opening, for noting details of the picture. Usually this is also placed on the same side of the transparency as the spot.

Binding. Finally, the lantern plate with its mask and cover glass are bound in register. First the slide and the cover glass are warmed to remove any trace of dampness. The slide must be completely dry before assembly or the heat of the projector will cause condensation. The inner surfaces of the slide and cover glass are then polished clean, wiped free from dust, and brought together ready for binding.

Where films are mounted between glass, slightly uneven contact between the film back and the glass surface may lead to Newton's rings. These are interference fringes and appear as very fine irregularly shaped parallel rings, rather like the coloured fringes on a thin layer of oil. Newton's rings frequently show up during projection, and can be avoided by using cover glasses with a faintly grained surface. The latter should face the film during binding. Such "anti-Newton" glasses are commercially available.

Binding strips are supplied either in 3¼ ins. lengths or in pieces long enough to bind all four edges without cutting. Avoid self-adhesive tape unless specially designed for binding slides. Usually such tapes "creep" especially when they get warm in the projector, causing packs of slides to stick together, while the sticky edge of the tape attracts dust and dirt.

When the 3¼ ins. strips are used, the slide and its cover glass are held firmly together and bound along opposite edges. A strip is first moistened and then allowed to dry for a few seconds. It is then laid along one edge of the slide so that it forms an even margin, and then turned sharply over to the face of the cover glass and pressed well down. The opposite edge is next treated in the same way, and then the two remaining edges. The moist binding is finally ironed into contact by rubbing it with a knife handle.

CC-0. Agamnigan Digital Preservation Foundation, Chandigarh

If a single length of binding strip is used, it is attached to one edge of the slide, mitred at the corner, and so on along all the edges, and overlapped at the point where it started. A special mounting jig eases the work of holding the assembly.

Titling. A slide may be titled or numbered for reference by gumming a printed slip of paper to the mask so that it appears above the binding when the picture is viewed the right way up and from the emulsion side. In this way the title can still be read when the slide is mounted in an exhibition viewing cabinet.

Filing. Small numbers of slides may be filed in dovetailed boxes, but collections of any size are more conveniently kept in boxes with compartments taking about twenty slides, without dovetails. Coloured binding tapes, or titles in white ink on the top edges are both used for identification. In some storage boxes the slides are held at an angle so that the top edges are exposed, allowing titles to be read easily. R.M.F. & C.D.M.

Slide magazines used in many modern still projectors are also suitable for storage. In this case a complete slide set is held ready in the magazine for projection whenever required. The magazines themselves may be stored in suitable cabinets.

COLOUR SLIDES

A number of manufacturers of reversal colour film automatically return processed transparencies ready mounted as 2 × 2 ins. slides. These are generally card frames into which the trimmed pieces of film, corresponding to a single frame, are inserted by a machine.

The card frames grip the edges of the film piece all round. This has the drawback that the film curves when the humidity of the air changes, and is liable to reverse its curl fairly abruptly during projection in the projector. This is known as "popping", and leads to a sudden going out of focus. Some processing laboratories therefore return the film in thin plastic frames which permit a certain amount of movement and so reduce popping. Usually films can also be returned, on request, in uncut strips of 5 or 6 frames for mounting by the user.

Making Colour Slides. While original colour transparencies are almost invariably made by exposure in the camera, duplicates can be produced in various ways. Processing laboratories frequently offer a duplicating service in which the transparencies are printed on to internegative film—a negative colour film specially designed for this purpose with a low image contrast. This negative is then used to produce further positives by contact or projection printing.

Colour negatives can also be printed on to positive film to yield transparencies. The procedure is very much the same as making colour prints, with colour control introduced by filters.

Duplicate colour slides can be made on reversal colour material. Where transparencies are intended for a duplication, they are best made on a special reversal duplicating film of contrast and colour characteristics more suited to duplication. Special printers are available for this purpose, but an ordinary miniature camera with appropriate close-up gear can also be used. Particular care is needed to ensure illumination of the original transparency with light of the correct colour quality.

Mounting Colour Slides. Colour transparencies in film form may be mounted between cover glasses in the same way as black-and-white miniature transparencies. In addition a number of alternative frames for mounting are available. Mostly these utilize glasses of the size of the transparency, let into plastic frames which then can be closed by snapping them together. This makes for fairly rapid mounting, and also permits transparencies to be changed in their frames if necessary.

MINIATURE TRANSPARENCY FRAMES. 1. Card frame. 2. Glassless plastic frame. 3. Plastic frame with glasses. 4. Plastic frame for card mounted slides. The centre openings of the upper and lower panels are in clear plastic and are in contact with the film. The corners of the card frame must be trimmed before insertion in this frame.

To mount transparencies in these plastic frames, first thoroughly clean the glasses and make sure that they and the transparency are absolutely dry. Slight warming near a radiator (but not too near) helps.

Next insert the first glass into the plastic frame, place the transparency in position, and cover with the second glass. Finally fit in the second half of the frame and snap shut. The exact method of doing this depends on the design of the frame, and the packings of slide frames usually carry full instructions.

Some plastic slide frames have one side white and the other brown or black. Here the transparency should be inserted to appear the right way round when viewed from the light side of the frame. This side should face the light source in the projector, to reduce the extent to which the slide gets warm.

Plastic slide frames frequently already incorporate a spot for orientation, to make separate spotting unnecessary. In this case insert the transparency in an orientation which corresponds to the position of the spot on the slide frame. (Usually there are two spots, one for horizontal and one for vertical slides). A legend or other details can also be written on a roughened panel on most plastic side frames. No masking of any kind is necessary, since the plastic slide frame acts as its own mask.

Many types of plastic slide frame are available with specially treated glasses to avoid Newton's rings.

A further type of plastic frame takes card mounted miniature transparencies. Here the complete slide, as returned by the film processing laboratory in the case of colour reversal film, is placed between two halves of a plastic frame, the corners of the card frame trimmed and the whole assembly snapped together. The plastic frame may be transparent, and part of this transparent section covers the image opening of the card frame. The main purpose of this type of frame is to provide additional protection of the transparency in its card frame, but the resulting assembly may be too thick for use in some automatic slide projectors.

The least expensive method of mounting miniature transparencies which are not already mounted in the course of processing is in card frames. These consist of a piece of card 4 × 2 ins. in size, scored in the middle for folding and carrying two cut-out apertures of the appropriate size for the transparency. One side of the card is coated with rubber adhesive. The transparency is placed on to one half of the frame, with the adhesive side of the latter facing upwards. Guide lines or other marks show the exact position for the transparency.

As the aperture is slightly smaller than the image area on the transparency, some slight adjustment is possible in placing the piece of film, so as to correct tilts, reduce unwanted foreground areas, etc.

With the transparency in position, the other half of the card is then folded over and pressed down, when the rubber-coated surfaces make contacts and stick together.

The mounted slide then needs spotting and tilting in the usual way.

Suitability for Projectors. Modern miniature slide projectors with automatic slide change working with magazines will only operate satisfactorily if the thickness of a slide falls between certain limits. For this purpose slides should not be thinner than 0·05 in., nor thicker than about 0·125 in. The lower limit is represented by card-mounted slides returned by the processing laboratories of colour film manufacturers; the upper limit corresponds to most plastic frames and glass mounted slides. Thinner slide frames are liable to jam the changing mechanism because the frame may get lodged between the feeding arm and the gate itself. Too thick slides may not be able to move in and out of the magazine compartment freely.

Slides must also be mounted cleanly, with no projections of binding tape at the corners (in the case of glass mounted slides) which may catch in the slide track and foul the mechanism. Plastic slide frames usually have slightly rounded corners and are not likely to give any trouble. However, where the frame is of metal, sharp corners or insufficiently bent down closing tabs of the frame may lead to difficulties.

SMEAR CAMERA. American term for streak camera, a type of high-speed camera where the image is spread across the film as a smear or streak and then reconstituted optically.

See also: *High-speed cinematography.*

SMYTH, CHARLES PIAZZI, 1819–1900. Astronomer Royal for Scotland. Photographed by magnesium ribbon light the interior of the Great Pyramid in 1865, using a miniature camera with plates 1 × 3 ins. sensitized and developed in the camera. In 1856 made astronomical investigations from the Peak of Teneriffe and described them in a book published in 1858, the first book illustrated with actual stereo-photographs.

SMYTHE, FRANCIS SYDNEY (1900–1949). English Alpinist and photographer. Chiefly known for his Himalayan explorations on Kanchenjunga, Kamet and Everest, 1933–36–38. Wrote many books about mountains using his own photographs as illustrations.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

SNAPSHOOTER. (Slang.) Sometimes applied by non-photographers to photographers in general; otherwise used by "serious" photographers to describe those whose approach is casual and limited to taking instantaneous hand-held exposures without observing the refinements of composition and technique.

SNAPSHOT. Term introduced by Sir John Herschel in 1860 to indicate an instantaneous exposure; nowadays it refers more and more to a casual photograph taken in a box or other simple camera, usually set for fixed focus working.

SNAPSHOT PHOTOGRAPHY. In the early days of time exposures made on plates, only experts could take photographs. Fast films and cheap cameras have changed this state of things and put picture making machines in the hands of millions of people who need to know nothing about photography. The combination of a fast film and a cheap lens working at a small stop makes it possible to turn out a camera that needs no focusing, the simplest shutter, and no stop. All the owner of such a camera needs to know is how to load it with a film, point it at the subject, and press the release. The photographic dealer looks after everything else and will even load and unload the camera. In clear weather out of doors, this simple procedure will produce a print that is reasonably sharp and correctly exposed.

The result of all this has been to create a special type of photograph—the snapshot. The snapshot has no artistic pretensions; it sets out to be no more than a record of a holiday scene, a corner of the back garden, or some place of interest, in which one or more friends or relations of the photographer feature prominently. The idea behind most snapshots seems to be to serve as a souvenir of the people, place, or occasion—or all three. The intention is never to produce a "photographer's photograph".

A snapshot is invariably an instantaneous exposure and it is usually made without a thought for photographic technique. The result is that the snapshot too often falls short of even its own humble standards.

Flash Snaps. Even the cheapest cameras nowadays are equipped for taking flash pictures, and the scope of the snapshooter now includes indoor pictures taken in this way. Cameras in this class are as a rule not synchronized for shutter speeds faster than 1/25 second, and many of them simply have "open flash" contacts. This means that the subject must be still or only moving slowly, so that the choice of subjects narrows down to more or less posed groups, pets, and party festivities.

In many ways flash photographs taken by the average snapshooter have a better chance of being free from faults than those made normally out of doors. This is because there is less risk of camera shake or subject movement, the smaller lens apertures used result in greater depth of field, so focusing becomes much less critical, and the exposure charts supplied by makers of flash bulbs are more accurate than any similar information that can be given about exposure in daylight.

Common Faults. Large numbers of films bought by snapshooters every year used to be wasted, but manufacturers have succeeded in building into their simpler cameras safeguards against most of the common faults. Double exposures and blanks have been eliminated by interlocking film transport and shutter release; wrong exposure (practically confined to under-exposure) is largely prevented by either built-in exposure meters or some system of automatic control; mis-focusing is less likely with the small-format cameras and faster sensitized materials of today, and fog-creating light leaks have disappeared with better standards of design and manufacture.

However, certain traditional mistakes of the beginner still remain and the camera manufacturer is not likely to be able to do much about them. These faults are mainly the result of carelessness—in holding the camera, in using exposure aids, in focusing and in handling the film. The only person who can get rid of these faults is the camera user, and the slight amount of extra trouble involved in avoiding them is fully repaid by the tremendous improvement that follows. F.P.

SNELL'S LAW. Law of optics which states that when light passes from one transparent material to another and suffers refraction, if both rays lie in a plane perpendicular to the common surface of the materials, then whatever the angle of the incident beam, the sine of the angle always bears a constant ratio to the sine of the angle of the refracted beam. This ratio is the index of refraction from the first material to the second.

SNOOT. Shield, often tubular in shape, for lamp reflectors or spotlights. It fits over the lamp and directs the light more or less in one direction. At the same time it also serves to shield light sources in front of the camera position from shining into the camera lens.

SNOW. One of the principal difficulties of photographing a snow-covered landscape is to judge the exposure correctly.

Exposure. The conventional type of photoelectric exposure meter is almost certain to indicate too short an exposure. This is because it is influenced disproportionately by the relatively large expanse of light-toned snow. A snow scene is at its best under a bright blue sky, in direct sunshine, and in such conditions allowance must be made for exposure to the deep shadow areas.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

A clear blue sky, especially at high altitudes, is not as brilliant as the snow-covered landscape, so that the procedure of tilting the meter as in landscape work cannot be applied here.

It is necessary to increase the exposure meter reading by at least 50 per cent to make sure of getting a certain amount of detail showing in the shadows. Unless the exposure is enough to bring out this, the resulting photograph will be mostly "soot and whitewash".

Lighting. A snowy landscape without sunshine is apt to make a flat and disappointing photograph because there is very little contrast and the scene tends to reproduce as a more or less uniform shade of grey. The most attractive snow pictures are those in which the sun is shining obliquely across the surface. Lighting of this type casts long, interesting shadows and emphasizes the crisp texture of the snow. Such ideal conditions are rare in the British Isles; they are found most easily in mountainous regions.

Filters. When the sky is included, a pale yellow filter used with either a panchromatic or orthochromatic film will give all the correction necessary.

Even when the sky does not appear in the picture, a yellow filter can still help, in that it darkens the shadows (which will be predominately blue), thus increasing the contrast.

Above about 5,000 feet, even a pale yellow filter tends to render the blue sky tone too dark, and a special colourless U.V. filter is used.

Snowflakes. Snowflakes themselves can be caught by the camera in the same way as raindrops—i.e., if they are in sunshine and the background is in shadow. As it is not possible to focus all the flakes sharply from the camera to infinity, the photograph is best taken from under a shelter so that there are no flakes falling near the camera.

Faking Snowflakes. A passable imitation of snowflakes can be added to a negative by spattering the reverse side with opaque pigment. An old toothbrush is loaded with pigment and the spattering effect is produced by rubbing the finger along the bristles.

The same effect can be applied to the print by covering the paper with a sheet of glass and spattering the top face of the glass. The image of the drops of pigment is blurred by being out of contact with the paper, and the result is a convincing substitute for real snow. P.J.

SOCIÉTÉ FRANÇAISE DE PHOTOGRAPHIE. Founded in Paris November 1854 under the presidency of Eugène Durieu and continued its activities until c. 1960, though greatly hampered by lack of premises since the end of World War II. Official organ of the Society was the *Bulletin*, which appeared monthly from January 1855 until 1892 (with certain breaks), fortnightly 1892–1909, and thereafter monthly.

SOCIÉTÉ HÉLIOGRAPHIQUE. The first photographic society in the world, established in Paris in January 1851 under the presidency of Baron Gros. It was discontinued some time prior to the foundation of the *Société Française de Photographie* in November 1854.

SOCIETY OF FILM AND TELEVISION ARTS, LTD. Non-profit-making company registered in 1958 with the object of maintaining the quality and standards of British film-making and television. Incorporates the British Film Academy (founded 1947) and the Guild of Television Producers and Directors (founded 1953).

Members are senior film-makers and production executives, and television producers, directors and senior creative technicians, elected by the Council. There is an Associate membership for other technicians in both media, and affiliateship is open to people interested in the work of the Society, who are not necessarily concerned professionally, but whose work brings them into contact with, film-making or television production. Patrons are companies and organizations which subscribe not less than one hundred pounds a year to the funds.

Weekly meetings are organized for members from September to June. At these meetings members see outstanding films, or engage in technical discussions on film and television subjects with prominent British and foreign technicians.

The Society publishes a quarterly Journal and is continuing the Academy's sponsorship of books concerned with the technique of film-making and television production. There is a library of books and other publications on both media, and a collection of British film scripts. It is hoped shortly to start a selective collection of British television scripts. Two sets of Awards are given annually. The British Film Academy Awards are five (bronzes) for the best films of the year and twelve (plaques) for the best technical contributions and acting performances. These Awards are presented at a Dinner in the Spring each year. The Guild of Television Producers and Directors Merit Awards are fourteen (bronzes) given for overall work during the year in drama, light entertainment, current events, etc., to producers and artists, and for script and design in television. These Awards are presented at the Television Ball held at the end of each year.

SOCIETY OF MOTION PICTURE AND TELEVISION ENGINEERS. American society for promoting the interests of all engaged in cinematography, television instrumentation

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

and high speed photography. It aims to advance the theory and practice of engineering in these areas; to develop standards of equipment and methods; to set and maintain a professional standard among its members, and to publish useful technical information.

The Society was founded in 1916; it now has 6,500 members in 60 different countries. It holds local meetings throughout the year in different parts of the United States and Canada, and holds two annual conventions and equipment exhibitions. In addition to frequent reports on matters of interest, the Society publishes a monthly Journal.

Active membership is open to anyone over 25 years who possesses three years professional experience; Associate membership is open to anyone over 18 years and there are no age or experience requirements for student members. Sponsors are necessary in all cases, and annual dues vary according to the type of membership.

The Society employs a permanent executive, editorial and technical advisory staff.

SOCIETY OF PHOTOGRAPHIC SCIENTISTS AND ENGINEERS. This is a professional association in the United States devoted solely to the advancement of the application of science to photography and of photography to science. Its membership is made up of men who use photography to obtain data in science and industry, or who are engaged in the design, development or production of photographic equipment and materials.

The Society was formed in 1947 as a local group in Washington, D.C. It was reorganized and incorporated in 1948 as the Society of Photographic Engineers to admit to regular membership persons everywhere who are engaged in photographic engineering on a responsible, professional level. The Society adopted its present name in 1957. Associate membership is available to adults with a serious interest in the technical aspects of photography, and full-time university students are eligible for Student membership.

Business organizations who wish to aid the Society are invited to become Sustaining Members.

The Society has members throughout the United States and in countries on every continent. Although its members work in many fields, they are all engaged in pursuits where photography plays a vital part.

The formation of local chapters is encouraged wherever there are sufficient members and the Society now has about a dozen chapters, some of which being in Washington, D.C.; Fort Monmouth, N.J.; New York, N.Y.; Los Angeles, Calif.; Dayton, Ohio; Chicago, Ill.; and Boston, Mass. Chapter meetings are devoted to the presentation of papers and organized discussion. The exchange of experiences affords each member opportunities to learn the techniques of other fields and to utilize them in his own work. Each chapter is self-governing and plans its own activities.

A National Conference on Progress in Photographic Engineering is held annually. Members meet for several days, during which papers are delivered and new equipment displayed.

Each member of the Society receives two bi-monthly publications. The journal, *Photographic Science and Engineering* provides authoritative information about the theory and applications of photographic science, the engineering of photographic materials, optics, and illuminants, and photographic instrumentation and data reduction systems. The *S.P.S.E. News* describes current activities of the Society and its members, the industry, new products and applications.

A Conference on Progress in Photography is held annually. Members meet for several days during which papers on new findings in photographic science and engineering are presented, and new equipment and materials are exhibited by the major companies. The Society also regularly convenes a Symposium on a single topic of suitable importance. These meetings are usually held in the autumn and for several days addresses and discussions study an area of interest, such as rapid processing, photography of electronic displays, or processing of colour materials.

The Society carries on its engineering, business, and professional activities through committees which conduct their work outside the chapter meetings. For example, development of standards is aided by S.P.S.E. representatives serving on each of the several photographic committees of the American Standards Association. Selected S.P.S.E. members are delegates to the Inter-Society Colour Council, while others photographically record the orbits of the man-made satellites for an S.P.S.E. project. Other objectives of the S.P.S.E. include the encouragement of better means for education in photographic engineering; the maintenance of a high level of competence among its members, wider use of scientific thinking and methods; and proper recognition of photographic engineering as a profession.

SODIUM ACETATE. Used in gold toners.

Formula and molecular weight: NaO_2CCH_3; $3H_2O$; 136.

Characteristics: White crystals.

Solubility: Highly soluble in water at room temperature.

SODIUM AURICHLORIDE. Gold sodium chloride. Chemical commonly used in gold toning positives.

SODIUM BIBORATE. Chemical used in certain fine grain developers and for toning. Synonym for sodium borate, or borax.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

SODIUM BICHROMATE. Sodium dichromate. Used in intensifiers, bleaching baths, and carbon, carbro, and other gelatin or gum-bichromate processes in place of potassium bichromate. The latter has the advantage of not being deliquescent, but is much less soluble.

Formula and molecular weight: $Na_2Cr_2O_7.2H_2O$; 298.

Characteristics: Deliquescent red crystals.

Solubility: Highly soluble in water.

SODIUM BISULPHATE. Sodium hydrogen sulphate. Used as an acidifying agent in acid fixing baths, especially in dry acid fixing powders where a mixture of sodium bisulphate and acetate acts like acetic acid.

Formula and molecular weight: $NaHSO_4.H_2O$; 138.

Characteristics: Small white crystals.

Solubility: Fairly soluble in water.

SODIUM BISULPHITE. May be used to replace potassium metabisulphite in stop baths and acid fixing baths, or as a preservative in developers. A fairly concentrated solution used to be sold as "bisulphite lye".

Formula and molecular weight; $NaHSO_3$; 104.

Characteristics: White salt, smells of sulphur dioxide.

Solubility: Fairly soluble in water.

SODIUM BISULPHITE LYE. Concentrated solution of sodium bisulphite (approximately 30 per cent), prepared by dissolving sodium sulphite in dilute sulphuric acid. Has the same uses as sodium bisulphite, but is nowadays rarely employed in this form.

SODIUM BORATE. Several borates of sodium are known, and are used as alkalis in developers. The main ones of photographic importance are sodium metaborate and sodium tetraborate (borax).

SODIUM BROMIDE. May be used to replace potassium bromide in bleachers or in developers. Six parts anhydrous sodium bromide are equivalent to 7 parts potassium bromide or 8 parts sodium bromide crystals.

Formula and molecular weight: NaBr; 103, and $NaBr.2H_2O$; 139.

Characteristics: Hygroscopic white crystals or white powder.

Solubility: Highly soluble in water at room temperature.

SODIUM CARBONATE. Soda; soda ash. Alkali in developers. Three parts anhydrous salt are approximately equivalent to 8 parts of crystals.

Formula and molecular weight: Na_2CO_3; 106, or $Na_2CO_3.10H_2O$; 286.

Characteristics: White powder or large colourless crystals. A monohydrate $Na_2CO_3.H_2O$; 124, also exists and is widely used in America.

Solubility: Freely soluble in water.

SODIUM CHLORIDE. Common salt. Used in some bleachers and reducers.

Formula and molecular weight: NaCl; 58·5.

Characteristics: White crystals.

Solubility: Freely soluble in water at room temperature.

SODIUM DIPHOSPHATE. Disodium phosphate. Chemical used as a weak alkali in some developers.

See also: *Sodium phosphate (dibasic).*

SODIUM GOLD CHLORIDE. Sodium aurichloride. Chemical commonly used in gold toning positives.

SODIUM HEXAMETAPHOSPHATE. Calgon. Water softener.

Formula and molecular weight: $(NaPO_3)_6$; 612.

Characteristics: White powder.

Solubility: Highly soluble in water at room temperature.

SODIUM HYDRATE. Caustic soda. Strong alkali. Commonly used in some developers for high activity and rapid processing.

See also: *Sodium hydroxide.*

SODIUM HYDROSULPHITE. Sodium hyposulphite. Used as blackener in reversal processing.

Formula and molecular weight: $Na_2S_2O_4.2H_2O$; 210.

Characteristics: White crystalline powder. Does not keep well; the solution in particular soon deteriorates.

Solubility: Freely soluble in water.

SODIUM HYDROXIDE. Caustic soda; sodium hydrate. Strong alkali in developers.

Formula and molecular weight: NaOH; 40.

Characteristics: Very hygroscopic sticks or pellets. A slightly less pure form is also sold as flakes. Solid and solution are corrosive.

Solubility: Highly soluble in water at room temperature. The solid generates heat as it dissolves.

SODIUM HYPOSULPHITE. Strictly speaking this is sodium hydrosulphite, but in photography the term is frequently applied to sodium thiosulphate.

SODIUM METABISULPHITE. Used in acid fixing baths and stop baths, and as a preservative in developers.

Formula and molecular weight: $Na_2S_2O_5$; 190.
Characteristics: White crystals.
Solubility: Fairly soluble in water.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

SODIUM METABORATE. Alkali in developers. Kodalk is a proprietary alkali of this type.
Formula and molecular weight: $NaBO_2.2H_2O$; 102.
Characteristics: White crystalline powder.
Solubility: Freely soluble in water at room temperature.

SODIUM PHOSPHATE (DIBASIC). Disodium phosphate, sodium hydrogen phosphate; sodium diphosphate. Weak alkali in developers.
Formula and molecular weight: $Na_2HPO_4.12H_2O$; 358.
Characteristics: White crystals.
Solubility: Fairly soluble in water at room temperature.

SODIUM PHOSPHATE (TRIBASIC). Trisodium phosphate; sodium orthophosphate. Alkali in developers.
Formula and molecular weight: $Na_3PO_4.12H_2O$; 380.
Characteristics: White crystals.
Solubility: Fairly soluble in water at room temperature.

SODIUM POTASSIUM TARTRATE. Rochelle salt. Used in some toners and sensitizers; also as a developing agent in the kallitype process.
Formula and molecular weight: $NaK(CO_2CHOH)_2.4H_2O$; 282.
Characteristics: White powder.
Solubility: Freely soluble in water.

SODIUM SULPHATE. Glauber's salt. Used in hot weather processing solutions to reduce swelling of the gelatin.
Formula and molecular weight: $Na_2SO_4.10H_2O$; 322.
Characteristics: White crystals. Also exists in an anhydrous powder form, 7 parts of which are equivalent to 16 parts of the crystalline salt.
Solubility: Fairly soluble in water at room temperature.

SODIUM SULPHIDE. Used in sulphide toners.
Formula and molecular weight: $Na_2S.9H_2O$; 240.
Characteristics: Very hygroscopic colourless crystals. Keep in well stoppered bottles. Dilute solutions do not keep.
Solubility: Freely soluble in water at room temperature. The solutions smell of hydrogen sulphide (rotten eggs).

SODIUM SULPHITE. Preservative in developers.
Formula and molecular weight: $Na_2SO_3.7H_2O$; 252.
Characteristics: White hexagonal crystals. Also exists in the form of an anhydrous powder. One part of the latter is equivalent to 2 parts of crystals.
Solubility: Freely soluble in water at room temperature.

SODIUM THIOANTIMONATE. Schlippe's salt. Used in certain intensifiers and sepia (sulphide) toners to obtain a range of comparatively cold tones.
Formula and molecular weight: $Na_3SbS_4.9H_2O$; 481.
Characteristics: Yellowish crystals.
Solubility: Freely soluble in water at room temperature.

SODIUM THIOCYANATE. Sodium sulphocyanide, sodium rhodanate. Used as a solvent in fine-grain developers in place of potassium thiocyanate.
Formula and molecular weight: NaCNS; 83.
Characteristics: White hygroscopic crystals. Poisonous.
Solubility: Highly soluble in water.

SODIUM THIOSULPHATE. Sodium hyposulphite; hypo. Fixing agent; also used in Farmer's reducer.
Formula and molecular weight: $Na_2S_2O_3.5H_2O$; 248.
Characteristics: Colourless hexagonal crystals. Also exists in an anhydrous powdered form. Two parts of the latter are approximately equivalent to 3 parts of the crystalline salt.
Solubility: Highly soluble in water at room temperature.

SODIUM VAPOUR LAMP. Vapour discharge lamp giving an intensely yellow light which has some special advantages for subject lighting in photography—e.g., in scientific work. Also used for darkroom illumination when handling materials which are completely insensitive to yellow.
See also: *Discharge lamp; Monochromatic illumination.*

SOFT FOCUS. Photographers do not always want a critically sharp image. Some subjects look better when the definition is more or less diffused so that the eye is freed from the distracting influence of unimportant detail, surface texture and blemishes—e.g., such as are caused by scratches on the negative.

There are several ways of arriving at a soft focus image: by using a soft focus lens in the camera, by using a diffusion attachment on the camera or enlarger lens, or by printing

through a diffusing screen. The image may be softened either in the camera or during printing in the enlarger.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Effect of Diffusion. Diffusion during enlarging differs in one respect from diffusion during exposure in the camera. In the camera diffusion spreads the light from the brighter parts of the image into the darker areas—i.e., the highlights of the negative spread into the shadows. When the diffused negative is printed, the bright parts of the print are surrounded by a kind of luminous halo.

When the diffusion takes place during enlarging, the effect is still to spread the bright parts of the projected image into the dark areas. But in this case the bright areas become the shadows in the developed print. So in the print the shadows spread into the highlights and reduce the brilliance of the picture.

Diffusion during printing also has the effect of subduing small scratches and other flaws, and playing down the grain of the negative when it would be otherwise noticeable.

Soft Focus in the Camera. One of the most effective ways of softening the image is to use a special soft focus lens, but this is only possible when the camera is equipped to take interchangeable lenses. Such a lens is deliberately undercorrected for spherical aberration, with the result that the image formed by the centre of the lens is sharp, while the marginal parts superimpose an unsharp image. The degree of unsharpness is controlled by the lens aperture; stopping the lens down reduces the diffusion.

SOFT FOCUS. **Left:** *When the subject is photographed with a soft focus attachment in front of the camera lens (or with a soft focus lens), the light scatter spreads highlights on the negative into the shadows, giving a halo-like glow in the print.* **Right:** *Diffusion of a straight negative during enlarging gives a soft print with shadows spreading into the highlights.*

An alternative method is to use a diffusion attachment. This is a disc made of either glass or clear plastic, engraved with a number of concentric circular lines. The depth and spacing of the lines govern the amount of diffusion.

Most diffusion attachments have a clear area in the centre. This allows a proportion of the light rays to pass without being diffused, and by progressively stopping down the lens from full aperture, the amount of diffusion can be controlled from a maximum to none at all.

Diffusion attachments are fitted with rim mounts and used in the same way as filters. They do not alter the normal exposure.

A diffusion attachment can be improvised from a piece of Cellophane mounted in front of the lens like a filter and having the centre cut away to about half the lens diameter.

While dirt and grease on the surface of the lens will also diffuse the image it would be a mistake to dull the lens deliberately to produce a soft focus effect.

Blur produced by movement or deliberate misfocusing is not a soft focus effect. These methods blur the entire image whereas true soft focus is created by superimposing a certain amount of blur on a perfectly sharp image.

Soft Focus in the Enlarger. The sharpness of an enlargement is softened for pictorial effect by the use of diffusion attachments mounted in front of the lens or diffusion screens over the paper on the easel.

Any delicate, finely woven fabric—e.g., chiffon, nylon, or silk—can be used to diffuse the image either by being held in front of the lens, or stretched on a frame above the paper. The effect varies according to the weave of the fabric and its distance from the lens or paper.

A coarse fabric superimposes its own texture on the image, giving it the effect of having been printed on—e.g., linen or canvas—but it does not give a soft focus effect.

For a texture effect the fabric or screen should be in contact with, or about ⅛ in. above, the paper. For diffusion to give a soft focus effect, the screen should be just in front of the lens.

The material used should preferably be black to reduce the risk of fogging the image by reflected rays. Transparent wrapping material, crumpled and then flattened out, can also be used to soften the image in much the same way.

With circular diffusion discs the degree of diffusion can usually be varied by stopping down the enlarger lens. The larger the lens aperture, the greater the diffusion.

Another way of controlling the diffusion is to expose the print for part of the time with, and part without, the diffusion attachment in front of the lens.

SOFT FOCUS ATTACHMENT. Disc of translucent or transparent material which can be fitted in front of the camera lens like a colour filter to soften the definition of the image.

See also: *Soft focus.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

SOFT FOCUS LENS. Any lens which fails to record crisp pin-point definition can be termed a soft focus lens. Softness of focus is due to the fact that a single bright object point is imaged by the lens as a patch of light having finite size and a complex distribution of light intensity instead of the ideal point image. This softness is brought about by the various forms of lens aberration. In portrait lenses spherical aberration is deliberately introduced to soften the focus.

See also: *Portrait lens.*

SOLARIZATION. Strictly speaking, solarization is the reversal of the image on a film or plate by an extreme amount of over-exposure —about 1,000 times the amount required to give a normal negative image on development.

The term has by this time almost lost its original meaning. Nowadays it is applied—by all practical photographers at least—to the technique for producing a partly reversed image by exposing the negative to unsafe light during development—actually, the phenomenon known as the Sabattier effect. It was first done for artistic effect by Man Ray in 1930.

The effect commonly referred to as solarization is produced when a negative is exposed to too strong or unsafe darkroom illumination during development. The already developed image acts as a negative through which the rest of the silver bromide is exposed. Some reversal of the image occurs and the result is part negative and part positive. If the exposure is heavy enough the resulting positive will, at any rate in the shadows, develop up to a greater density than the original negative image.

Mackie Line. There is a further characteristic effect: a narrow band or rim of low density, called the Mackie Line, is formed at the boundaries between adjacent highlight and shadow areas. This happens partly because there is always an increased concentration of bromide ions in the emulsion at the boundary separating a completely developed area from one that is just developing. The bromide (partly produced from the silver bromide during development, and partly due to the potassium bromide from the developer) along such boundaries greatly retards development, forming a more or less clear rim. In the print the rim appears as a black outline around the principal image contours.

Method. While a solarized negative is often the result of an error, it can be produced intentionally for effect. Negatives with large areas of dark tone and simple outlines are most suitable for the process.

Solarization can equally be applied during printing. Further, the print from a solarized negative can be solarized once more, and there are various degrees to which the process can be carried.

For proper control of the process it is necessary to match the primary exposure of the negative (or print), the initial development, the second exposure that produces the solarization, and the final development.

The primary exposure must be adequate to yield a correctly exposed negative on normal development. If development is interrupted halfway through the process, the image already formed should be adequate to have a reasonable covering effect on the unexposed silver salts in the emulsion, but not so weak as to cause the solarizing exposure to swamp all the initial image formed.

For the same reason the first development must be adequate to form an image which is clearly visible on the surface of the film or paper. Excessive first exposure and first development brings up too much of the image and leaves not enough silver salts to be fogged by the solarizing exposure; hence the latter will not lead to a vigorous continuation of the development process and fail to produce the border outlines.

Once the image is of the right depth the emulsion is brought close to a fairly bright safelight and exposed for a few seconds. The safelight should be definitely unsafe with the material in use. Alternatively, a brief white light exposure can be given.

Development is then continued until the desired appearance is achieved.

The timing of the solarization exposure is important. The thinner half tones gain additional density after the exposure and if the solarization exposure is given too soon, the half tones will be very dense and have poor tone gradation. If the exposure is given too late, the solarization effect will be slight. The solarizing exposure itself must also be sufficient. Too little leads to a flat and fogged positive (on the negative film) or negative on the positive print) or only a partially solarized image with weak border outlines. Excessive solarizing exposure leads to complete blackening of the whole emulsion with little trace of an image.

The duration of the final development is also important. Insufficient development yields a partially solarized image with no sharp outlines. Excessive development after the solarizing exposure kills the border outlines formed in the first place. This is because the retarding effect of the bromide concentration is only temporary. If the final development goes on long enough, the previously underdeveloped outlines catch up with the rest of the image and disappear. It is clear from what has been said that solarization is by no means an exact technique; only the broad principles can be stated; the rest is a matter of individual experiment.

Results similar to solarization can be produced by extreme over-exposure of the negative in the first place followed by a brief exposure to an unsafe light before development.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

True solarization often occurs when a very intense light source—e.g., an electric arc—appears in the picture and is grossly over-exposed. Because of solarization, the source reproduces as a black patch on the print instead of a clear white. L.A.M.

SOLENOID. Electrical device capable of exerting a push or pull when energized with electric current. It consists of a spirally wound coil of insulated wire with a free, soft iron armature. When the armature is displaced from the centre of the coil and a current is passed through the wire the magnetic field created by the passage of the current tends to pull the armature back into the centre of the coil. This force is used to provide remote control of shutter operation, film transport, etc.

See also: *Flash synchronization; Shutter releases.*

SOLUBILITY. Generally understood as the ability of a solid to dissolve in a liquid—e.g., to mix homogeneously with it. Quantitatively the solubility of a substance is the amount of it that will dissolve in a given quantity of the liquid at a specified temperature.

The substance that is dissolved is the solute and the liquid that dissolves it is the solvent.

In photography the solutes are the various chemicals which are used for processing; the solvent is generally water. Some chemicals are very freely soluble (e.g., potassium thiocyanate, sodium hydroxide, and others), some are moderately soluble, and some are practically insoluble (e.g., the silver halides).

A substance may be very slightly soluble or completely insoluble in pure water and yet freely soluble in an aqueous solution of another substance. This is usually due to some chemical interaction between the insoluble substance and the chemical already in solution. For example silver bromide is practically insoluble in water, but dissolves in a solution of sodium thiosulphate because of the formation of complexions or double salts.

Solubilities are generally quoted as the number of grams of solute that will dissolve in 100 grams of solvent. Where the solvent is water the solubility may generally be taken as the number of grams of solute that will dissolve in 100 millilitres. A solution which will not dissolve any more of the solvent is said to be saturated.

Substances with a solubility of 50 grams or more are regarded as highly soluble, 20–50 grams as freely soluble, 5–20 grams as fairly soluble, and below 5 grams as slightly soluble.

Solubility and Temperature. Solubility also depends on the temperature of the solvent. Most substances are more soluble at high temperatures, some do not vary a great deal with temperature, and a few are more soluble at lower temperatures. With a substance that is more soluble at higher temperatures, cooling a saturated or nearly saturated solution causes some of the dissolved solute to reform as solid crystals.

Solubility of Liquids. Liquids which are soluble in each other are termed miscible. Such liquids may be completely miscible in all proportions (e.g., acetic acid and water, or alcohol and water), or they may be partly miscible (e.g., ether and water) or not miscible (e.g., petrol or oil and water). Partly miscible or non-miscible liquids will separate out in two layers if stirred together. Where the liquids are partly miscible each layer is a saturated solution of the other.

Solubility of Gases. Water also dissolves many gases. The solubility of a gas is generally highest at low temperatures, and the gases can be driven off by boiling. Thus tap water contains dissolved air; water for making developer stock solutions should therefore be boiled first to drive off the dissolved air which might otherwise oxidize the solution. A number of aqueous solutions of gases are used in photography, e.g., ammonia (which forms ammonium hydroxide), hydrogen chloride (which forms hydrochloric acid), and formaldehyde (which forms the formalin solutions used for hardening emulsions). L.A.M.

SOLUTIONS

Most photographic processing operations are carried out by solutions of chemicals in water. That is the only way in which most processing chemicals can act on the light-sensitive compounds in the emulsion of the film, plate, or paper.

Many of the solutions are sold in bottles (usually of concentrated stock solutions which require dilution). Alternatively, the photographer can make up his own solutions from packets or tablets containing pre-weighed amounts of the various ingredients in their correct proportion, or even weigh out the ingredients himself.

Tablets. Tablet chemicals contain the various ingredients ready weighed out and compressed into one or two tablets. They are intended for making working solutions as and when required, as the tablets are very easy to dissolve. The steps in the preparation are:

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

(1) Measure out the required amount of water in a beaker or dish.

(2) Drop in the tablet or tablets, and crush with a stirring rod. Stir up until all solid has dissolved. (Tablet developers contain the developing agents in one small tablet, and the alkali and sulphite in a larger tablet. The smaller tablet generally has to be dissolved first.)

(3) In the case of paper developers and other solutions, use the bath as it stands. In the case of negative developers it may be advisable to filter the solution.

Packet Developers. Developers sold in packets or tins may make either stock or working solutions. With packets the chemicals are usually contained in two plastic or paper bags, the smaller holding the developing agents and the larger the alkali, preservative, etc. The developing agents in developers packed in tins may be packed separately in glass tubes or contained in a separate compartment of the tin.

The steps in the preparation of the solution are:

(1) Boil enough water for the total amount of solution required, and let it cool down to about 120° F. (50° C.). This drives off most of the dissolved air and thus improves the keeping quality of stock developers.

(2) Pour about three-quarters of the final volume of water required into a glass beaker, or a clean dish (glass, porcelain, glazed earthenware, or enamelled or stainless steel, but not galvanized iron or other metal).

(3) If the water is hard, add the recommended amount of a water softener like sodium hexametaphosphate (Calgon). This is however, not essential.

(4) Pour the contents of the small packet of the developer pack into the water, and stir well until fully dissolved.

(5) Pour in the contents of the main packet, stirring all the time.

(6) Filter the solution into a clean bottle.

(7) Add enough of the boiled water (preferably cooled down) to make up the required final volume. It is best to choose a bottle of the correct capacity so that the solution fills it completely.

The solution can then be used at full strength or diluted as recommended. The bottle should always be correctly labelled; some manufacturers include printed, gummed labels in the pack for the purpose.

Other Packed Chemicals. Proceed in the same way as for developer packets, but note any special instructions regarding the order of mixing, and the temperature of the water—acid hardening fixers, for instance, should not be dissolved in water warmer than 70° F. (21° C.).

Where the chemicals are mixed in one package, it is often convenient to dissolve them directly in the stock solution bottle. In that case fill a bottle of the correct size three-

MAKING UP A SOLUTION. 1. Weigh out the required amount of each chemical on a balance. 2. Boil enough water for the total amount of the solution to drive off most of dissolved air, then cool to about 120° F. and pour out three-quarters of the final volume into a beaker. 3. Dissolve the chemicals one by one in the order specified in the formula, waiting until each chemical is dissolved before adding the next. 4. Filter the solution into a clean bottle of the right size to take just the final volume of solution. 5. Add enough boiled and cooled water to make up to the final volume specified. Label the bottle.

quarters full of water, put a wide-necked dry funnel into the neck of the bottle, and slowly pour the powdered chemicals down the funnel. Then fill up to the required level with water, close the bottle, and shake it from time to time until the solid has all dissolved. Filter if necessary.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Some manufacturers have started to pack pre-weighed chemicals in soluble plastic bags. These dissolve in water so that making up a solution only involves dropping the complete packet into the specified amount of water and stirring.

The dissolved plastic is inert and does not affect the activity of the processing solution in any noticeable way.

Making up Published Formulae. Chemicals are made up to published formulae by weighing out the separate ingredients and dissolving them in the appropriate amount of water. The procedure is as follows.

(1) Weigh out the required amount of each chemical on a balance. The chemicals should be weighed on a piece of paper or a watch glass, never directly on the balance pans. Large amounts of any particular chemical—e.g., sulphite or carbonate in developers—are best weighed in several smaller lots.

(2) Boil enough water for the total amount of solution required to drive off most of the dissolved air, and let the water cool down to about 120° F. (50° C.). Alternatively heat the water to this temperature, and dissolve a little sulphite in it.

(3) Pour about three-quarters of the final volume of water required into a glass beaker or clean dish.

(4) If the water is hard, add the recommended amount of a water softener like sodium hexametaphosphate (Calgon).

(5) Dissolve the chemicals one by one, stirring the solution thoroughly. Wait until each chemical is completely dissolved before adding the next. Dissolve the chemicals in the order specified for the formula.

(6) Filter the solution into a clean bottle of the required size.

(7) Add enough of the boiled water (preferably cooled down) to make up to the required final volume. The final level may be marked beforehand on the bottle.

(8) Label the bottle correctly.

(9) Dilute as recommended for use.

Certain formulae need a special procedure for dissolving. Thus some chemicals may have to be dissolved separately and the solutions mixed in a given order.

In some cases cold water is necessary—e.g., with hardening fixers.

Sodium hydroxide should always be dissolved separately in a little cold water.

With solutions incorporating sulphuric acid use either dilute acid or mix the acid by pouring it into the water (never the other way round) with constant stirring.

All the chemicals should be weighed out before starting to dissolve any of them.

Ingredients used in small quantities need accurate weighing—e.g., developing agents must be weighed to the nearest 0·05 gram or to the nearest grain—bulk chemicals may be weighed more roughly. In some cases powders may be measured by volume in suitably calibrated measures. This applies especially to fixing powders and the like where high accuracy is not required since the chemical is used for a reaction that has to go to completion.

Percentage Solutions. Individual chemicals which keep well in solution may conveniently be stored in percentage solutions. This makes measuring out easier, since no weighing is involved apart from making up the original solution. Thus whole formulae—e.g., certain toners—can be made up in a series of percentage stock solutions of the individual ingredients.

Usually 10 per cent solutions are most practical, or 5 per cent solutions if the chemical is not sufficiently soluble at normal temperatures. Substances required in large amounts—e.g., sodium thiosulphate—may be stored in more concentrated solutions provided the solubility is high enough. The same applies to chemicals which deteriorate in dilute solution—e.g., sodium sulphide.

Percentage solutions are also convenient where very small quantities of a chemical are required. It is, for instance, easier to measure out 5 c.cm. of a 10 per cent potassium bromide solution for a developer than to weigh out accurately 0·5 gram. Where the amounts are very small, the solution may have to be more dilute still (e.g., 1 per cent). L.A.M.

SOUND CAMERA. Cine camera with built-in or connected provision for recording live sound effects or commentary. This may be done on the film actually exposed in the camera (usually carrying a magnetic sound stripe) or on a tape recorder linked with the camera.

Various systems exist for reproducing the sound in synchronism with the film during projection.

See also: *Cine camera; Projection practice; Sound recording; Sound synchronization.*

SOUND RECORDING

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Nowadays all commercial motion pictures include sound either recorded at the time of taking the picture, or added afterwards. Even when there is no speech, the film is projected to the accompaniment of background music or the sounds normally associated with the scene being shown. Amateurs too have begun to use sound increasingly since the introduction of wire and tape recorders. A number of commercial recording studios will also add sound records to amateur films at a reasonable cost.

The principal recording systems are disc, optical, magnetic tape, and magnetic stripe. Of these, the magnetic systems are the best that the amateur can normally use most conveniently.

Disc Recording. Recordings on gramophone discs were used for the earliest sound films in both professional and amateur fields. For the amateur, the technical difficulty of sound-on-disc recording used to be an objection, but nowadays these recordings can always be made at a commercial recording studio. The system of using discs, however, is inflexible and little favoured. For accurate synchronization of sound and picture, mechanical or electrical coupling between turntable and projector is necessary to maintain a rigid speed relationship. Any lengths of film that are cut out because of damage produce loss of synchronization since the equivalent part of the sound record cannot be removed at the same time. The limited playing time of discs is less serious at 33⅓ r.p.m.

RECORDING SYSTEM. The microphone electrical pulsations, after amplification, may be recorded in various ways. A, mechanical recording on discs; the impulses energize vibrations in a cutting stylus. B, optical recording on film; the impulses modulate the strength of a light source which exposes the sound track. C, magnetic recording on tape; the impulses selectively magnetize an iron oxide coating.

Optical Recording. Optical sound recordings are widely used by both professionals and amateurs. In optical recording the sound is recorded photographically as a variable silver deposit along one edge of the film and so synchronization cannot be lost even when sections of the film are removed. Sound reproduction is effected by scanning the track with a narrow slit of light. Variations in the light transmitted by the silver deposit produce corresponding variations in the current delivered by a photocell on to which the light is directed. The current is subsequently amplified to operate a loudspeaker. Films are projected at a speed of 24 frames per second. Since the film moves intermittently through the picture gate, the sound track is scanned some distance farther on after all irregularities in the film motion have been absorbed.

Optical sound film projectors are available for all three narrow film gauges. The quality of 8 mm. optical sound is rather lower, owing to the reduced linear speed of the film through its projector. Recording sound optically is a highly technical process, but commercial studio facilities are available to users of 16 mm.

Magnetic Tape Recording. Magnetic recorders using wire, or preferably magnetically coated tape, provide the cheapest way of adding high-quality sound to amateur films of all gauges. The sounds in this system are recorded by an electro-magnet as varying degrees of magnetization along a tape wound at uniform speed from one reel to another by a capstan. By operating a switch, the recording machine can be made to play back the sound, thus enabling the record to be checked for volume and quality, or even erased and re-recorded.

The technique of magnetic recording is simple; recordings may be checked immediately without any processing and erased and replaced as often as necessary. As the tape is unperforated, however, it is extremely difficult to maintain a rigid speed relationship between tape and film. The accuracy attainable is good enough for music and commentaries, but not usually for synchronizing speech to the lip movement of characters on the screen.

Recorders operating from A.C. mains run at a speed determined primarily by the mains frequency. Approximate synchronization can therefore be assured by adjusting the projector speed to make the bars of a stroboscopic disc on the flywheel or sprocket appear stationary when illuminated by a neon lamp connected to the same mains supply, or by part of the projector beam itself.

Mechanical coupling between the tape recorder and the projector is a more reliable

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

TYPES OF OPTICAL SOUND TRACK. Left: *The variable area track records the sound impulses as a wavy image spreading across the track.* Centre: *Bilateral tracks are more common and are in effect two variable area tracks side by side.* Right: *The variable density track records sound impulses as variations in density along the track.*

method of synchronization. In some cases tape recorder and projector are combined in one, being driven by the same motor.

Slight stretch or shrinkage of the tape and slip between the tape and capstans may still give rise to progressive synchroning errors. To overcome this, some machines use perforated magnetic tape. For constant synchronism magnetic stripe systems are inevitably more reliable.

Magnetic Stripe Recording. Magnetic sound film projectors reproduce sound from a narrow magnetic track applied to one margin of the film. Special attachments with magnetic sound head can also convert existing silent projectors. On 16 mm. films, this magnetic stripe may occupy all or half of the 100 mils (0·100 in.) normally used for the optical sound track. Since the projector is usually designed to reproduce optical sound films as well, either optical or magnetic sound may be reproduced from a film to which a half-track has been applied over an optical track. When striping is used, a balancing stripe is also added to the other margins of the film for even spooling.

To avoid the complications incurred by using single-perforated film in the camera, most amateurs prefer to have 16 mm. edge-striped. In this case a 30-mil track is applied between the perforations and the edge of the film. A similar arrangement is used on 8 mm. films. On 9·5 mm. films the 30-mil stripe is also along the edge of the film and allows the same picture format to be used as for silent projection. Satisfactory recordings of speech can be made on 16 mm. and 9·5 mm. magnetic sound films run at the speed normally used for silent films—i.e., 16 frames per second. But the film must be run at 24 frames per second for quality to compare with that of a good domestic tape recorder. In 8 mm. films, the difference is more pronounced and a speed of 24 frames per second is desirable. With Super-8 mm. film, the greater image spacing and a speed of 18 f.p.s. provide improved sound quality.

As with optical sound films, the sound recording is made some distance ahead of the corresponding picture. This is 28 frames on 16 mm. film, 56 frames on standard 8 mm. film and 18 frames on Super-8 mm. film. The flexibility of editing is thus not as great in the magnetic stripe systems as with a separate tape recording. On the other hand the magnetic sound film is simpler to handle and provides infallible synchronization of picture and sound.

Because of the editing difficulties mentioned already, the magnetic stripe system is less convenient for recording the sound while the film is being taken. With careful rehearsal, however, speech can be post-recorded in synchronism with lip movements of the projected, edited picture film. Once recorded correctly, the speech will always be reproduced in synchronism with the action. With magnetic tape this is not generally possible.

Recording on tape can be done during actual filming, and the record later transferred to optical sound film. Small synchronization errors are then corrected as the sound and

FILM GAUGES AND THEIR SOUND POSSIBILITIES. 1. *Standard 8 mm. film. A 30 mil magnetic stripe can be applied along the perforated edge.* 2. *Super 8 mm. film, with increased pitch and enlarged image area. A 30 mil magnetic stripe or optical sound track is applied along the unperforated edge.* 3. *9.5 mm. magnetic sound film. A 30 mil stripe along the film edge does not detract from the projected picture width even though it encroaches on the exposed picture.* 4. *Double perforated 16 mm. film can have a 30 mil magnetic stripe along one edge outside the perforations. A balancing stripe is always applied along the other edge.* 5. *Single perforated 16 mm. film with 100 mil (full stripe) magnetic track. Again a balancing stripe is applied along the perforated edge.* 6. *A half-stripe of 50 mil width can also be applied over the optical track of 16 mm. optical sound film.*

picture negatives are edited shot by shot. The two negatives are then printed on to a single film to produce a conventional married print, i.e. a positive carrying both optical sound and picture records. D.M.N.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Sound Quality. While the ear remains the best judge of the quality of reproduced sound, there are properties, all of them measurable, by which the performance of different recording and reproducing systems may be compared.

An ideal system would respond equally to sounds in the frequency range 20 to 20,000 cycles per second, which is the region of sensitivity of the human ear. In practice, the very high and very low frequencies tend to be lost, and irregularities often occur in the middle range response. However, variations in level of plus or minus 2 decibels (dB) are unimportant and a response of 30–10,000 c.p.s. ± 2dB would be considered very good for all but the most exacting applications.

The dynamic range of a system also affects the sound quality, that is the range between the faintest and the loudest sound it can handle without distortion. A range of 70dB is very good, and 45dB is adequate for most purposes.

Distortion. Besides failing to reproduce the full frequency and dynamic ranges of sounds, systems can introduce various types of distortion. A non-linear response to changes in signal level has the effect of creating new sound frequencies which interfere with the original sounds to give a harsh, discordant effect.

There are three types:

(1) In harmonic distortion, the spurious tones are direct multiples of the original frequencies, e.g. a note at 1,000 c.p.s. would be accompanied by fainter notes at 2,000, 3,000 c.p.s., etc.

(2) In intermodulation distortion, sum and difference tones are treated by interference between pairs of frequencies, e.g. 1,000 and 1,100 c.p.s. would produce 2,100 or 100 c.p.s., etc.

(3) In transient distortion, sharp changes in signal level are imperfectly followed by some parts of the system. These resonate or "ring" at their sum natural frequency and so blur the sound.

These types of distortion are inherent in valve and transistor amplifiers; disc, tape and film recording; microphones and loudspeakers. They are kept to a minimum by careful design, high quality components and regular maintenance.

Recording Systems Compared. Though disc, optical, magnetic tape and magnetic stripe recording systems are all capable of good quality, the results fall short of the ideal, more especially on amateur grades of equipment.

All these systems involve movement of the recording medium, and they share the disadvantage that a wide frequency response demands a high running speed. Everything else being equal, halving the running speed of a tape machine, for example, reduces the high frequency response by one octave. It is for this reason that the faster speeds of 7½ and 15 ins. per second are preferred for music recording. However, some domestic recorders achieve fairly extended high frequency response at 3¾ and even 1⅞ i.p.s. by incorporating special circuitry and narrow gap record/replay heads.

Books: *How to Add Sound*, by I. M. Neale; *How to Produce Magnetic Sound*, by J. D. Chittock; *Sound Facts and Figures*, by John Borwick; *The All-in-One Tape Recorder Book*, by J. M. Lloyd; *Tape Recording and Reproduction*, by A. A. McWilliams; *The Technique of the Sound Studio*, by A. Nisbett (all London).

SOUND SYNCHRONIZATION. The expense and the difficulty of correcting mistakes in the laying of optical sound tracks for cine films have made amateurs and other low budget film-makers turn to magnetic recording for most purposes. Standard ¼-in. tape may be used, or striped film in which the magnetic coating is applied to the processed film, optical prints sometimes being produced finally for exhibition.

When tape is used, it becomes necessary to adopt some method of keeping the tape and film running speeds in precise synchronization. There are various systems.

Stroboscopic Synchronization. The simplest arrangement is to cause the tape to drive a stroboscopic disc and adjust the speed control on the projector so that the disc pattern remains stationary. The disc is illuminated by the flickering light from the projector lens, and the pattern will appear stationary only when the flicker rate is correct. At 16 frames per second, for example, a 3-blade shutter will produce a flicker rate of 48 per second. Should either machine drift from the nominal speed, the disc pattern will appear to rotate. The correction is always applied to the projector speed, of course, since the pitch of the sound would change if the tape speed were altered. In any case, no fine speed adjustment is normally fitted on tape machines.

Alternatively, a stroboscopic scale is sometimes printed direct on the tape. This has the advantage that the possibility of slip between tape and disc is avoided.

Loop Synchronization. Manual control of the projector speed, while watching a stroboscopic pattern, is operationally difficult and replaced by automatic control in a number of systems.

The loop synch system makes the tape travel round a supplementary drive roller which is operated by a flexible coupling cable from the projector motor. At the same time, the tape is looped round a spring-loaded jockey roller in such a way that synchronous running of tape and film maintains an even tension on the jockey arm. However, any discrepancy in the

STROBOSCOPIC TAPE AND FILM SYNCHRONIZATION. A mirror reflects part of the projection beam on to a stroboscopic disc driven by the tape of the recorder passing over a pulley. As long as the sectors on the stroboscopic disc remain stationary, the projector and tape recorder are running in step. Adjustment of the projector speed to keep in synchronization must be made manually.

running speed will cause the tape loop to tighten or slacken and the resultant movement of the jockey arm activates a variable resistance in series with the projector. The projector speed is then automatically corrected. This loop synch system can be obtained as a separate unit or built into the projector.

Pulse Synchronization. Another automatic system uses a special synchronizing signal recorded as a separate track on the tape, at the time of filming. In one version, pulses are recorded at twice the frame frequency, and compared with the perforation rate on the film during projection. The control track is inseparable from the sound track and can give perfect synchronization or "lip synch". It is even possible to amplify the control signal and use this to drive the projector. The tape speed then controls the projector speed directly.

Perforated tape has also been used for sound synchronization. The sprocket holes correspond with those on narrow-gauge film and so exact synchronization and dual editing can take place.

Striped Film. The need for more or less complicated synchronizing techniques is eliminated in the other type of magnetic recording referred to, namely striped film. Here the film stock, 16, 9·5 or 8 mm., carries a narrow coating of magnetic oxide and is run on special projectors which possess the necessary erase and record/replay heads and amplifiers. The magnetic stripe is laid along the narrow space between the sprocket holes and the edge of the film on 8 mm. stock, and on the edge opposite the holes on 16 mm. film with perforations on one side only. In the latter case it is usual to lay a thin balancing stripe on the unused edge to prevent the film leaning over as it is spooled up. It is also possible to cut a recess in the film during the striping process, into which the magnetic coating is laid, so that the increase in overall thickness is minimized.

In the usual procedure films are sent to be striped, after processing and editing, at prices around 1½d. per foot. But pre-striped film is used with certain sound cameras which incorporate a recording head to permit simultaneous shooting of picture and sound.

Using ordinary cine cameras, location sound recording must be carried out on separate tape machines. If simultaneous recording is done, the noise of the camera will tend to be recorded on the tape unless the microphone can be taken some distance away or the camera is masked or "blimped" effectively. For certain scenes it is possible to make a separate recording before or after filming, particularly if no speech or action requiring accurate synchronization is included.

When the film is returned from striping and loaded on the projector, it is then possible to record commentary, music and other sounds in the same way as with a standard tape recorder. However, attempts to record the sound track while projecting the film, whether on to the stripe or a separate tape, are spoilt by the continuous background noise of the projector fan and motor. A better practice is to record a series of cue sounds only, at points where specific sounds or scripted phrases are to appear. It is then possible to re-run the tape or film in short sections, as often as may be necessary, placing chinagraph pencil marks on the appropriate spots. Then the recording can be

PULSE SYNCHRONIZATION. Left: A contact breaker in the camera closes and opens with the passage of every frame of film. By electrical connection with the tape recorder, this records corresponding pulses on the tape. Right: On transfer to the sound track on the film, the pulses from the tape are "compared" with pulses from the perforations on the sound recording film. This provides a basis for perfect speed matching; if the tape pulses are faster than the film (A) or slower (B), the speed is adjusted until both correspond (C).

made in short takes as each mark reaches the recording head.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Magnetic Film. Yet another method of magnetic recording exists. Magnetic film equipment is available in which a film, carrying a magnetic coating but quite independent from the main film, is used for the sound track or tracks. Greater track widths are possible than with striped film, so that better sound quality is achieved. Widths of up to 0·2 in. are commonly used, which compares very favourably with the 0·029 in. of a 16 mm. edge stripe.

The possibility of laying a number of separate tracks simplifies the building up of complicated sequences of speech, music and sound effects. The British Standard allows for up to six tracks on 35 mm. film and two on 16 mm., but other track arrangements are found, for example to permit stereophonic sound recording.

The independence of magnetic film, besides giving better sound quality, gives greater freedom in editing. But projecting the finished film would involve synchronization problems. The magnetic film is therefore regarded as a means to an end, and the usual practice is to dub the sound eventually to optical film printed alongside the picture. J.Bo.

SOUP. (Slang.) Processing solution; generally restricted to developer, sometimes one of a home-made type.

SOUTH AFRICA. Although the archives are singularly poor in subject matter relating to the origins and progress of photography in South Africa before Union (1910), old family photographs in the possession of private people help to prove that photography was practised in the Cape Province shortly after its introduction to Europe and England in 1839. Sir John F. W. Herschel, an outstanding pioneer of photography, lived in the Cape in 1834; in all probability he was the first photographer in South Africa.

As the country opened up to the north and around the coastline, photographic studios started to operate in numerous towns and villages. Today every large town in South Africa boasts of numbers of professional photographers, whilst almost every dorp (village) has a studio.

In the years following World War II photography has become enormously popular in South Africa. A high standard of living, together with the excellent climate, help to contribute considerably to this trend.

Due to the clarity of the atmosphere on the Highveld (6,000 feet above sea-level), and also at places like Bloemfontein, Yale University has established observatories with high-powered telescopes to photograph the heavens. As a point of interest, the first President of the Cape Town Photographic Society, Dr. David Gill, was Astronomer Royal at the Cape. Together with a foundation member, A. H. Allis, he took the first known photograph of a star.

Industry and Trade. While the applications of photography in South Africa have kept up with the rest of the world, both amongst amateurs and professionals, little progress has been made towards establishing a photographic industry. No sensitized papers or films are made in the country at all and amongst photographic chemicals, only hypo and sodium sulphite are produced.

In post-war years a certain beginning has been made to manufacture photographic accessories, and this business is likely to expand. Cameras, photographic equipment and sensitized materials are not manufactured in the Republic, but there is limited production of such items as developing dishes, slide mounts, projection stands, screens, floodlamps, dry mounting presses and snap albums.

On the other hand, South Africa is a considerable importer of photographic goods. 78,178 movie and still cameras entered the Republic during 1961, total value at port of entry being £610,899. Also imported were unexposed films valued at £539,338, and other photographic equipment to a value of £385,490. Main sources supplying the cameras were: Japan (24·6 per cent), West Germany (18·9 per cent), United Kingdom (11·2 per cent), Hong Kong (10·3 per cent), and the United States (9·3 per cent). Those made in Hong Kong were very low priced models.

Since World War II, import restrictions have been continually eased or tightened. Since 1962 there has been a striking improvement in the economy, and imports of all products have substantially increased.

Leading overseas film manufacturers have lately been establishing their own processing laboratories in South Africa, or arranging for both cine and still films to be handled by existing local laboratories.

Clubs and Societies. Amateur photography is growing rapidly in the Union of South Africa and there are today over 40 clubs and societies devoted to the pursuit of pictorial photography.

In 1954 the Photographic Society of Southern Africa was formed to act as a liaison body for photographers in all parts of the country. The two largest societies in the Union exist in Johannesburg—the Camera Club of Johannesburg (founded in 1934) and the Johannesburg Photographic and Cine Society (founded in 1930). Cape Town Photographic Society is the oldest society, having been established in 1890. There are professional organizations in three out of four of the Provinces—the Transvaal, the Cape, and Natal.

The amateur bodies organize international salons which are well patronized by world photographers. The Cape International Salon, the Witwatersrand International Salon and the

South African Salon all rate highly amongst photographic competitors everywhere. While the vast majority of 8 mm. movie-camera users are casual photographers who enjoy recording holidays and family activities, there are numerous active cine clubs which encourage their members to create really worthwhile films.

Publications. Two monthly photographic magazines are published in South Africa—*Amateur Photography* was founded in 1959, and in January 1964 *Photography and Travel* began publication.

While such places as the Kruger National Park (the largest wild game sanctuary in the world) have been over-photographed, on film South Africa presents the photographer with a veritable paradise, especially because of the unparalleled climate and interesting native peoples. E.E. (C.H.)

SOUTH AMERICA. Photography as a hobby began to be practised in Latin America towards the end of the nineteenth century, mostly among chemists, curious intellectuals and other knowledgeable people who had heard not only of photography, but also of the work of its creators Daguerre, Niépce, Fox-Talbot and others.

History. At Villa San Carlos, Campina, in the Brazilian State of Sao Paulo, a French chemi s named Hércules Florence, who had arrived in Brazil with an expedition in 1824 and had settled there permanently, continued the experiments he had started years earlier in France with Daguerre himself. Florence had in fact managed to build a "machine for the fixation of light" in 1832, seven years before Arago announced the discovery of photography before the French Academy in Paris. Hércules Florence was not alone, however. He performed his experiments with the co-operation of a Brazilian botanist named Joaquim Correo de Mello whose knowledge of bio-chemistry helped him in the preparation of the necessary formulae to develop and fix exposed images of silver film on paper and glass. Today some essays, a few pictures, and other evidence of the work of this more or less unknown father of photography can still be seen on exhibition at the Museo do Patrimônio Histórico e Artistico Nacional do Brazil (Museum of Historical and Artistic Patrimony in Brazil).

Photography also became fashionable among the Argentine upper classes, and well-to-do families who traditionally travelled in Europe would, on their return home, exhibit their skill with the black-box. In 1894 an Argentinian traveller brought back and exhibited in Buenos Aires a strange apparatus called the kinethoscope, which had been created three years earlier by Thomas Alva Edison, and which was a forerunner of cinematography. In 1896, Edison's vivomatograph, or vitascope, was exhibited in a theatre in Buenos Aires for the first time in South America. In 1901 Argentine photographer Eugenio Py introduced the first movie camera into South America.

Industry. Argentina has a greater photographic industry than the other Latin American countries, and its beginnings date back to 1935. Photographic chemicals, paper, films, enlargers and varied accessories are all produced in Argentina. Two internationally known manufacturers produce photographic paper in Brazil, and these same two companies also have representatives and colour processing laboratories in the principal cities of most Latin American countries.

Societies and Clubs. The Sociedad Fotográfica Argentina de Aficionados (Argentine Amateur Photographic Society), was founded in 1889 in Buenos Aires. It was followed by the Academia de Dilectantes Fotógrafos (Academy of Photographic Amateurs) of Buenos Aires of 1903, the Sociedad Alemana de Aficionados (German Society of Amateurs) in 1917, and the photographic section of the Fine Arts Society of Buenos Aires in 1927.

There are at present more than 150 photo and cine clubs in Latin America. Eighty-two of these are in Argentina, and thirty-two in Brazil. Almost all the Argentinian clubs are affiliated with the Federación Argentina de Fotografía (Argentine Federation of Photography). The Buenos Aires Photo Club has more than 2,000 members. The Argentine Photo Club has over 600 amateur members and a further photographic club, the Peña Fotográfica Rosarina (Rosarina Photographic Group) has 400.

The leading club in Brazil is the Foto Cine Clube Bandeirante (Photo-Cine Club Bandeirante), of Sao Paulo, followed by the Associacão Brasileira de Arte Fotográfica (Brazilian Association of Photographic Art), in Rio de Janeiro. Other prominent clubs in South America are the Foto Club Uruguayo (Uruguay Photo Club), of Montevideo; the Foto Club Chile (Chile Photo Club), of Santiago; the Federación Mexicana de Fotografía (Mexican Federation of Photography); and the Photo Club of Cuba at Havana.

In May 1964 the first Convención Americana de Fotografía (American Convention of Photography) was held in Mexico City. All Federations belonging to the Federation Internationale de l'Art Photographique (F.I.A.P.), and the Photographic Society of America, were represented. The Comité Regional Americano F.I.A.P. (Regional American Committee of Photography) was organized, with the purpose of spreading knowledge of the inter-American world of art and photography.

The Argentine Cine Club was established in Buenos Aires in 1932, and from its ranks have emerged some of Argentina's leading professional movie makers.

Publications. The Argentine Amateur Photographic Society, founded in 1889, produced a periodical magazine, the first of its kind in South America. In 1893 the *Revista Fotografica*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Ilustrada del Rio de la Plata (Illustrated Photographic Review of the River Plate) was founded. In 1920 *Foto Revista* (Photo-Review) was founded, and a year later came *Correo Fotográfico* (The Photographic Mail). These were followed by *Foto Magazin* (Photo-Magazine) in 1927, by *Foto* in 1936 and in 1938 by *Fotocamara-Cinecamara* which, in 1963, became *Fotocamera Con Popular Photography*. Of all the above only the last one still circulates throughout Latin America, being published in Buenos Aires as the official organ of the *Federation Internatiinal de l'Art Photographique* (F.I.A.P.) for all Latin American federations. Also worthy of mention are the *Boletin del Foto Club Uruguayo* (Bulletin of the Uruguayan Photo-Club), of Montevideo, and *Foto-Cine* of the Photo-Cine-Club Bandeirante of Sao Paulo, Brazil.

Exhibitions. Annual Salons with world-wide participation are held in Latin America. The leading exhibitions, in order of importance, are those held by the Peña Fotográfica Rosarina, Rosario, Argentina; the Foto Club Buenos Aires; the Foto Club Uruguayo, Montevideo; the Foto Cine Clube Bandeirante, Sao Paulo, Brazil; and the Foto Club of Valparaiso, Chile. Argentina, Brazil, Uruguay and Mexico are the countries whose photographers have most distinguished themselves in International Salons. Professional Associations hold a River Plate Salon for Argentine and Uruguayan photographers annually in Montevideo, Uruguay. A national Salon for Brazilian professionals is held in Rio de Janeiro. H.Y.F.

SPAIN. Photography is widely practised in Spain today, and it has been the subject of popular interest since its inception, but, generally speaking, the emphasis is more on artistic output than on the manufacture of cameras and photographic equipment.

History. The first photograph to be taken in Spain by Daguerre's process was exposed at Barcelona on the 10th November, 1839, at one o'clock in the afternoon.

The official test was carried out in what was then known as Plaza de la Constitución, now Plaza de Palacio. A daguerreotype plate was exposed in the presence of the authorities, men of science and artists, besides a large public.

The experiment was carried out under the auspices of the Academia de Ciencias Físicas y Naturales (the Academy of Physical and Natural Sciences) at the instigation of Dr. Pedro Felipe Monlau and on the initiative of Don Ramon Alabern an artist-engraver and disciple of Daguerre., The cost—1946 reals (486 gold pesetas)—of the apparatus used to take this first photograph was borne by fourteen members of the Academy.

The experiment was entirely successful and lots were drawn for the first daguerreotype produced. The camera can now be seen in the Fabra observatory in Barcelona.

The daguerreotype process was popular for a long period, with the result that today many families treasure portraits of their ancestors which were made in this way.

Until the dry plate appeared, photography was practised only by professionals. Leading in the collodion period was Charles Clifford, photographer to the Queen of Spain and an Englishman by birth. When working conditions became easier as a result of this innovation, many amateurs entered the field. After a hesitant beginning, amateurs soon developed a style of photography of considerable merit, for they were not concerned with making profits but rather to give aesthetic enjoyment.

Among practising photographers in Spain at the end of the nineteenth century the most noteworthy was Dr. Ferrán. He carried out many experiments in photographic chemistry, and prepared photographic papers giving results similar to Fresson paper. Some of Dr. Ferrán's most important work is dealt with in his book, *La Instantaneidad en Fotografía*, (Instantaneous Photography), published in 1879 at Tortosa. This book was produced with the collaboration of I. Paulí. This was the period of the pigment processes, which workers of those times used in an effort to get a better rendering than was possible with the materials then available. Pissaca introduced the gum bichromate process into Spain and had a considerable following.

In 1952 the centenary of the birth of Dr. Ferrán was celebrated and a commemorative postage stamp issued bearing his portrait.

Another figure in photography in the late nineteenth century was Don Antonio Cánovas del Castillo.

In 1939, the Agrupación Fotográfica de Cataluña (the Photographic Society of Catalonia) celebrated the centenary of the first photograph taken in Spain and the Academy of Science offered its full collaboration, including facilities for research. The celebration and its associated functions were confined to practising photographers, the population as a whole being engaged in recovering from the difficult times through which the country had just passed.

Clubs and Societies. Throughout the Iberian peninsula there are flourishing groups, societies and clubs of enthusiasts whose aim is the spreading of technical skill and artistic appreciation.

The largest of these bodies is Agrupación Fotográfica de Cataluña (the Photographic Society of Catalonia), established in 1923, which at present numbers about 1,000 members. Next in importance comes the Real Sociedad Fotográfica de Madrid (the Royal Photographic Society of Madrid), which includes photographers of world repute amongst its members; the Sociedad Fotográfica de Zaragoza (the Photographic Society of Saragossa), likewise with a distinguished member-

ship; and the Sociedad Fotográfica Guipuzcoana (the Photographic Society of Guipuzcoa), representing the best Basque photographic talent. All these societies hold an annual international salon. There are also bodies active in Igualada, Alicante, Alcira, Palma (Majorca), Valencia and Bilbao, in addition to others which cater for specialized interests. Many tourist centres have their own photographic clubs and here members tend to specialize in landscapes and mountain studies.

There are today some 94 photographic clubs in the country. The greatest number of active amateur photographers is in Catalonia, where there are 47 clubs; 20 in Barcelona city alone.

Industry and Trade. There are now three important photographic firms engaged in the manufacture of photographic paper, plates and films which they distribute to Spanish dealers.

The manufacture of cameras and accessories is restricted to the simple popular types. There are a few specially built cameras for professional purposes, but even these are fitted with foreign lenses.

The following are typical figures for imports into Spain for the month of December 1962, as published in The Report of Spanish Exports and Imports: Lenses, prisms, and polarizing materials, 1·7 million pesetas; cameras, 12 million pesetas; electronic flash units, 1·4 million; cinematographic equipment, including projection equipment and accessories, 9 million; still projection equipment, and enlarging and reducing apparatus, 1·7 million; apparatus for photomicrography, cine-micrography, and allied work, 2 million; all X-ray equipment, 5·6 million; apparatus and equipment for cine and still processing laboratories, photo-copying equipment, etc., 2·3 million; and films in roll and sheet, black and white and colour, 26·7 million pesetas.

Exports are on a considerably smaller scale, amounting for the entire above-listed materials to only about 900,000 pesetas. The export of cinematographic equipment, including projection equipment and accessories, still projection equipment and enlarging and reducing apparatus account for 800,000 of the above figure, while X-ray equipment of all kinds accounts for the remainder.

The photographic wholesale and retail trade in Spain is centred around Barcelona, and the majority of agents and representatives of foreign manufacturers are also in this area.

Publications. Since the year 1923 there has appeared in Barcelona a monthly bulletin which is the organ of the Agrupación Fotográfica de Cataluña (Photographic Group of Catalonia), an organization with the largest membership in the area. From 1925 to 1930 a Catalan-language magazine entitled *Art de la llum* (Art of Light) was also published. From 1949, for a period of about four years, the magazine *Sombras* (Shadows) appeared in Madrid. At the present time *A.F. (Arte fotográfica)*, a handsomely produced magazine, regularly publishes contributions from the best-known names in the world of photography. *Afal*, which was originally a bulletin of the Agrupación Fotográfica Almeriense (The Photographic Society of Almeria, a town in southern Spain), and is now a magazine for subscribers only, has in recent years been representative of the latest trends.

Most photographic clubs publish bulletins for their members.

A number of text-books for teaching purposes have been written by the photographer, artist and engraver Francisco Ollé Pinell, of Barcelona. One of the oldest and most complete Spanish manuals is a book by Felipe Picatoste, *Manual de Fotografía*, published at Madrid in 1882. Numerous shorter works on particular items were, however, published some time earlier.

Edicones Omega of Barcelona have produced and published a comprehensive list of technical books on photographic and cinematographic subjects.

Activities. Apart from a few short courses, run either by photographic clubs or by photographic retailers, there is no organized photographic teaching in Spain. Generally speaking, experience is the only way of achieving a mastery of the subject, although some professional workers manage to learn colour processes and techniques abroad, particularly in France and Switzerland.

Active photography is on the increase in Spain, and there are today some 3,000 professionals engaged in one sphere of photography or another on a full-time basis. Furthermore, although Spain does not contribute greatly to the world's photographic trade and scientific development, the country has a large number of workers—both professional and amateur—who are actively engaged in artistic photography.

When portrait photography was first practised, a number of studios were established in the larger Spanish cities, and some of these remain to this day. In 1897 there was in Madrid the Hamer y Menet phototype shop, and at about the same time there were established in Barcelona the Basque engravers Mariezcurrena and Joaristi, who made gravures through the autotype process. From this it may be inferred that at the end of the century the use of photography as a means of graphic communication was well established in Spain. It was, however, mainly the use of the pigment processes by amateurs which made the name of Spain known abroad.

Prominent among those who cultivated these processes, i.e., bromoil, transfer, Fresson, gum bichromate, etc., was José Ortis Exagüe. He made a great impact in international competitions, but his name will be particularly remembered in the history of world photo-

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

graphy for his publication of the Series *España, tipes y trajes* (Spain, Types and Costumes), a work in several volumes.

At the present time one of the most comprehensive photographic archives in Spain is that belonging to Francisco Catalá Roca, a photographer who produces work mainly for publication purposes. A notable contemporary photographer is Leopoldo Pomés, who shows very modern trends, and engages mainly in publicity photography. M.C-B. (J-M.C.)

SPARK PHOTOGRAPHY. Method of securing an image of an object moving at high speed by illuminating it with the instantaneous light of an electric spark. The spark is produced by discharging a condenser across a spark gap on one side of the path of the moving object so that it records a silhouette of the object on a plate on the opposite side. There is no need for a lens in the set-up as the spark when placed at a distance behind the subject gives a reasonably close approximation to parallel lighting and forms a sharp edged shadow.

The first demonstration of spark photography was made by F. Talbot in 1851. He photographed a rapidly revolving wheel.

Ernst Mach at Prague, and Dr. Salcher at Fiume, photographed bullets in flight in 1885–86. In 1892 Sir Charles V. Boys published a detailed description of a number of successful experiments on photographing bullets in flight at higher speeds.

The original circuit in modified form is still in use today. It consists of a spark condenser connected on the one hand to a suitable D.C. supply through a current-limiting resistance and on the other to two spark gaps in series. One gap forms the light source while the other is a triggering gap. The combined resistance of both gaps is just too much for the condenser voltage to break down, but, if the small triggering gap is short circuited, the main condenser immediately discharges across the large gap.

SPARK PHOTOGRAPHY CIRCUIT. A, *main capacitor,* B, *main spark gap.* C, *secondary spark gap.* D, *triggering capacitor.* E, *triggering wires.* F, *projectile being photographed.*

Triggering is achieved by discharging a small condenser across the triggering gap, the passage of the current ionizing the air in the gap and lowering its resistance enough to allow the main spark condenser to discharge. The triggering condenser is connected to its spark gap through a pair of triggering leads which are suspended in the path of the projectile. As the projectile strikes the leads it completes the triggering circuit and initiates the photographic spark. (The small spark from the triggering gap is shielded so that it does not affect the sensitized plate.)

The greater part of the actinic light of this type of sparking between open metal electrodes is in the ultra-violet region of the spectrum and of a wavelength to which ordinary optical glass is practically opaque. So the absence of a lens means that all the actinic light is allowed to fall on the plate and what is visually a relatively feeble spark does in fact provide an adequate exposure even during the short period of the flash.

Even in the early days of spark photography exposures as short as one-millionth of a second were achieved, but today exposures at one-tenth of that speed are normal. By modifying the circuit to give a continuously interrupted spark it is possible to produce a succession of profiles of the subject on a moving film up to as many as 200,000 per second.

For many kinds of high speed photography the open spark has been superseded by the electronic flash discharge tube, but it is still used, notably in ballistics. Modern circuits employ main spark condensers of from 0·1 to 1 microfarad, charged from 5,000 to as much as 10,000 volts. The circuit is usually triggered by a mercury tube or thyratron. F.P.

SPECIFIC GRAVITY. Weight of a volume of any substance compared to the weight of the same volume of water. The specific gravity of a liquid (and hence in many cases the concentration of any dissolved substance) can be measured directly with a hydrometer.

SPECTACLE LENS. Single uncorrected lens, unsuitable for photography where good definition is important, but satisfactory for use as a supplementary lens in conjunction with the camera lens. When used in front of the lens to shorten or lengthen the effective focal length, the camera lens should be stopped well down to restore good definition.

SPECTACLES AND EYESIGHT. People who suffer from defective eyesight often wonder whether wearing spectacles will prevent them from taking up photography. Broadly speak-

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

ing, there is no reason why spectacles should interfere with the use of any other photographic equipment; there are occasions when they are inconvenient, but there is always a satisfactory answer for those who care to look for it.

Viewfinders. Eye-level finders of either optical or frame types do not affect the clarity of the picture seen by the wearer of glasses. But these finders require the eye to be placed as close as possible to the back sight, and people wearing glasses cannot get close enough. The result is that they see a smaller amount of the scene than the viewfinder—and the negative—actually cover.

There are four solutions to the problem:

(1) If the wearer's sight is good enough to give a reasonable impression without the glasses they should be removed for sighting.

(2) A few experiments will show just how much more will appear on the negative than can be seen in the viewfinder with the spectacles in use. With practice, the wearer is able to make a satisfactory estimate of the actual picture area based on the proportion in the finder.

(3) Any good ophthalmic optician will compute and supply a lens to fit to the viewfinder to take the place of the corresponding spectacle lens. The spectacles can then be discarded while taking the photograph. This course is apt to be too expensive for the casual photographer, but it is the best solution for the professional to apply to his regular camera, at least. The cost of such supplementary lenses varies with the optical prescription. Usually the most expensive part of the arrangement is the mounting and fitting of the lens.

(4) Many busy photographers who must wear glasses habitually for all work find that contact lenses worn on the actual eye itself are the ideal solution.

The large "brilliant" type of finder gives no trouble at all to the spectacle wearer since it is viewed from a distance. Users of this type of finder will see the image clearly if they keep on the glasses that they normally wear for distance. There is nothing to be gained by wearing reading glasses with such finders.

Many spectacled photographers have found that the ordinary frame type of finder can be improved by fastening thin cross wires to mark the centre of the front frame. This helps them to look straight through the centre of the frame at the centre of the subject. Without the cross wires, it is easy for the eye to look through the finder at an angle because of the separation between it and the back sight of the finder.

Focusing Screens. The image given by a focusing screen is a real image, and behaves differently from the virtual image given by optical and "brilliant" types of finder. In this case the image has to be focused like a page of print at the same distance. This applies both to normal and reflex focusing screens. And as these screens are viewed from a distance, there is no difficulty about wearing glasses when using them.

People of middle age who experience difficulty in reading at the normal viewing distance of 10 ins. will have the same difficulty in seeing the image on the focusing screen. If they wear the glasses that they normally use for reading they will not be able to see the subject clearly when they take their eyes off the screen because the glasses are unsuitable for both near and distant sight. There are two answers to this trouble—either to wear glasses with bifocal lenses, or frames fitted with half-lenses which allow the wearer to look over the top for viewing distant objects. Anyone who normally wears bifocal lenses anyway will find them satisfactory for both focusing and direct viewing.

Rangefinders. All types of rangefinder can be used by wearers of spectacles without difficulty. In this case the spectacles should be the ones normally worn for distance. About the only trouble likely to be experienced is from confusing light reflections on the lens of the spectacle, but these can be cut out by simply shielding the viewing eye with the hand or the brim of the hat. Some rangefinders are fitted with a focusing eyepiece which can be adjusted for use with or without glasses.

Where the rangefinder and viewfinder are combined, there may be the difficulty already mentioned of getting the eye close enough when spectacles are worn.

Focusing Aids. All the various types of magnifier used as aids for focusing the image on the camera focusing screen or on the enlarging easel can be used by wearers of glasses without inconvenience. People who normally wear glasses for reading only can dispense with them when using a direct optical magnifier type of aid—i.e., one which does not give the magnified image on a ground glass screen. Where the magnified image is projected on to a ground glass viewing screen—e.g., in one type of enlarger focusing aid—then if glasses are normally worn for reading they must be used for focusing.

Removing Glasses. One of the minor problems of the photographer who either removes or changes over glasses when taking photographs is to know what to do with the glasses he is not wearing. The most convenient parking place is the breast pocket, but there is always a risk of their falling out if the photographer bends down, and this pocket is not easy to get at when wearing an overcoat. A satisfactory solution is to hang the spectacles around the neck on a special cord fitted with quick clips at the ends. These spectacles cords can be obtained from most opticians. C.W.G.W.

SPECTRAL ENERGY DISTRIBUTION. Distribution of energy of a light source throughout the spectrum of radiations emitted by that

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

source. Usually shown in the form of a curve which plots energy against wavelength. The spectral energy distribution curve completely specifies the colour quality of an illuminant, and is applicable to light sources with a continuous as well as a discontinuous spectrum. It is thus a more reliable specification than the colour temperature. Two light sources of different spectral energy distribution may give the same colour temperature reading when measured with a colour temperature meter.

See also: *Colour temperature meter; Light sources; Spectrum.*

SPECTRAL SENSITIVITY. Response of a photographic emulsion to each of the separate colours of the spectrum.

Ideally, spectral sensitivity should be defined with reference to a spectrum which contains equal amounts of energy in each colour band. From this absolute spectral sensitivity, the sensitivity distribution towards other light sources can be worked out if the distribution of light of different colours in the source is known.

Spectral sensitivities are as a rule determined by means of a wedge spectrograph. This is an instrument which separates white light into its component rainbow or spectrum colours. The light passes through either a glass prism or a diffraction grating consisting of a piece of glass or a mirror on which very many fine lines have been ruled. The ability of a grating to split up light into its component colours can be demonstrated by looking at a lamp through a piece of very finely woven fabric.

Wedge Spectrogram. In the wedge spectrograph a light absorbing wedge of uniformly increasing density is placed across the spectrum formed by the prism or grating, with the density gradient of the wedge at right angles to the extension of the spectrum. The photographic material under test is placed under the wedge. Under any one colour, therefore, the photographic material receives a range of exposures the intensity being relatively high at the thin end of the wedge and low at its dark end. So the degree of blackening on development at each step along the spectrum indicates the relative

WEDGE SPECTROGRAPH. The light from an illuminated slit is split up into a spectrum and projected through a density wedge on to the material under test, being in contact with the wedge. The result is a wedge spectrogram.

WEDGE SPECTROGRAMS. These show the relative response of the material tested to light of different colours. B, blue-sensitive (e.g., process) materials; slightly sensitive to blue-green as well. O, orthochromatic materials; sensitive to green and yellow as well, but not red. P, panchromatic; sensitivity extended to orange and red. R, panchromatic with increased red sensitivity.

sensitivity of the emulsion to light of that particular colour. If it is completely insensitive, that strip of the material remains clear. If it is sensitive, part at least of the strip under the colour will be blackened.

If now a print is made from the wedge spectrogram on high-contrast paper, all the heavily exposed portions of the spectrogram will appear light in the print, and the weakly exposed parts will appear dark. The separation line between the light and dark portion is a contour line of constant density in the negative. The light portion of the print will be wider at those places where the emulsion is most sensitive to the colour of that part of the spectrum. The wedge spectrogram is thus a very simple method of representing the colour sensitivity of a photographic material.

Correction for Ultra-Violet. The wedge spectrum falls off rapidly towards the ultra-violet because the instruments usually employed hold back ultra-violet rays. So what appears to be a falling off in sensitivity to ultra-violet is not genuine; most materials are evenly sensitive in that region.

Correction for Lighting. Further, the nature of the light used to illuminate the wedge spectrograph must be taken into account.

This should emit equal energies at all wavelengths, or otherwise the contour of the wedge spectrogram will depend on the spectral emis-

sion of the source as well as on the response of the emulsion. This in fact happens with all common light sources, even daylight and fluorescent strip lighting. The light from some sources, such as mercury vapour lamps, is not even approximately uniform in its energy distribution throughout the normal visible spectrum.

For most purposes it is sufficient to be able to assess the spectral sensitivity of a material towards average daylight and tungsten light. Wedge spectra for these two types of lighting are frequently published by manufacturers for the convenience of their customers. W.F.B.

SPECTROGRAPHY

A spectrum is a series of light or other electromagnetic rays sorted out according to wavelength from radiation initially heterogeneous—i.e., which is composed of more than one wavelength. The rays can be of any type—X-rays, ultra-violet, visible, infra-red, etc. If they are in the visible region (4,000–7,000 A) the familiar colours of the spectrum are observed, since each wavelength is associated with a different colour—violet, blue, green, yellow, orange, red.

It is commonly, though quite wrongly, believed that Sir Isaac Newton, by his famous experiment in 1666 with a prism and a beam of sunlight, was the first to see an artificially produced spectrum. In fact, his explanation of how the prism separated the colours latent in white light only clarified a conclusion towards which many others had long been groping. Newton did not, of course, associate the colours he saw with wavelengths, since he rejected the hypothesis that light was a wave motion. This was not established until the beginning of the nineteenth century.

After about 1820 rapid progress was made in the production, measurement and classification of spectra. Fraunhofer, shortly after Young's work, produced the first instrument resembling the modern spectroscope, and with it discovered the lines in the solar spectrum still named after him. Spectroscopy was later developed as an analytical tool by many others, particularly Bunsen, Kirchoff and Angstrom. In 1884, Sir W. N. Hartley recorded spectra photographically, and since then valuable contributions have been made by de Gramont, Kayser, Lundegårdh, Gerlach and others.

Spectrographs and Spectroscopes. Spectra are produced and examined today in a spectrograph or spectroscope. Either instrument consists of a slit to admit the light, a prism or grating to disperse it, and a lens system (which must be exceptionally free from chromatic aberration) to focus an image of the slit. In a spectrograph this is received on a photographic emulsion; in a spectroscope it is examined visually through a telescope.

The slit consists of two parallel metal jaws, machined straight to an accuracy of 1/10,000 in. and separated by an adjustable distance, which is usually in practice a few thousandths of an inch. The lenses form two groups—the collimator receiving the radiation from the slit, and the telescope (in the spectroscope) or focusing lenses (in the spectrograph) focusing it after dispersion.

Only the spectrograph uses photography, but much of what is said here applies to either instrument.

The spectrograph usually employes a 60° prism. For the visible region and the nearer (photographic) infra-red (4,000—approx. 12,000 A) it is made of highly dispersive flint glass. Other materials are used for wavelengths to which glass is opaque. Quartz is used for the ultra-violet (wavelengths less than 4,000 A) and rock salt for the far infra-red (wavelengths over 20,000 A).

Instead of a prism, a diffraction grating may be used. This is an optically flat mirror or transparent plate with a large number (up to 20,000 per centimetre) of fine straight parallel lines engraved on the surface. This produces a spectrum by resolving the light through diffraction and interference.

Which method of dispersion is used depends on circumstances. A prism produces the brightest spectra, and is therefore used with faint sources emitting little radiation (e.g., stars). It has, however, the disadvantage that dispersion is much less for long than for short wavelengths. A grating on the other hand produces a normal spectrum, and also gives a much greater absolute dispersion. (A normal spectrum is one in which a given wavelength difference is represented by the same separation at any wavelength.) But only a small proportion of the incident light is dispersed in a grating spectrum, which is therefore faint.

SPECTROGRAPH. A, slit illuminated by light source to be examined, or by standard light source. B, collimator lens. C, prism. D, focusing lens, projects sharp image of spectrum on to photographic plate or film.

TYPES OF SPECTRA. Top: *Emission line spectrum of a luminous source (e.g. discharge tube).* Centre: *Absorption line spectrum (e.g. the line of the solar spectrum).* Bottom: *Emission band spectrum due to molecular groupings in luminous gases.*

Also, a grating produces in fact several spectra, of increasing faintness as they are of higher order, and these, by overlapping, may lead to confusion and difficulty in interpreting the results.

Types of Spectrum. The spectrum of a luminous source may be of one of three kinds.

(1) Continuous. This contains every possible wavelength within the limits of the spectrum. Over the visible region it therefore appears to the eye as a band of continuously varying colour, and is recorded photographically as an unbroken, though not necessarily uniform, exposed strip. Continuous spectra are emitted by incandescent solids and liquids (e.g., an electric lamp filament, molten iron) and by gases under certain conditions. They are in themselves of little scientific utility, but can be used in the examination of absorption spectra.

(2) Line. Gases made luminous, either by heat or by an electrical discharge, normally emit only certain definite wavelengths, which are characteristic of the elements present. Their spectra therefore consist of a series of lines (usually of varying intensity and irregularly spaced), each line being an image of the slit formed by one wavelength.

(3) Band. These are emitted by molecular groupings in a luminous gas, and consist of groups of lines too closely spaced to be resolved except by a very large dispersion. The Swan bands emitted by a carbon arc in air at 3,600–3,900 A are the best known.

These are all emission spectra. Radiation which has passed through a material absorbing certain wavelengths but not others can be dispersed to form an absorption spectrum. This will be a line spectrum if the absorbing substance is gaseous; the Fraunhofer lines in the solar spectrum represent absorption by the sun's atmosphere from the total radiation emitted by the (much hotter) interior. If the absorbing medium is solid or liquid, the spectra consists of series of bands, which are quite diffuse, and cannot be resolved into constituent lines. The position and intensity of these bands is characteristic of the absorbing substance.

Spectra are also classified in practice according to the wavelength region under investigation, different regions needing different techniques.

(1) Infra-red absorption spectra, in the region 2–15μ (i.e., 20,000–150,000 A), cannot be recorded photographically, as they are outside the region to which emulsions can be sensitized.

(2) Visible and near infra-red (4,000 approx.–14,000 A) emission and absorption spectra are usually recorded photographically in a spectrograph with glass components.

(3) Ultra-violet (2,100–4,000 A) emission and absorption spectra are also recorded photographically, but quartz must be used in place of glass.

(4) Far ultra-violet (approx. 100–2,100 A) emission spectra can also be recorded photographically, but very special and difficult techniques are necessary, as both air and gelatin are opaque in this region.

(5) X-ray "spectra": X-rays cannot be dispersed by any mechanical device, as their wavelength is too short (0·05 to, say, 10 A), but they can be diffracted by crystals, which act as natural gratings by reason of the regular arrangement of the atoms in them, spaced perhaps 1–2 A apart. A photographic record after diffraction shows a series of lines representing different angles of reflection. These are not true spectra at all, since "monochromatic" X-rays of a single wavelength are used. True X-ray spectra can be produced, but they are something quite different.

Spectrum Photography. Visible and ultra-violet spectra are recorded on ordinary photographic plates. An emulsion is chosen which has the maximum sensitivity to the particular wavelength region under investigation. Plates are preferred because of the greater accuracy with which line separations can subsequently be measured. Many spectrographs incorporate a device for printing a wavelength scale beside the spectrum.

In some spectrographs the focal plane is slightly curved; the plates must then be coated on extra thin glass, which can be bent slightly.

The sizes of plates used depend on the dispersion. The smallest laboratory spectrograph takes quarter-plates. A much used size disperses the region 2,000–10,000 A over about 9 ins., and takes plates 4 × 10 ins. Still larger prism spectrographs have three times this dispersion, and take three 4 × 10 ins. plates to cover the same region. Still greater dispersion is used for special purposes; spectra over 100 feet long have been photographed on cinema film with a grating of very high dispersion.

In the 2,000–2,300 A region of the ultra-violet, and still more in the far ultra-violet, ordinary emulsions are at a disadvantage owing to absorption by the gelatin. For the region 1,900–2,300 A the emulsion may be coated with a film of fluorescent oil, but this is messy and the oil must be removed before develop-

ment. Alternatively, special emulsions containing the minimum of gelatin may be used: there are, however, always coarse-grained and inconveniently sensitive to the slightest pressure on the surface. For the far ultra-violet (wavelengths less than about 1,900 A) "emulsions" containing no gelatin at all (Schumann plates) must be used.

CC-0. Vigyan Digital Preservation Foundation, Chandigarh

X-ray "spectra" are recorded on ordinary X-ray film. Film is usually employed because it can be made more sensitive to X-rays by double coating, and because it may have to be bent round a curve of small radius.

Uses. Spectrography in one form or another is used in practically every field of science and industry. The majority of its uses depend however on two basic facts.

The first of these two is that in line-emission spectra the wavelengths present are characteristic of the elements present in the emitting gas, and can be used as an infallible index of their presence. This gives a now essential tool to modern astromony, providing the only means of ascertaining the composition (and indirectly temperature, mass, etc.) of the stars. The photographically recorded displacement of certain spectrum lines from their normal wavelength is in fact the crucial experimental evidence for the modern conception of the universe expanding like a soap bubble.

The second fact basic to spectrographic analysis is that, in an electric arc or spark, the material of the electrodes is present in the discharge as a luminous gas, at a temperature at which practically all compounds are decomposed into their elements. Hence spectrography of an arc or spark discharge between electrodes composed of, or impregnated with, the material under investigation gives a rapid and convenient method of qualitative elementary analysis of a great variety, of materials. The method is far more sensitive than chemical analysis procedures.

Since most of the analytically useful lines lie in the ultra-violet, photographic recording is essential.

This type of analysis can also be made quantitative. For example, an alloy containing 0·1 per cent of magnesium will show more intense magnesium lines in its spectrum than one containing 0·01 per cent. In general, the intensities of the lines of a minor constituent on a developed plate, as measured by a microdensitometer, relative to the intensities of suitably chosen lines of the major constituent, can be used to determine the proportion of the minor constituent present.

This type of quantitative analysis is widely used for rapid production control of materials whose chemical composition is of critical importance—e.g., alloy in the aircraft and machine tool industries.

There are numerous other special uses of emission and absorption spectra, and of X-ray spectra, as an analytical tool in chemistry, physics, medical research and the applied sciences. H.J.Wa.

SPECTRUM. A prism disperses rays of light according to their wavelength. Using an illuminated narrow slit as source, a lens and a prism can separate the different wavelengths or colours present in white light, each wavelength forming a separate image of the slit so making a spectrum.

A rainbow is an imperfect spectrum formed by myriads of raindrops.

The visible rays are only a part of the complete spectrum of so-called electro-magnetic radiation; there are others that cannot be seen but which can be detected by other means. The visible part varies in colour from red to orange, yellow, green, blue, indigo and violet. These colours are physical sensations produced by the action of light on a three colour receptor system in the eye, and the resultant interpretation by the mind.

Wavelength Characteristics. The visible spectrum extends from 4,000 to 7,000 A. and the human eye is most sensitive to the wavelength of 5,500 A. corresponding to yellow-green. The near infra-red is usually regarded as extending to about 15,000 A. The near ultra-violet is regarded for all practical purposes as extending to about 3,000 A. Below 3,500 A. all rays are stopped by ordinary optical glass.

For optical systems below 3,500 A. it is necessary to use components of transparent crystalline quartz.

Below 2,100 A. the rays are absorbed by the gelatin of normal photographic emulsions, and special emulsions are used with no or very little gelatin.

Below 1,900 A. it becomes necessary to remove all traces of water vapour from the system.

Between 2,200 and 3,000 A. the absorption of gelatin and of the silver halide emulsion crystals reduces the depth to which the light can penetrate to a mere surface layer. This reduces the density of the silver deposit that forms the image in the developed emulsion.

The silver halide salts in photographic emulsions absorb light of all wavelengths below 5,000 A. This is the region of their normal sensitivity. But certain light-absorbing dyes will extend the sensitivity to include the whole of the visible spectrum and even part of the infra-red. Fast infra-red emulsions are sensitive only as far as 9,000 A., but some slower emulsions with special sensitization go as far as 14,000 A.

ELECTRO-MAGNETIC WAVES. These waves, travelling through empty space at about 186,000 miles per second, range in wave length from 0·01 Angstrom unit to thousands of kilometres, and in frequency from almost zero to 3 × 10^{20} cycles per second. A, gamma rays, covering 7 octaves. B, X-rays, covering 13 octaves. C, ultra-violet radiations, covering about 4 octaves. D, one octave of visible light and one of near infra-red radiation. All the radiations so far can be recorded photographically. The following ones cannot. E, far infra-red and heat rays. F, Hertzian waves (22 octaves). G, television and radio frequencies. H, audio frequencies.

Equal Energy Spectrum. In the spectrum of white light produced by a prism, the energy is not distributed evenly over the various colours —some colour bands contain more actual light energy than others. This type of spectrum is no use as a basis for studying the way in which the sensitivity of a photographic emulsion or the human eye changes with the colour of the light. What might appear to be high sensitivity to red, for instance, might simply mean that there was more light energy in the red band of the spectrum employed than in the other regions.

The only real basis of comparison is a spectrum in which the energy is distributed evenly over the whole range. Such a spectrum is called an equal energy spectrum; it is the reference for most published colour sensitivity curves for sensitized materials and of similar curves showing the response of the human eye to colour.

Colour sensitivity can be related to an equal energy spectrum without actually producing one. (It would in fact be very difficult to produce at all.) The energy distribution in a given spectrum can be measured accurately in terms of heat energy distribution. Once this is known, it is an easy matter to convert the sensitivity curve it gives into terms of an equal energy spectrum by simple proportion.

For example, if the response ratio of an emulsion to a given spectrum is blue: green: red = 2 : 3 : 5, and the energy is distributed in the test spectrum in the ratio blue : green : red = 1 : 2 : 4, then the sensitivity to an equal energy spectrum would be in the ratio blue : green : red

$$= \frac{2}{1} : \frac{3}{2} : \frac{5}{4} = 2 : 1{\cdot}5 : 1{\cdot}25.$$

These figures show that although the test spectrum gives the sensitivity of the emulsion as being twice as great to red as to green, it is in fact slightly less in terms of an equal energy spectrum. R.B.M.

SPEED FLASH. Another name for electronic flash lighting; the duration of the flash is usually extremely short—often 1/1000 to 1/10,000 second or even less—so this type of flash is particularly suitable for freezing the action of very fast-moving objects provided other lighting present is of a relatively low power to the flash.

See also: *Flash (electronic).*

SPEEDGUN. Popular name for a flash unit and mechanical synchronizer designed to give short instantaneous flash exposures by opening and closing the shutter during the period of peak brilliance of the flash bulb.

This type of flash equipment has been almost completely superseded by internally synchronized shutters and by electronic flash lighting.

See also: *Flash equipment; Flash synchronization.*

SPEED LAMP. Alternative name (current mostly in America) for an electronic flash lamp, which is very useful in photographing fast action.

See also: *Flash (electronic).*

SPEED MIDGET (S.M.). Type of now obsolete flash bulb containing an explosive paste (e.g., zirconium hydride) the combustion of which provides the light. These bulbs have no metal wire filling; they are fired in the usual way by an electrically heated metal filament.

Speed Midget bulbs are characterized by a short firing delay and flash duration (both of the order of 5–10 milliseconds). They are specially suitable for use with shutters having simple X or F-synchronization, as fitted to inexpensive amateur cameras.

See also: *Flash synchronization.*

SPEED OF SENSITIZED MATERIALS

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

The speed of a sensitized material is an expression of its sensitivity to light.

The speed is measured by giving samples of the material a range of exposures under standard conditions of illumination. The amount of blackening produced after carefully controlled development is measured and plotted (usually logarithmically) against the exposure. The speed of the material and much other information can be derived from the resulting graph, which is known as the characteristic curve.

Speed Figures. The data obtained from the characteristic curve have to be translated into a speed figure to state the speed of the material tested. This is done by means of a speed formula, which defines the speed as a function of the exposure at a specific point of the characteristic curve. The choice of such a point has been the subject of a great deal of argument in the past, since various speed systems used to base their criterion on what were to some extent arbitrary considerations.

The aim has been to define for any one photographic material a suitable point on the characteristic curve at which the exposure has a constant relationship to the camera exposure required to produce a satisfactory negative.

Arithmetic and Logarithmic Speeds. Once a point has been chosen on the characteristic curve for speed determination, there are two basic ways of stating the speed. In other words there are two kinds of speed formula.

The simplest type of formula is:

$$\text{Speed} = \text{Constant}/\text{Exposure}$$

The exposure is in this case the sensitometric exposure (time × light intensity) corresponding to the selected reference point on the characteristic curve. Such a speed figure is known as an arithmetic speed, because it is inversely proportional to the exposure. Thus under a given set of circumstances, a material of twice the speed of another material needs half the exposure of the latter to produce the same image density.

The constant in the speed formula is an arbitrary one, chosen to yield speed figures that are convenient to handle. The most straightforward speed formula uses a constant of 1, with the exposure measured in metre-candle-seconds.

An alternative kind of speed formula yields so-called logarithmic speeds:

$$\text{Speed} = C - K \times \log \text{exposure}$$

The speed figures in this case may be characterized by the sign ° (degrees) to distinguish them from arithmetic speeds.

The constants again serve to make the speed figures easy to handle. Usually K is made equal to 10, to yield suitable intervals of single degrees. A ten-fold increase in speed therefore corresponds to an increase of 10°, or a doubling of the speed to approximately 3°. The second constant C simply is made large enough to keep the speed degrees positive.

The logarithmic system yields a more compact range of figures. A scale of logarithmic degrees from 0 to 30° corresponds to an arithmetic speed from 1 to 1,000. Further, since characteristic curves are plotted logarithmically, curve displacements immediately show the speed difference in logarithmic units.

An alternative logarithmic system is based on a similar formula, but using the logarithm to the base 2 of the exposure and a constant with a value of 1 for K. This yields speed degrees where a doubling of the speed corresponds to an increase of 1°. This is even more compact since an arithmetic speed range from 1 to 1/1,000 corresponds to a scale of only 0 to 10°. This kind of speed scale further has the advantage of giving numerical intervals similar to those of exposure values, and it is suitable also for exposure calculations by the APEX system.

MODERN SPEED SYSTEMS

Black-and-White Negative Materials. After a large number of attempts to define speed in a number of different ways, present-day speed systems use a reference point on a characteristic curve based on the minimum exposure to produce a minimum density above a specified fog level. This is the method employed in current A.S.A., B.S. and D.I.N. standards (A.S.A.: PH2.5–1960; B.S. 1380: Part 1: 1962; D.I.N. 4512, Part 1: 1961).

The speed criterion is an exposure required to produce a density of 0·1 above the base plus fog density. The standards also specify the development with the aid of a second reference point on the characteristic curve. This point is 1·30 log exposure units (measured in metre-

SPEED CRITERION FOR ASA, BS AND DIN SPEED SYSTEMS. The speed point A is located at a density level of 0.1 above fog plus base density. The material is developed so that the density of a second point B, 1.3 log E units farther on than A, has a density of 0.8 above that of the point A. Both arithmetic and logarithmic speeds are derived from the exposure corresponding to the point A on the curve.

CC-0. Agamnigam Institute. Digital Preservation Foundation, Chandigarh

candela seconds) to the right of the reference point. This corresponds to an arithmetic exposure ratio of 200 : 1. When the test sample is developed under the specified processing conditions to the right degree, the density interval of the two points must be exactly 0·8.

From this criterion altogether four speed figures can be derived. The first is the B.S. and A.S.A. arithmetic speed, defined by the formula:

$$\text{Speed} = 0{\cdot}8/E,$$

where E is the exposure corresponding to the point on the characteristic curve at which the density is 0·1 above the base plus fog density under the processing conditions specified above.

The second speed figure is a logarithmic one derived from the equation:

$$\text{Speed (log base 2)} = \log_2 (0{\cdot}24/E)$$

where E is again the same exposure point.

The two speeds are thus related by the equation:

$$\text{Speed (log base 2)} = \log_2 (0{\cdot}3 \times \text{arith. speed}) = 3{\cdot}3 \log_{10}(0{\cdot}3 \times \text{arith. speed})$$

The above arithmetical and logarithmic figures are those used in the B.S. and A.S.A. systems, and the actual figures are rounded off to yield values rising in steps of cube-root—of —2 (1, 1·25, 1·6, 2, 2·5, etc.). The logarithmic figures are rounded off to give intervals of 0·5°. Arithmetic and logarithmic figures are frequently quoted together: e.g. 100/5°.

The logarithmic base 2 figure is also intended to be the basis of a forthcoming international standard.

The third speed figure is a logarithmic speed to the base 10, derived from the formula:

$$\text{Speed} = 10 \times \log (1/E) = -10 \log_{10}E.$$

This gives intervals where a doubling of the speed corresponds to an increase of 3 steps in the speed numbers. The actual values obtained are again rounded off to give whole numbers. This speed figure is used in the German D.I.N. standard.

A fourth logarithmic figure is similar to the DIN number, but ten steps higher throughout. This is specified in the British Standard No. B.S.1380: Part 1: 1962 as an obsolescent scale, taken over from an earlier British Standard.

The speed figures obtained in these four ways are directly inter-convertible, and are compared in the table above.

Reversal Colour Films. A criterion based on a minimum exposure point is by itself inapplicable to a reversal film, since in a transparency the whole tone range is important. The American Standard PH2.21–1961 and the British Standard B.S. 1380: Part 2: 1963 therefore use as the reference point on the characteristic curve a mean exposure derived from a minimum and a maximum exposure point. The maximum exposure point is one that yields a minimum density of 0·2 above base plus fog density on the colour film; the minimum point is derived by the exposure level at which the shoulder of the curve begins (where the change in the slope reverses its sign) or at a density point 2·0 above the minimum density, whichever is the lower. The mean exposure used as the reference point is the square root of the product of this minimum and maximum exposure level.

CURRENT SPEED FIGURES COMPARED

A.S.A. B.S. Arith.	A.S.A. B.S. log.	D.I.N.	B.S. log. (Obsolescent)	Relative exposure needed	
3,200	10°	36	46°	1	Special extreme speed

SPEED CRITERION FOR REVERSAL COLOUR EMULSIONS. An exposure point A for highlights is located at a level 0.2 above the minimum density. From this point a straight line is drawn tangent to the D log E curve to establish a shadow point B at a density not more than 2.0 above minimum density. A mean exposure, being the square root of the product $E_A \times E_B$ (corresponding to exposures of points A and B) is the basis of the speed figure.

An arithmetic and a logarithmic speed can be derived from this exposure by the following:

CC-0. Academy of Gandhian Studies. Digital Preservation Foundation, Chandigarh

$$\text{Arithmetic speed} = 8/E$$
$$\text{Log (base 2) speed} = \log_2(2{\cdot}4/E)$$

In both cases E is the mean exposure point mentioned above. Since this corresponds to a lower exposure (assumed to be on the average by a factor of 10) than the minimum exposure point, the constant in the above speed formulae is ten times larger than for black-and-white negative film speeds.

The speed figures obtained take the same form as for black-and-white negative materials; e.g. 100/5°.

The standards for reversal colour film speeds specify the illumination and exposure procedure, but no processing; the latter is assumed to be carried out in accordance with the film manufacturer's recommendations.

This method of rating colour film speeds is not as arbitrary as it appears at first sight, but was worked out to give a sensitometric method that gave speed figures agreeing closely with empirical speed estimations. The latter were based on the verdicts of large numbers of observers judging colour transparencies exposed to different degrees in the camera.

EARLIER SPEED SYSTEMS

While a reference exposure point based on a minimum density above fog is one of the most obvious systems, early photographic scientists also employed a number of alternative criteria. Some of these were based on minimum exposures to produce a threshold density, on the inertia point, on practical comparative speed tests, on a minimum exposure needed for a negative that would yield a good print, on a point at which the gradient of the characteristic curve reaches a specified value, and so on.

All the earlier systems applied to black-and-white negative materials only. Speeds for reversal and colour materials were expressed as equivalent values, indicating that by setting the quoted speed on an exposure meter or using it in exposure tables, correctly exposed results could normally be expected.

Safety Factors. Some of the earlier film speed ratings, especially the original A.S.A. and B.S. index numbers, were said to include a safety factor. This safety factor is not strictly speaking a feature of the film speed standard, but of exposure meter calibration standards with which these film speed ratings were to be used. The safety factor simply means that the film speed, measured under such a system, and used with an exposure meter, would yield an exposure recommendation about 2½ times higher than a minimum correct exposure. According to more modern views on exposure, such a safety factor is unnecessary and in many cases undesirable. Since it was not practical to revise the standards for exposure meters (which would make all existing meters obsolete) the current A.S.A. and B.S. speed ratings eliminated the safety factor by specifying a higher speed rating for a given exposure criterion. For this reason many films rated according to older speed systems appear to be slower than according to the modern ones.

Scheiner Speed. One of the earliest methods was originated by Professor Julius Scheiner. This criterion is based on the exposure necessary to produce a just visible density above fog.

The speed formula of Scheiner speeds is:

$$°\text{Sch.} = C - 10 \log \text{exposure}$$

Modern high-speed negative materials are reckoned to have European Scheiner ratings between 30° and 38°, colour films between 22° and 34°.

Although this system was used for many years it tends to give misleading exposure recommendations when the characteristic curve of the material has an abnormally extended toe. This raises appreciable difficulties in defining a just visible density. A further drawback is the fact that Professor Scheiner's original specifications for making the sensitometric tests are obsolete, and were based on the use of virtually colour-blind emulsions. The adoption, in the early days of photography, of the Scheiner criterion on the Continent caused what has become known as the "Scheiner inflation". This led to a continuous increase in published speed figures without any real increase in sensitivity.

A number of different Scheiner scales were in existence, differing only in the value of the constant C in the speed formula. The best known was the European Scheiner speed; American Scheiner degrees are about 5° lower. So-called Weston Scheiner degrees are similar numerically to American Scheiner, but are in fact based on Weston speed.

H. & D. Speed. This system was introduced by Hurter and Driffield and utilizes the inertia of the characteristic curve given by the exposure at a point where an extension of the straight-line portion of the characteristic curve cuts the fog level line. The speed formula is:

$$\text{Speed} = 34/\text{exposure}$$

where the exposure is the value in metre-candle-seconds at the inertia point of the material. The speed figures are thus arithmetic.

H. & D. speeds are now virtually obsolete (except in photomechanical applications), partly because modern materials and developers do not behave in the same way with respect to inertia points as the plates used by Hurter and Driffield.

Older DIN Speeds. This criterion for the original German DIN standard was fundamentally the same as for the current one, but specified a development method to bring out the maximum possible film speed. This does not correspond to general photographic practice, and the original DIN speeds do not therefore

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

H. & D. SPEED CRITERION. Characteristic curves are drawn for a range of development times in a bromide-free developer, and the inertia point determined where the straight-line portions cut the fog level line.

indicate truly how the materials behaved in normal use.

The speed formula, based on the exposure necessary to produce a density of 0·1 above fog, is logarithmic:

$$\text{Speed} = C - \log \text{exposure}$$

This gave decimal numbers for the speed figures, which were therefore expressed as fractions of 10. A speed of 1·3 was written as 13/10° DIN. The constant C was chosen so as to give a speed number in the numerator of the fraction about 10° lower than the then current Scheiner figures.

The DIN system was the first attempt at large-scale standardization of a speed criterion, and is in its present form widely used in Germany and on the European Continent. The artificial maximum-speed development specification however prevented international adoption. In 1958 the DIN standard was therefore revised to meet these objections, by specifying a more normal development procedure similar to that used today.

The constant C was changed to give numerically similar DIN speeds under the new conditions to the original DIN degrees. At the same time the /10° suffix was dropped, and DIN speeds were expressed as simple degrees, e.g. 15° DIN.

When DIN speed ratings were further revised in 1961 to fall into step with the current A.S.A. and B.S. systems, the degree sign was also eliminated, so that 15° DIN became 15 DIN.

Weston and Other Meter Speeds. To provide reliable speed figures for use with certain makes of exposure meter, some meter manufacturers concerned issued their own film speed systems. These were based not on any sensitometric calculations, but on practical tests and experiments.

The best known of the meter speed systems was the Weston scale which provides arithmetic numbers. Logarithmic Weston speeds (also known as Weston Scheiner) can be obtained for certain purposes by the formula:

$$\text{Log Speed} = 10 \log \text{Weston} + 9$$

Current Weston exposure meters have abandoned the Weston scale and use A.S.A./B.S. arithmetical speed numbers.

A number of other meter speed systems have been published, either numerically similar to Weston speeds, or utilizing lettered speed groups, etc. Practically all these were dropped on the introduction of the B.S. and A.S.A. speed numbers.

GOST Figures. This system is in use in Soviet Russia and a number of East European countries. In principle the criterion is similar (but not identical) with the D.I.N. standard, and several different kinds of development are specified for different types of material. The speed figures are expressed in an arithmetic series, and are fairly similar quantitatively to the A.S.A. and B.S. arithmetic index.

Original A.S.A. and B.S. Index. At a time when existing film speed criteria were based on a variety of not easily reconciled assumptions about speed, attempts were made to establish an empirical system based on judgement of print quality, and to construct a sensitometric method to give a corresponding speed value. With this end in view, Jones and Nelson have correlated various speed criteria with the minimum exposure necessary to produce excellent prints as judged by a large number of observers. They found that the best correlation was given by a criterion which defined the speed by the exposure necessary to reach a point on the characteristic curve where the slope was 0·3 of the average gradient of the characteristic curve between that point and a point where the corresponding exposure was

EARLY B.S.I. AND A.S.A. SPEEDS. The slope of the curve at M is 0·3 times the slope MA, where BC is equal to a log exposure range of 1·5. M is then the A.S.A. and B.S.I. speed point.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

thirty times as great. The 0·3 criterion where $\bar{G}$ (gee-bar) stands for average gradient, was adopted by both the American and British Standard organizations.

From this criterion several types of speed figure or exposure index were derived.

(1) The speed of a material was defined as 1/E, where E was the exposure measured in metre-candle-seconds (mcs), to reach the speed criterion. Speed figures carried the prefix "0": speed 500 = 0500. The Exposure Index was one-quarter of the speed and was the number recommended for use with exposure aids (125).

(2) The other type of speed figure was the logarithmic exposure index, characterized by the ° sign (degree) given by the formula 5–10 log E. In the above example, the speed would be 32°.

Conversion Tables. The older speed systems are not strictly comparable since they are all based on different properties of the characteristic curve. But the curves of modern photographic materials are sufficiently similar to allow the figures to be compared approximately. The figures in the table below may be regarded as a rough and ready guide.

COMPARISON OF OLDER SPEED SYSTEMS

SPECIAL MATERIALS

The speed systems discussed so far apply to continuous-tone black-and-white negative materials—that is, to emulsions intended for ordinary picture taking. Moreover, the speeds refer to daylight. Artificial light speeds—where given by manufacturers—are empirical equivalents.

There is a current standard for reversal colour films (still, not cine) but none for either black-and-white reversal films or for negative colour films.

Existing speed systems further do not cover emulsions for radiography, aerial photography, cinematography, or infra-red work; nor do they include graphic arts and process materials. Some of the latter are, in fact, too slow and too variable in speed to be measured to fit into the scales of the speed systems employed for general camera materials.

Logically infra-red, aerial and motion-picture films could be tested under similar conditions to black-and-white still films. Speeds quoted for such materials would however have to be based on different processing conditions applicable to these materials, and also on possibly different standards of evaluation to meet the requirements under which such materials are used. The Russian GOST system tries to allow for this in part, by specifying different degrees of development and different developers for, for instance, aerial films and motion picture films.

Graphic arts and process films are not amenable to speed measurement by any of these methods, owing to the shape of their characteristic curve. Moreover, since such materials are used under a variety of widely different conditions, any speed figure would have comparatively little meaning.

Printing Materials. There is no standard method of testing or expressing the speed of papers and other printing materials. Generally there is no need for such speed ratings, because printing and enlarging exposures depend on the exposing light and other characteristics of the printing or enlarging set-up and are determined by exposure tests.

Some manufacturers give relative speeds of their different types of printing material. These are neither standardized nor consistent from one manufacturer to another, and do not compare with the speeds of different makes. They do, however, give a basis for exposure tests when changing from one type of paper to another with the same printing equipment. The following is a very approximate comparison.

COMPARATIVE SPEEDS OF PRINTING MATERIALS

Material	*Relative speed*
Contact papers and contact lantern plates ...	1
Slow chlorobromide papers	10–20
Fast chlorobromide papers and warm-tone lantern plates	50–100
Bromide papers and bromide lantern plates, positive films	100–500
(High-speed pan film or plate ... around	100,000)

SPHERICAL ABERRATION. One of the aberrations of lenses. It causes general loss of sharpness in the image. In some cases it may be introduced intentionally, as is done with soft focus lenses.

See also: *Aberrations of lenses.*

SPILL RINGS. Concentric rings of sheet metal mounted in front of narrow-angle lamp reflectors to cut out the spreading direct rays of light from the light source.

SPIRIT PHOTOGRAPHY. Spirit photography is claimed to have been accidentally discovered by William Mumler of Boston, Mass., in 1861. Mumler, it is said, focused the lens of his camera on a vacant chair with the object of taking a self-portrait. His story was that after uncapping the lens he immediately jumped into position on the chair and sat there for a few seconds. On developing the plate he found an additional image of a little girl sitting on his knee. Mumler claimed that he recognized this photograph as being that of a young relative who had died some twelve years previously. He continued his experiments and stated that the extra figures of his plates became so frequent as to be embarrassing. In this way Mumler became the first professional spirit photographer.

Early Frauds. Mumler claimed that the extra figures were actual objective photographs of spirit forms present in the studio; invisible to the naked eye but capable of being recorded by the camera. For a while, Mumler's theory was accepted until it was found that photographs of living people appeared on his plates. He was accused of fraud and died in poverty in 1884. His results show every evidence of having been produced by double exposure.

Mumler was imitated by many others (usually professional photographers) both in this country and the U.S.A. Almost without exception, these self-styled spirit photographers were convicted of fraud. In many instances they actually confessed to trickery. In 1906, the London *Daily Mail* appointed a committee to investigate the claims in regard to spirit photography, but for lack of the human material with which to experiment the venture produced no results.

The Crewe Circle. It was about this time (1908) that a group of spiritualists, who went by the name of the Crewe Circle, began to attract attention. These people conducted operations from a private house at Crewe. They claimed to be non-professional and had no fixed fees, but the sitters were expected to make a financial contribution towards "expenses". This circle attracted world-wide attention and many investigators made the pilgrimage to the little house at Crewe.

In actual fact, the Crewe circle was founded upon a Mr. William Hope who was undoubtedly a schizophrenic. On one side of his character was an alert, witty and patently honest North-countryman, whilst on the other hand there was the bogus medium who used prayers and psalm-singing as a cloak for his fraudulent operations.

Hope described his work as "psychic photography" and he and his followers maintained that the results produced were not actually photographs of spirits but were spirit-produced photographs.

For the extraneous forms on these so-called psychic photographs they used the name of "extras".

By the simple method of employing several cameras simultaneously, independent investigators easily proved that there was no question of objective spirit forms since the "extra" appeared on one of the plates only—and that, the one under Hope's control.

The usual procedure was for a sitter to take along an unopened box of plates which he loaded in Hope's darkroom. He then sat for Hope to take his portrait after which they both retired to the darkroom again to develop the plates. One of these usually showed an "extra". In every observed instance where there was an "extra" on the plate Hope either handled, or could have handled, the plate before exposure.

Although many of the sitters for whom "extras" appeared were unknown to Hope, it was significant that out of over a thousand cases investigated, where the extra was a recognizable likeness of someone known to the sitter, it was an exact copy of some existing photograph or illustration.

At first Hope appears to have produced his "extras" by substituting his own doctored plates for the sitter's. After he was caught at this he elaborated new methods. One of these appears to have involved the use of luminous paint. A positive transparency backed with calcium sulphide and pressed into contact with an unexposed plate will leave an "extra" negative image in addition to anything else that may be recorded there before or after.

Psychographs. Written messages obtained by the Crewe Circle on photographic plates held between the hands and not exposed in the camera were named "psychographs".

These psychographs were of somewhat rare occurrence and, apart from the actual handwriting, they provided little of evidential value. Many of them were in Hope's handwriting and contained grammatical and spelling mistakes such as he was in the habit of making. Careful investigation proved that in no single instance had Hope produced a message in facsimile handwriting from persons with whom he had not corresponded during their lifetime.

Examination showed that he had built up his psychographs by cutting out words and phrases from these letters and filling in the blanks in his own hand. There were obvious attempts to conceal the cut edges, and Hope's

own style was only too evident in the forged writing.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Hope's fraudulent methods were eventually confirmed by one of his greatest friends and supporters, and when he died in 1932 the Crewe Circle died with him.

The late Sir Arthur Conan Doyle was a keen supporter of Hope and his works. It has now been proved that he and others of his time were sadly lacking in the critical faculty desirable for analysing the claims of such people as Hope. The truth is that Sir Arthur was so thoroughly honest himself that he could not believe it possible that trickery was rampant in what, to him, was a very sacred subject.

Investigations. There have been many other variations on the above themes, but in every case impartial investigation has revealed evidence of substituted plates and double exposure. Examination of the wrappings of the plates taken to the seance by the sitter in many cases shows signs of opening and re-sealing. With one medium, the substituted "extra" bearing plates were found to have one roughened edge. This indicated the top of the plate so that it could be inserted in the dark slide the right way for the "extra" to appear upright with respect to the image of the sitter.

Plates that have previously been exposed to give an "extra" can usually be detected by examining the margins; the clean rebate almost always has a doubled edge because the plate never lies in exactly the same position in the holder for the two exposures.

Finally, the Society for Psychical Research have made it clear, in a report covering some hundreds of claims, that so far their investigators have never seen any alleged "spirit" photograph that could not have been produced by natural means.

The publication of this report may explain why spirit photography has now gone out of fashion in Great Britain. Elsewhere, however, claims still continue to be made. F.B.

SPLICING

Method of joining length of cine film or magnetic tape during editing or to repair breaks. A good splice should be at least as strong as the original material and it should run through the equipment without any noticeable hitch. A splice can be made by hand or by using a more or less automatic splicing jig. The latter makes a quicker and more accurate job.

SPLICING CINE FILM. Top: Before joining, the film ends are trimmed together, and the emulsion scraped off one of them. This permits the film cement to weld the two strips together. Upper centre: Standard square splice. Lower centre: Diagonal splice. Bottom: Cross-section of two films joined together by a black patch of film. No scraping is necessary as only the shiny sides are in contact.

Splicing Cine Film. When joining lengths of cine film it is not enough to make a strong and accurately lined-up joint; the spacing of the sprocket holes must be maintained from one side of the splice to the other.

There are three ways of splicing: the usual way is to cut the ends of the film square and join them by lapping one over the other; 16 mm. films are sometimes cut diagonally to give a long splice that does not weaken the film as much as the normal splice; the ends may be cut off square, butted together, and joined by cementing a strip of black film or adhesive tape across the emulsion-free side of the join.

When the splice is made by lapping one end of the film over the other, the emulsion is first scraped away from the coated side of one end. The clear edge is then brushed over with film cement and the other end of the film is quickly brought into register and pressed down on it, uncoated side down. It is essential for the two lengths of film to be in line and for the sprocket holes to coincide. Negative films—subjected to less strain—normally have a narrower splice.

A more modern method of making the splice involves scraping the two ends of the film at an angle. The two bevelled edges are then joined up, so that the join itself is not thicker than the film. This method is particularly suitable for frame-line splicing, where the joint does not encroach on the picture area of the frame on either side of it.

Splicer. The lengths of film to be joined may be held in line with drawing pins. The operation can then be carried out by scraping off the

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

USING A SPLICER. Top left: *Trim film end, place on left pins, emulsion up.* Top right: *Hold down film by cover plate and scrape emulsion off exposed strip.* Bottom left: *Place end of other film on upper registration pins, emulsion down, and trim flush with pressure plate. Apply cement to scraped portion.* Bottom right: *Lower the pressure plate, bringing the two films together, and clamp down.*

emulsion with a razor blade, applying cement and pressing the ends together by hand.

After some practice it is possible to turn out a good splice in this way in a minute or so, but where there is a lot of splicing to be done there is something to be said for using a special splicer. This consists of a bedplate with pegs for registering the sprocket holes. There are two hinged flaps which can be folded down on to the film when it is in position on the pegs.

One piece of film is trimmed and held in position on the bed by one flap so that a narrow strip the width of the splice projects beyond the flap. The emulsion is scraped away from this strip with a safety razor blade, or a special scraper incorporated in the splicer.

The other half of the film is placed on the open flap and trimmed square with the edge. A smear of cement is wiped over the prepared end of the first piece of film and the second is immediately pressed into contact with it, shiny side down, by folding down the open flap. A spring clip locks the second flap and keeps pressure on the splice until it is set.

Film Cements. There are various proprietary film cements available. In all of them the action is the same; the cement softens the film base as soon as it is applied, and a few seconds later it is absorbed by the base. The two halves of the splice must be pressed together while the base is still in the soft condition. Properly made a splice should be stronger than the film.

The basis of most cements for nitrate film (now obsolete) is amyl acetate and for acetate film, acetic acid.

A suitable formula for both nitrate and acetate films is:—

Acetone	8 parts
Ether	10 parts
Acetic acid, glacial	1 part

To this is added about 1 part of 16 mm. film (with the emulsion removed) per 3–4 ounces (100 c.cm.) of solvent. More may be added to make a thicker cement.

Butt Splicing. A modern method of film splicing uses transparent self-adhesive tape. There the film ends are cut square and abutted end to end A piece of self-adhesive tape is then stuck over the join on both sides. Splices for this purpose have provision for accurate lining up of the film ends and for trimming them; they further perforate the tape once it is in position so that the film runs smoothly through the projector.

The tape should preferably be a polyester tape for maximum strength. Ordinary adhesive cellulose tapes are liable to stretch and to creep, making the join inaccurate.

Where the spliced films carry an optical sound track it is best to paint the join over with black dye (so-called blooping ink) to avoid the otherwise obvious click as the splice goes through the sound head.

SPLICING TAPE. 1. *Place the two tape ends in the channel of the splicing block, overlapping across the cutting line.* 2. *Cut through both layers of tape with a sharp razor blade at the appropriate angle.* 3. *Remove the short end cut off at the top.* 4. *Apply a piece of splicing tape across the join and trim off along the edges.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Splicing Magnetic Tape. There are two ways of splicing magnetic tape: (1) by making a butt joint (where the ends join but do not overlap) with splicing tape, and (2) by making a lap joint with jointing compound. Broadly speaking jointing tape is used for a temporary joint and compound for a permanent joint.

(1) Joining with splicing tape. In this method the ends of the tape are first trimmed across at an angle of 45° with a razor blade or scissors. They are then brought together so that there is no gap between the ends and secured by pressing a short length of special adhesive splicing tape over the join on the polished—not the coated—side of the tape. Ordinary adhesive tape is again unsuitable because the adhesive is too soft and tends to squeeze out of the joint. When it does this it makes a sticky place on the tape. This has two unpleasant effects: it makes the tape jerk as it goes through the sound channel (causing a sudden drop in the pitch of the sound) and it usually transfers itself to the capstan or pressure roller and sets up wow or flutter.

The 45° cut ensures that the splice goes past the sound head with the minimum of noticeable noise.

(2) Joining with jointing compound. This method is basically similar to the one used for splicing cine film. The ends of the tape may be cut across at 45° or 90°. About ⅛ in. of the magnetic oxide coating is removed from one end of the tape by wetting it with tape jointing compound and immediately wiping it off. The clear end of the tape is wet a second time with compound and the other end is pressed on to it so that the polished back of the tape lies over the prepared surface. The joint is kept under slight pressure for 10 to 15 seconds, after which it can be used normally. As magnetic tape may have an acetate, PVC or mylar base it is essential to use the correct type of compound or the two ends of the tape will not weld together.

TAPE SLICER. The two tape ends are placed on the channel in the centre of the block and held down by the two clamps. The block carries grooves for cutting the tape at the appropriate angle and for slicing off surplus joining tape from the edges.

Magnetic Tape Splicers. To hold the ends of tape in position for splicing an editing block is generally used. This has a channel to take the two tape ends and may further include a pair of clamps to hold them in position. A 45-degree groove acts as a guide for a razor blade to cut the tape ends at the correct angle before sticking the joining tape on top of them. Further grooves may aid in trimming the tape away at the sides of the join.

The editing block may be plastic or a non-ferrous metal such as bronze (iron might interfere with the magnetization of the tape).

F.P. (L.A.M.)

Books: *How to Edit*, by H. Baddeley (London); *The Tape Editing Guide*, by Ronald Hack (London).

SPOOL. Core or bobbin carrying the film in cameras and film projectors. There is a wide variety of shapes and sizes.

Spools for Still Cameras. Spools for roll film cameras are standardized in size and thickness for the different film widths. Some spools have wooden cores with metal ends, but currently the tendency is to make the spools completely of metal or, in a few cases, plastic.

The spool core carries a slit to take the end of the backing paper, while the spool ends contain keyed holes to engage the peg of the transport shaft in the camera.

Spools of 35 mm. cameras usually form part of the film cassette, being contained inside a light-tight shell. There the spool itself is made of metal or plastic and fitted with a knob at one end which protrudes from the cassette. The other end of the spool has a hole with a suitable fitting inside to engage the shaft of the rewind knob.

The core of a 35 mm. spool carries a slit or similar device to anchor the end of the film.

Most 33 mm. cameras also have a take-up spool on which the film is wound up during exposure. Usually this take-up spool is built into the camera and turned by the film transport through a friction drive. Some cameras, however, have removable take-up spools. The anchoring of the film to the take-up spool must permit easy disengagement after the film has been rewound into the cassette.

Spools for Cine Cameras and Projectors. The film for 8 and 16 mm. cameras (other than magazine loading types) is sold on 25, 50, or 100 feet spools. These again consist of a metal core and flat disc-type metal ends. The latter are considerably larger than the core to hold the greater lengths of film involved.

Projector spools take still greater lengths of film (some up to 2,000 feet) and the metal ends (or cheeks in this case) are usually only frames. They are made of metal (or sometimes plastic) and often carry a gauge for estimating the amount of film wound up by measuring the thickness from the core outwards.

SPORT

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Taking photographs at sporting and athletic events of any kind usually means taking pictures of action so that movement does not show in the final print. The principal attraction about this branch of photography is that it can present a sharp and permanent picture of a split second of exciting movement which the eye normally misses or sees as a fleeting blur.

Movement can be arrested in this way by the use of a shutter speed so short that the amount of blur caused is too small for the eye to detect.

EQUIPMENT AND TECHNIQUE

The equipment need for sports photography will depend on the type of sport photographed, although simple equipment is satisfactory in many cases. But whatever the equipment, the technique must be studied carefully.

Camera. Any camera—even a simple box—will turn out satisfactory sports pictures so long as it is used intelligently within its own limitations. Pictures of the instant before the start of a sprint race, or long-distance views of a football match, are well within the scope of the box camera, but close shots of the runners in motion or of a scrimmage in the goal mouth call for a camera with a very much better lens and shutter than are found on a cheap camera.

The two cameras most used for outdoor sports pictures are the press and the 35 mm. Newspaper cameramen used to prefer the press camera because they found the relatively large plates or sheet film easier to process and print quickly than the 35 mm. film, but in recent years the 35 mm. camera, especially the single-lens reflex, has gained great popularity among press men.

35 mm. cameras are used more for occasions when the full load of 36 exposures is likely to be needed and where more time can be given to processing the negatives—e.g., when making pictures for weekly or monthly publications.

A camera for serious sports photography must have a shutter with a maximum speed of at least 1/500 second.

Lens. A long-focus lens—or even a telephoto—has distinct advantages for certain sports, but it is generally better to work with a normal angle lens close to the subject wherever this is possible. The telephoto lens gives the subject a flat, unpleasing perspective and tends to dwarf the subject against its background. But for subjects like the Boat Race, batsmen in action, and aquatic sports, a telephoto lens is essential.

No matter what type of lens is used it must have an aperture of *f* 4·5 or larger so that really fast shutter speeds may be used even in poor light.

Viewfinder. An open frame or wire viewfinder is best for sports photography. This type gives a direct view of the subject as a whole with the part included within the picture area clearly marked by the finder frame. The view in the normal direct vision optical finder does not extend beyond the picture area and this makes it difficult to find a fast moving subject.

The Albada type of direct vision optical finder is excellent for sports photography as it combines the compactness of the optical finder with an open-frame view of the subject.

Waist-level reflex viewfinders and focusing screens are unsuitable because they reverse the image from right to left and the camera has to be swung in the opposite direction to the movement of the image—an action that calls for considerable practice.

A number of reflex cameras have eye-level reflex finders with a penta prism or similar optical system. This shows an upright and right-way-round image, and does not suffer from the drawback mentioned.

Filters. Filters are not much used in sports photography because they demand an increase in exposure—i.e., either a slower shutter speed or a wider lens aperture, both undesirable. But a pale yellow filter is sometimes useful for giving some tone to the sky when it forms the background to a low angle shot.

Sensitized Materials. It is almost always advisable to use the fastest available panchromatic material because, in this class of photography, speed is more important than anything else.

Exposure. The exposure is dictated by the strength of the light as in any other kind of photography, but the shutter speed that must be used to arrest the movement of the subject depends upon how far the subject is from the camera and its speed and direction of movement. This in turn limits the smallest lens aperture that can be used, and hence the

IRREGULAR MOTION. The legs and arms of a jumper need a high shutter speed, though his body will come out sharp at a slower speed. The whole of him is practically motionless for an instant at the top of the jump—the dead point.

maximum depth of field at the photographer's disposal.

CC-0. Agamnigmi Digital Preservation Foundation, Chandigarh

Lighting. Most sports photographs are taken on in daylight. But there are some sporting events—e.g., boxing, fencing, wrestling—which take place indoors. For these sports synchronized flash lighting—either flash bulb or electronic flash—is used where permitted, otherwise the photographer has to make the best of the existing artificial lighting.

NOTES ON TAKING

The technique for photographing sports varies. The following summarizes the points to watch in most sports.

Association Football. The best position is on one of the goal lines, using shutter speeds up to 1/1000 second. Alternatively, shoot from among the spectators, about 20 yards from the corner flag, looking into the goal mouth. Use a long focus lens except in the goal area.

Badminton. The best position is at either end of the net, covering both courts. Use a normal angle lens, synchro flash lighting with shutter speeds of at least 1/500 second.

Billiards and Snooker. The best position is at the top end of the table. A lens of *f* 1·5. or *f* 2·0. will take pictures at 1/15 to 1/30 second by normal table lighting; otherwise use flash and a small aperture to give maximum depth of field. There is no point in exposing during the action; slow shutter speeds at static moments in the game are quite suitable.

Bowls. Needs only normal technique with practically any type of camera. The light is usually good and movement never very fast. Speeds of 1/60 to 1/125 second are fast enough.

Boxing. The best positions are at the ringside, so that the camera can shoot through the ropes, or in the gallery with a long focus lens. A wide aperture lens is needed to keep shutter speeds down to 1/250 to 1/500 second by normal ring lighting (flash is not normally permitted during a bout but may be used before and after).

Cricket. The best position is somewhere above ground level, so that the camera looks down on the players against a background of the pitch. A long focus lens is essential. The shutter speeds for players in action—up to 1/500 second.

Curling. This is very similar to bowls, but played on ice. The movements of players are also similar and the same technique can therefore be used. Shutter speeds of 1/60 to 1/125 second are normally suitable.

Diving. The best position is one where the sun is behind or to the side of the camera and where divers can be caught against the sky. Use a normal angle lens and a yellow filter. A shutter speed of 1/250 to 1/500 second should be used.

Fencing. It is possible to work with slow shutter speeds provided the right moment is chosen for the exposure. Concentrate on one contestant and catch the various stances, or try to get both from an elevated viewpoint. The light is often poor, so flash may be necessary. For dead points in the action, use a shutter speed of 1/50 second, varying up to 1/500 second for fast action.

Field Events. Pictures of jumping, vaulting, throwing the javelin, discus, etc., call more for accurate timing than special equipment. In good weather, most events can be handled with a shutter speed of 1/250 second. Fairly close positions are best where a normal angle lens will give a reasonable size of the image.

Foot Races. The best position, if it can be obtained, is where there is a high oblique or head-on view of the sprinters approaching the tape. The shutter speed must be fast enough to arrest the movement of limbs—e.g., up to 1/1000 second during sprints.

Golf. Players object to the click of the shutter while concentrating on a stroke, so expose after. Otherwise use normal equipment and technique. Shutter speeds for players in action —up to 1/250 second.

Greyhound Racing. The best position is near the track, but as a rule there is no alternative to working from among the spectators with a long focus lens. The lighting of tracks after dark is too dim for high speed photography and flash is not permitted. Action shots of dogs call for speeds up to 1/1000 second.

Hockey. The best position is in range of the "striking circle". Fast movement of sticks and ball need shutter speeds up to 1/500 second.

Horse Racing. The best position is at start and finishing lines, and on the course with a view of a corner where horses will bunch together. Pictures in the paddock are also worth going after. Shutter speeds—up to 1/250 second in the paddock and 1/500 during a race. Use normal and long focus lenses and fastest pan film.

Ice Hockey. The best positions are above ground level—at either end of the gallery, midway between goal and corner. Lighting is best in the smaller rinks where roof and lights are lower. Use normal or long focus lenses. Shutter speeds of 1/150 second can be used at *f* 2 with fastest pan films.

Lawn Tennis. The best positions are at the centre of the side or at the end. Doubles are best photographed from a stand or other elevation. The best method is to set the focusing for one particular zone and shoot when action comes into it. Use a normal focus lens and fast films. Shutter speeds: up to 1/1000 second.

Motor Racing. The best position is a high viewpoint looking down on the width of the track. When shooting from the side, the background should be plain and clear of spectators or somewhat out of focus. Try to include more than one car in each shot. Use a normal angle lens. Shutter speeds—1/250 to 1/500 second, or slower if the camera is carefully "swung" with the moving vehicle. This method, when used with skill, will make the background appear blurred, giving a very realistic impression of speed.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Rowing. The best position is on the river bank as close to the boats as possible, or shooting at an oblique angle from a bridge. The peaks of movement are as the oars enter and leave the water. Use a normal or long focus lens with fast film. Shutter speeds—1/250 to 1/500 second.

Rugby. The best positions are along the side-lines as there is not the same interest in the goal as in Association Football. The greatest interest lies in shots taken with the camera set at medium zone focus; then wait until action takes place in the zone. Close range shots need 1/500 second and distant general views 1/250 second.

Skating. The best position for races out of doors is on the outside of the track where skaters can be taken head-on, the camera being pre-focused on a particular spot and the exposure made as skaters reach it. Indoor shots of figure skating should be taken from a position dictated by placing of the spotlights—preferably after a preview to decide the when and where.

Shutter speeds should be 1/250 second and, for races, up to 1/500 second.

Ski-ing. The best position is often where skiers appear against the light—preferably about 20 feet below a turn, to catch the snow with back lighting. Jumps are best shot from the side and well below the take-off. Shutter speeds—up to 1/500 second.

Speedway Racing. The best position is looking obliquely at the first bend. Beware of flying cinders as riders draw level. Shutter speeds—1/250 to 1/500 second.

Steeplechasing. The best position is in front or at the side of the jump, preferably "open ditch" and water jump. Use a low shooting angle. Shutter speeds—1/250 to 1/500 second, or faster if lighting conditions permit.

Swimming Races. The best position is at the start to catch the swimmers diving into the water; elsewhere there is little interest. Photographs of water sports are often improved by the use of a polarizing screen, which cuts out a lot of the distracting reflections from the surface of the water, though this also destroys atmosphere.

For actual swimming, shutter speeds up to 1/250 seconds should be used; for the start of the race, use 1/500 second.

Table Tennis. The best position for taking doubles is a high viewpoint to prevent one player masking the other. Singles may be taken from a lower viewpoint, concentrating on one player.

Practically the only way of making action shots is to use synchronized speed flash with the lens stopped down to at least *f* 8 to give the necessary depth of field.

Wrestling. As for boxing, except that the action is slower and shutter speeds of 1/125 to 1/250 second at *f* 2 can be used with the existing lighting.

Yachting. Normal technique and equipment are all that is needed. As the light is usually very good, a medium speed film with its finer grain and higher contrast can be used with a filter to make the white sails stand out against the sky. Shutter speeds of 1/125 to 1/250 second are fast enough for most subjects. L.V.

SPOTLIGHT. A spotlight combines a compact source lamp, a reflector, and a lens, in a single unit. It is designed to give a uniform light that can be varied at will from a narrow, sharply defined beam to a broad diverging cone.

The concentration of the beam is varied by moving the lamp and reflector together towards or away from the lens. In all such arrangements the lamp is fixed at the focus of the reflector and the two are subsequently adjusted as a single unit.

The duty of the reflector in this combination is to reflect the rays of light back through the plane of the lamp filament. By doing this it enables both the glowing filament and its reflection to be focused at the same time by the lens.

So the arrangement always consists of a spherical mirror with the lamp filament at its focal point—i.e., at the centre of curvature of the mirror.

The focal length of the lens in a spotlight is kept short so that the lamp works close to the lens and throws the maximum amount of direct light on to it. An ordinary type of lens with a suitably short focal length would be unduly

SPOTLIGHT EFFICIENCY. Intensity across illuminated field of a Fresnel spotlight with various lamp positions. A, lamp back from condenser (spot position). B, mid-way position. C, lamp near condenser for full flood effect. The vertical centre line of the graph represents a position directly in front of the lamp.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

SPOTLIGHT SYSTEMS. Upper group: *When a lamp is placed at a distance from a condenser equal to its focal length, the beam is substantially parallel (actually slightly divergent because of the finite size of the source). When the lamp is brought nearer to the condenser, the beam diverges, and when it is moved away from the condenser, the beam converges.* Lower group: *For a given diameter, a short focus condenser takes in a greater angle of light from the lamp, and therefore is more efficient than one of longer focal length.*

thick and heavy, so a special optical arrangement known as a Fresnel lens is used instead.

The back of the lens is flat, and the front, instead of being a continuous curve, is built up in concentric rings, each being a section of a curved surface. The final effect gives a field of illumination that is actually more evenly distributed than the field of the equivalent, but much heavier, plano-convex lens of the same focal length.

A Fresnel lens is relatively easy to correct for optical aberrations and it withstands heat better than a "solid" lens, since the reduced thickness at all points is less likely to set up strains.

Spotlights are designed for use with projection-type filament lamps, carbon arcs, and high pressure mercury vapour lamps.

The front of the spotlight generally carries a pair of guides to take such accessories as colour and diffusion screens and cut-out metal masks which can be focused by a separate lens mounted in front to project a sharp-edged area of light.

Beam restricting devices. Beam restricting devices—e.g., snoots and barn doors—may also be attached to the front of a spotlight where the spot must be confined to a particular area of the subject.

A slide projector also makes a useful spotlamp, especially for small-scale set-ups.

Integral Reflector Spotlights. Photoflood lamps are also available with an integral reflector which concentrates the light into a narrow beam similar to that of a studio spotlight. While the light cannot be focused like that of the normal studio spot, the cost of the lamp is much lower and it is an acceptable alternative that is attractive to the amateur worker.

Quartz-iodine lamps also exist with permanently built-in reflectors. The whole unit then resembles a sealed-beam motor car headlamp.

Consumption and light output of these lamps are the same as those of the equivalent photoflood—e.g. a typical lamp has a consumption of 500 watts and a life of 25 hours when run off the 240 volt supply.

Another type of integral reflector lamp is manufactured with a narrow beam for illuminating very small areas. These lamps have a concentrated filament run at a relatively high current to approximate as closely as possible to a point source. The inner surface of the glass behind the filament is silvered and shaped to reflect a pencil beam which covers an area of about two inches in diameter at a distance of about 12 ins. The filament runs at a low voltage —12 or 24 volts—and must be connected to the mains through a transformer. Lamps of this type are used in the commercial photography of manufactured goods to provide local highlights. They are also useful sources of illumination in laboratory photographic and photomicrographic work. F.P.

SPOTS. Black or white spots due to faulty processing attract attention out of all proportion to their size and should never be allowed to appear on a finished print.

The spots may come from the negative or they may be only on the print. They may be either dark spots on a light area, or light spots on a dark area. They are best avoided by careful technique, but once they are there, they can be removed—or at least rendered unobtrusive—by any of the normal techniques of spotting or retouching.

Spots on the Negative. Dark spots on the negative (which produce light spots on the print), may be caused by particles of dust or solid matter picked up during processing, or they may be specks of developed silver or chemical impurity.

Loose dust particles should always be wiped off the back and front of the negative immediately before printing. One gentle wipe is all

that should be given; rubbing builds up static and makes the dust cling. Again an anti-static brush is used).

Specks of developed silver in the emulsion mean that pin-points of light have leaked through to the material either through a punctured blind (in a focal plane shutter) or a defective dark slide in a plate holder.

Dark spots on the negative, of course, leave light patches on the print.

Occasionally, air bubbles or particles of dust cling to the surface of the emulsion in the fixing bath. These may prevent the emulsion from fixing, and subsequently the undissolved silver bromide turns dark or black on exposure to light.

The commonest cause of light spots on the negative is the air bubbles that cling to the surface of the emulsion during development. At this stage the bubbles prevent the developer from acting on the emulsion and when the undeveloped silver bromide is removed during fixing, it leaves a clear patch.

The remedy is either to brush the surface of the emulsion lightly as soon as it is under the developer, or to agitate the solution well. A few drops of wetting agent in the developer will greatly reduce the tendency of bubbles to form.

Light spots on the negative may also be caused by dust on the plate at the time of exposure. The particles shield the sensitive surface from the action of light and leave a clear spot of unexposed emulsion on development. They may also be formed when specks of active chemical fall on the surface of the emulsion when it is left to dry. Certain chemicals—e.g., acid fixer—will bleach out the silver image and leave a clear patch. The remedy is scrupulous care in handling chemicals in the darkroom, and the frequent use of a vacuum cleaner throughout the room.

Light spots can also be the result of physical damage from such causes as particles of grit in the washing water, and contact with the corner of another plate or with the curled-back end of a length of film. The trouble can be avoided by care in handling the material during processing—particularly when developing more than one plate at a time, or when developing a roll film by the see-saw method.

Clear spots on the negative make black spots on the print.

Spots on the Print. Here also the spots may be lighter or darker than the surrounding image. Most of the causes of spots on negatives apply equally to prints.

Those light spots on the print which are not the result of dark spots on the negative, may be caused by dust particles on the glass surfaces of a negative carrier, paper holder, or printing frame. Although the use of glassless negative carriers eliminates several surfaces which could gather dust, particles can still cling to the surface of the negative or paper.

Light spots on the print are fairly easy to deal with by spotting them out with dye or pigment. Dark spots, however, have to be removed by either bleaching or knifing which are more difficult techniques. For this reason it is always better to cover a clear spot on the negative with a spot of dye or pigment even if in the process the spot is enlarged. It will then print out as a light spot which is comparatively easy to get rid of. F.P.

See also: *Dust; Faults.*
Book: *Retouching*, by O. R. Croy (London).

SPOTTING. Technique of filling in pinholes on the negative or white spots on the print with an opaque medium.

The term is also applied to marking lantern slides with white paper spots. This is done to indicate the correct way round for loading slides into a projector.

See also: *Retouching; Spots.*

SPREAD FUNCTION. Density distribution of the actual image of a point of light. Due to the scattering of light within the film layer during exposure, and also to chemical effects during development, the photographic image of such a point of light is spread out along the film layer. This "blurred" density distribution is termed the spread function. A lens system may also be characterized by a spread function, which in this case represents the image degradations due to diffraction and aberrations.

See also: *Information in the image.*

SPROCKET HOLES. Regular perforations made along one or both edges or down the middle of a cinematograph or still camera film so that it can be advanced from frame to frame by the teeth of a sprocket or claw.

See also: *Cine film; Perforations.*

SPY CAMERA. Essentially a small camera disguised to look like something else so that it can be used for taking photographs without attracting attention. Cameras of this type began to appear soon after the invention of the dry plate about 1880—they would have been impracticable with the earlier wet plate process.

For many years designers exercised their imagination to cloak cameras in increasingly improbable disguises. There was one magazine camera, taking up to 24, 4 × 4 cm. plates, which was made to look like a book. The lens looked out of the spine of the book and the shutter was released by pulling a "bookmark".

Other cameras were built into top hats, field glass cases, and even ladies' handbags. A miniature camera, that looked like a watch when closed, had a body built up of concentric telescopic sleeves, like a collapsible drinking cup. Some spy cameras were concealed in articles of dress. There was a cravat camera, a midget that peeped through the button-hole of the jacket, and one that strapped around the

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

waist and took photographs through a lens which was disguised as a waistcoat button.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Most of these cameras used magazines of miniature plates, and incorporated ingenious (but rarely dependable) mechanisms for moving a fresh plate into position after exposure. Some types used miniature films—e.g., the walking stick handle camera, which used 16 mm. film and took 20 exposure 15 × 20 mm.

The vogue for spy cameras was ended by the arrival of the precision miniature and sub-miniature instruments. These are small enough to conceal—often in the palm of the hand—and can be used so unobtrusively that there is no point in trying to disguise them.

The last real "spy" camera was a post-war wrist-watch camera, a sub-miniature taking 8 exposures on a circular flat film through a 12 mm. *f* 2·5 lens.

See also: *Camera history; Ultra-miniature camera*

SQUEEGEE. Device for pressing the water out of wet prints and squeezing them into contact with the glazing sheet. The simplest type of squeegee consists of a strip of rubber about ¼ in. thick and 6 to 8 ins. long, mounted in a wooden holder. The most popular type consists of a rubber-faced roller running in plain or ball bearings in a frame fitted with a handle. An efficient squeegee is an essential in the carbro and a number of other control printing processes.

STABILIZATION. Alternative process to normal fixing which may be used when prints are required in a hurry and absolute permanence is not essential. The unused silver halides are converted into more or less stable colourless compounds by the action of suitable agents. After stabilization, there is no need to wash the print. The process thus amounts to one of incomplete fixation.

A 2-3 per cent solution of thiourea acidified with a few drops of acetic acid will stabilize the emulsion in 2–3 minutes. The commonest stabilizing agent, however, is sodium thiosulphate (hypo) itself. A print or negative immersed in the following solution is stabilized in 30 seconds; i.e., the silver thiosulphate complexes formed in that time are reasonably stable, though complete fixation would take longer.

Sodium sulphite, anhydrous	265 grains	15 grams
Sodium bisulphite	2 ounces	50 grams
Hypo	4–24 ounces	100–600 grams
Water to make	40 ounces	1,000 c.cm.

A 30 to 35 per cent solution of potassium or ammonium thiocyanate will also stabilize unused silver halides.

A 5 per cent acid stop bath should be used after development and the stability of the print can be improved by a 10 seconds rinse in water or in a 5 per cent borax solution.

Stabilization techniques are widely used in photo copying systems and also in rapid access photography. In both these fields a ready processed image is usually required in a hurry, but not for long-term filing. If the image is required for archival storage, stabilization can be followed—after the print or negative has served its immediate purposes—by normal fixing in a conventional fixing bath. After that the stability of the image will be equal to one fixed in the normal way.

If conventional fixing is not possible until a long time after stabilization, some interaction between the stabilized image and the emulsion support may take place, affecting the future permanence of the image. Document copying papers with a fine grain image are particularly sensitive to this, especially if the stabilizer solution was strongly acid. The deterioration of a stabilized film image is very much less, and films can be refixed quite a long time after the original stabilization without noticeable disadvantage.

See also: *Rapid processing.*

STAGE PHOTOGRAPHY. Photographs of scenes from shows are regularly used by amateur and professional companies for publicity and front-of-the-house display. Many photographers concentrate on this type of work and take their pictures at special photo-call rehearsals. In addition, modern wide aperture lenses and high speed sensitized materials have made photographs possible from the auditorium during the actual performance.

See also: *Theatre.*

STAINED GLASS WINDOWS. The most suitable time for photographing stained glass windows is on a bright day when the sun is not shining directly into the glass; otherwise the result will be patchy with poor colour rendering. Diffused lighting from a background of pale clouds picks out the pattern very effectively with an even tone range all over.

Equipment. Often a memorial window is so awkwardly situated that it is not easy to include it without tilting the camera, except when the latter has a generous rising front or swing back. For this reason, the most satisfactory apparatus, containing all the requisite movements, is the field or stand camera.

A lens hood must be used to prevent stray light from the other windows reaching the lens, and a rigid tripod is also necessary for time exposures. As an additional precaution it is advisable to fit rubber feet to the tripod legs to provide a reliable grip on the smooth surface of stone church floors. A foundation of coconut matting would be an ideal substitute for rubber feet.

The tripod must also have a strong ball and socket head for tilting the camera or levelling it when on an uneven surface.

Medium speed panchromatic film is best because of its fine grain.

CC-0. Agamnigay Digital Preservation Foundation, Chandigarh

Exposure and Development. A reliable meter is an advantage since the exposure may be anything from a fraction of a second to around one minute. The exact exposure time will depend upon the principal colours in the window. The design containing a greater proportion of dark browns and deep blues, for example, is going to take a much longer time to register on the film than a window consisting mainly of weak colours.

Stained glass windows can generally be well rendered by measuring or calculating the exposure necessary to photograph them from the outside, and giving from 6 to 10 times this exposure inside. This rather generous exposure followed by development curtailed one-third the normal time for general interiors, will give excellent negatives.

Sometimes a subject is a combination of beautiful stonework and design in the glass. This calls for a particularly careful assessment of the exposure in order to secure details of both in one negative: the exposure must be long enough to record the stonework but not so long as to lose detail in the glass.

If the subject is the whole of the church interior, it will be difficult to register detail in the building as well as the windows. An exposure calculated for the shadows will overexpose the windows. This problem may be solved by making two separate exposures on the same plate; between these two exposures the camera must not be moved and the photographer will need the complete co-operation of the custodians of the building. The first exposure is calculated for the window under suitable daylight conditions. The lens is then capped until after darkness when the second exposure is made by flashlight or by the normal illumination with which the building is provided.

Filters. The use of filters requires special care. To render the design of the glass in its correct colour values, a light-green filter will give good results. But occasionally it will be necessary to secure contrast too. If there is much red or green in the design a contrast filter which will darken one colour and lighten another may be helpful (e.g., a red filter would lighten the reds and darken the greens).

Colour. With reversal colour, material balanced for daylight should be used, and the picture should be taken, if possible, against a neutral grey sky—not a blue one. T.P.F.

See also: *Against the light; Architecture; Lighting the subject; Light sources in the picture; Negatives from colour slides; Paintings and drawings.*

STAINING DEVELOPER. Developer in which the oxidation products of the developing agent stain the gelatin. This occurs in particular with developers incorporating pyrogallol or pyrocatechin, but not containing sufficient sodium sulphite to counteract the staining.

The stain is put to practical use in certain maximum energy developers, notably pyro-amidol, where it helps to provide an adequate printing density in the shadows of the negative. Since the stain also appears strongly in the highlights, the contrast of such negatives is greatly increased. The stain in this case is yellow and thus of comparatively high actinic, even if low visual, density.

The production of a stain during development, which is proportional to the density of the developed silver image, was also the basis of the earliest colour development processes. R. Fischer in 1913 used a pyro developer to produce a yellow stain image, and indoxyl carboxylic acid and thioindoxyl carboxylic respectively for blue and red stain images. The effect of the modern colour coupling developers is similar, though the mechanism is different.

STAINS. Photographic images may show a variety of stains which usually arise during processing and are due to unwanted side reactions in the developer and fixer solutions.

Most stains are some kind of chemical fog caused by deposition of silver from the developer or fixer, oxidation products of the developer, or toning action in exhausted or too warm fixers.

Other causes are insufficient rinsing between development and fixing, prints sticking together in the fixing bath, premature exposure to white light before the process of development has stopped, and not enough attention to cleanliness in working.

Stains may also arise during various toning operations, and are then usually due to incomplete fixing; traces of silver halide remaining in the emulsion become toned in the same way as the image proper.

A number of photographic chemicals—in particular such developers as pyro and amidol—will stain the fingers. But it is never necessary for the fingers to be immersed in such solutions; there is scarcely any process that cannot be carried out with dry hands from start to finish, simply by planning the routine to avoid wetting the fingers and by using tongs to handle the material being processed.

The staining effect of any solution can be minimized by dipping the fingers into clean water before putting them into the solution. This dilutes the chemical contacting the skin.

Pyro and many other developers will not stain the fingers if, after coming into contact with the developer, they are rinsed, dipped for a second or two in an acid fixing bath, and then rinsed again and dried. This treatment will also remove permanganate stains.

Most stains on the fingers disappear if they are rubbed with a crystal of citric acid or a slice of lemon.

An alternative to some of the above methods is to wear rubber gloves. Barrier creams may also be effective.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

STALE MATERIALS. When stored in dry, cool conditions, most sensitized materials will keep for years without suffering, but in a damp or warm place they tend to deteriorate.

If materials have been badly stored, fog and mottle will generally result. However, it is possible to effect some remedy if this happens. The methods of restoring such materials described below must all be carried out in the darkroom by the appropriate safelight for the material concerned.

Plates and Films. Negative materials that have deteriorated through being carelessly stored or which have been accidentally fogged—e.g., by being exposed to an unsafe light in the darkroom—may be treated so that they will once again yield a fog-free image. In the process, however, the sensitivity is reduced up to one-tenth of the original speed.

The materials should be soaked for five minutes in either of the following baths:

(1)	Chromic acid	60 grains	3·5 grams
	Potassium bromide	120 grains	7 grams
	Water to make	20 ounces	500 c.cm.
(2)	Potassium bichromate	70 grains	4 grams
	Hydrochloric acid	½ ounce	12 c.cm.
	Water to make	20 ounces	500 c.cm.

After removal from the bath the material must be thoroughly washed and then left to dry in the dark.

Fast and medium speed plates that have deteriorated or been accidentally fogged can be turned into excellent slow-speed transparency material by soaking for ten minutes or so in a bath prepared as follows:

Potassium bromide	105 grains	6 grams
Potassium iodide	14 grains	·75 grams
Hot water, only sufficient to dissolve		

to this add the following:

Hydrochloric acid	½ ounce	12 grams
Potassium bichromate	105 grains	6 grams
Water to make	20 ounces	500 c.cm.

This converts the latent silver image into undevelopable silver halide again.

After treatment, the plates are thoroughly washed and dried in the dark. The reduction in speed may be twenty times or more depending on the material.

Bromide Paper. If there is any reason to suspect that a package of paper has deteriorated in store, it is always worth trying the effect of one of the proprietary developer improvers before throwing the paper away. These additives delay fog formation, improve the blacks and keep the whites clean. They will often give an image of acceptable quality from old paper that would otherwise give a grey and muddy print.

If the paper has gone beyond this treatment, it will sometimes respond to a bath in a weak acidified solution of potassium permanganate, for example:

Potassium permanganate	4 grains	0·2 grams
Sulphuric acid, 10 per cent	½ ounce	12·5 c.cm.
Water to make	20 ounces	500 c.cm.

After soaking for a minute in this bath the paper is transferred to a clearing bath of 2 per cent (anhydrous) sodium sulphite for a further minute. It may then be rinsed and exposed wet, or dried and used later.

The same treatment will often save paper that has become fogged from any other cause. F.P.

STAMPS. Postage stamps are often photographed for record, comparison, catalogues, etc. The operation may call for specialized technical treatment of the stamps.

See also: *Philately.*

STAND. Substantial and adjustable support for the studio type of camera; generally applied also to any type of camera support from an ordinary tripod to a heavy duty stand with full pan and tilt adjustments.

See also: *Camera supports.*

STANDARD CANDLE. Used to be a candle manufactured to a standard specification (burning spermacetti wax at a rate of 120 grains per hour). It has long been obsolete, but a candle power defined in terms of such a candle is used as the basic reference unit of intensity for all light measurements in photometry and sensitometry.

See also: *Light units.*

STANDARDIZATION IN PHOTOGRAPHY

The organized standardization of parts used and manufactured in industry was first introduced by Great Britain in 1901, and since then it has been adopted on an increasing scale all over the world. A great number of photographic products, equipment and techniques has already been standardized, and new items are regularly added to the list.

The principle of standardization, in general, involves the examination of the appropriate aspect of the material or article in question by representatives of the chief manufacturers and users or consumers concerned. In a particular case it may be only one aspect—e.g., dimensions, or purity of the product—that may be considered worthy of standardization. Eventually a range of sizes or limits of composition, as the case may be, will be determined and circulated to, or published for the use of, the appropriate section of the community.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The main advantage of standardization is the economy of labour, plant and materials achieved in manufacture by reducing a wide variety of sizes or compositions of a product to the smallest number sufficient to cover all its applications. Standardization results in a simplification of stocks in the distributive channels and a lower price to the consumer. While manufacturer, designer and customer are all intended to treat such standards as a guide, they are always free to adopt their own individual standards except in special circumstances where standards have statutory effect for reasons of public safety, health, etc.

Authorities. In the United Kingdom the British Standards Institution is the authority on standardization, having been in existence for over sixty years. At the present time there are nearly 5,000 British Standards published, ranging from single- or two-page documents of a few simple requirements to technical specifications with hundreds of pages of clauses, methods of test, formulae, diagrams and tables of data. All standards are kept under constant review so that amendments or revisions may be made to take into account the latest developments in materials, design or manufacturing technique.

International standards are co-ordinated by the International Organization for Standardization (I.S.O.) which was formed in 1946. This body holds meetings of its technical committees from time to time, their members representing national standardizing bodies. The outcome of these meetings determines the issue of I.S.O. recommendations.

The British Standards Institution is not a Government department; it is financed by subscriptions from industry and the Government and from the sale of its publications. Industry recognizes the benefits of standardization by freely providing the services of the thousands of technical experts who serve on the numerous B.S.I. committees. The Institution provides the secretariat for the meetings.

The American counterpart of the B.S.I. is the American Standards Association, Inc. Its constitution is rather different from that of the B.S.I., but it nevertheless fulfils the same functions with comparable effectiveness. Similar bodies exist, and do similar work, in most other countries, notably—from the photographers point of view—Germany and France.

Procedure. The preparation of a British Standard starts with the request from a recognized body representing the manufacturers or the users—e.g., a trade association or a Government department. Even ordinary amateur photographers can have their views considered if presented by someone with standing in the photographic world—e.g. the editor of a photographic journal. If the proposed standard is related to others already published, the matter is dealt with next by the existing standards committee for that particular section of the industry. Otherwise a special committee is constituted for the purpose and the exact scope of the proposed standard is defined for the guidance of the technical committee or panel responsible for the detailed drafting.

Eventually an agreed draft is circulated for the comments of all appropriate industrial organizations, professional institutions, Government departments and kindred bodies in this country, who are not directly represented on the drafting committee (which must obviously be limited to a workable number), as well as to standardizing bodies throughout the Commonwealth. By this system the B.S.I. ensures that the published standards are acceptable generally to the manufacturing and consuming interests concerned, even before publication.

The A.S.A. similarly provides the machinery for creating voluntary standards, although unlike the B.S.I. its constitution enables it to take the initiative and agreement is reached as between members of a federation. Standards so produced are automatically regarded as nationally acceptable, and are designated "American Standard".

There are very many A.S.A. standards covering much the same fields as the B.S.I. Standards. In photography there are one or two instances where nomenclature is standardized, such as the parts of a lens.

Scope. Photographic standards deal largely with sizes of sensitized material and related items such as spools, masks and reels. There are also specifications dealing with qualitative aspects, such as speed, transmission density, performance requirements for components—e.g., resolving power of lenses—equipment for processing and various accessories.

SOME BRITISH PHOTOGRAPHIC STANDARDS

B.S. No.	*Subject*
967	Identity and passport photographs.
1112	Sizes of printing paper.
3368	Identification of exposed colour film.
1019	Photographic lenses; definitions; markings.
1383	Photo-electric exposure meters (under revision).
1496	Safelight screens and housings.
1592	Photographic shutters.
1613	Resolving power of lenses.
1915	35 mm. projectors (still).
1917	Film-strip and lantern slides.
2833	Classification of flash bulbs.
3205	Electronic flash equipment.
1380	Film speed determination
	Part 1. Monochrome negative material.
	Part 2. Reversal colour film.
1437	Determining filter factors.
1384	Determining transmission density.
930	Light output of cine projectors.
1488	Test-films for 16 mm. projectors.
3675	Performance of 16 mm. sound projectors.
CP 412	Optical projection apparatus for education.
2954	Screen luminance for 16 mm. film.
3115	Originals for television.
1153	Storage of microfilm.
1359	Photographic conversion tables.
3216	Stereo still pictures on 35 mm. film.

A.S.A. No.	Subject
PH1.12	Dimensions of printing papers.
PH1.20	70 mm. film for still cameras; dimensions.
PH2.11	Photometric exposure of daylight colour film.
PH2.12	Photo-electric exposure meters.
PH2.13	Testing flash lamps.
PH2.21	Speed of reversal colour film.
PH3.2	Performance of focal-plane shutters.
PH3.3	Performance of front shutters.
PH3.11	Stereo on 35 mm. film; sizes.
PH3.13	Focal length markings of lenses.
PH3.16	Resolving power of projector lenses.
PH3.18	Synchronization of front shutters.
PH3.20	Focusing scales.
PH3.28	Slide-film projectors.
PH3.31	Testing enlargers.
PH3.40	Electronic flash, performance.
PH4.5	Temperature tolerances in processing.
PH4.7	Photographic thermometers.
PH4.14	Definition of a fine-grain developer.
	Cine (excluding 35 mm.)
PH22.27	Transmission density of films.
PH22.41	Photographic sound record (16 mm.).
PH22.42	16 mm. sound-focusing test films.
PH22.43	16 mm. flutter test film.
PH22.44	16 mm. multi-frequency test film.
PH22.53	Resolving power of projector lenses.
PH22.88	Magnetic striping of 8 mm. film.
PH22.89	Scene-change cueing.
PH22.100	16 mm. screen brightness.
PH22.112	Picture-sound separation (16 mm.).
PH22.124	Screen luminance.

SOME GERMAN PHOTOGRAPHIC STANDARDS

D.I.N. No.	Subject
4521	Camera lenses; markings.
15741	Projector lenses for 8 and 16 mm. films.
19010	Photo-electric exposure meters.
19011	Guide numbers for artificial light sources.
19012	Flash lamps; technical characteristics.
19013	Flashlight technique.
19015	Measurements on front shutters.
19016	Measurements on focal-plane shutters.
19017	Exposure values;
4512	(1) Sensitivity of monochrome films.
	(2) Blue, green, and red sensitivity of monochrome films.
	(3) Optical density of transparent diffusing layers.
	(4) (draft) Sensitivity of reversal colour film.
108	(1) Still projection (general).
	(2) Preparation of glass slides.
4531	(1) Stereoscopy (general).
	(2) Stereoscopy; sizes, separations, arrangement of pictures.
6170	Anaglyphic stereoscopy.
19021	Light and temperature measurements in still projectors.
15603	16 mm. sound film; relation sound and picture.
15881	8 mm. film; positive with stripe.

SOME FRENCH PHOTOGRAPHIC STANDARDS

N.F.–S. No.	Subject
20–001	Speed of fast negative emulsions.
20–002	Sensitometry.
22–001	Exposure-time markings.
22–002	Stop-scale markings.
24–105	Sound-recording (16 mm.).
24–108	Splices in 16 mm. negative film.
28–002	Photometric calibration of camera lenses.
28–003	Measuring optical characteristics of 35 and 16 mm. projectors.
28–006	Testing projector lamps.
28–007	Characteristics of projection screens.

In many fields much of the current technical nomenclature is also standardized, but so far no attempt has been made to standardize photographic terms and descriptions.

Dimensional Standards. Dimensional standardization is of greatest service in fields where small mass-produced items have to be fitted together before use by the general public. This necessary interchangeability, if devised intelligently from the outset, can form an immense incentive to world-wide standardization, with consequent benefits to exporting producers. The problem can, however, lead to difficulties over tolerances which are necessary evils of production.

A designer of a camera which is to use a film having dimensions already standardized must ensure that the camera will accept a fully-loaded standard spool made to the maximum dimensions as well as one made to the minimum dimensions. He must also arrange that the film window is positioned so that the numbers on the backing paper can be seen even when printed at their extreme standard limits. He can then be sure that his camera will accept all films of the size for which it is intended.

Dimensional British Standards are published for photographic paper, recording materials, ordinary sheet film and X-ray film, film strip and lantern slides, amateur (including 35 mm.) and service roll film and spools. Related accessories for which standards are issued include masks, dishes, film clips, safelight screens and many other components dealt with in more comprehensive specifications.

Other Photographic Standards. Other standards of less immediate bearing on photographic products sold to the public apply to routine test and development work. (It is no less important to secure uniformity between laboratory testing methods than to make sure that all 35 mm. film is correctly perforated.) Examples of such standards are those relating to film speed, measurement of transmission density and the determination of filter factors.

Another section of British Standards is concerned with the optical and mechanical performance of lenses and shutters, and equipment—e.g., for processing X-ray film. In processing equipment, of course, a detailed specification is out of the question, but it is of immense help to the user and supplier to know that the standard components incorporated are interchangeable between units and that essential service connexions of standard type are fitted and readily accessible and that suitable requirements for temperature, ventilation and chemical resistance properties of the materials used have been specified.

Other standards concerned with apparatus of a complex nature, like projectors, optical lanterns and microfilm readers, include not only standard dimensions for interchangeability of lenses, etc., but also electrical, optical,

CC-0. Arunachalam Digital Preservation Foundation, Chandigarh

and illumination performance requirements to ensure efficient and safe functioning from both the operator's and audience's point of view.

Collaboration Between Standards Organizations. Although full international agreement on standards is achieved through the I.S.O., some degree of collaboration between standards organizations is often desirable in the interests of trade between two countries, as a step towards international standardization, or perhaps to prevent confusion in cases where some standard designation may be used outside its own country. To this end conferences between organizations may be held periodically.

The question of film speeds is an example of collaboration of this kind. The numerous systems that have been current in the past—some sponsored by film-makers, some by makers of exposure meters—led at one time to much confusion. In the last fifteen years or so close co-operation between the standardizing bodies of U.S.A. and Britain has resulted in a method of measuring, and expressing, film-speed common to the entire English-speaking world, and most, if not all, exposure-meter makers have scaled their instruments to suit it. This is the A.S.A. arithmetical system. But Germany, followed by most of Europe, has long used the D.I.N. system, originally based on tests sufficiently different from those used to determine A.S.A. speeds to make it possible for two films having the same speed on one system to have different speeds on the other. By successive concessions on both sides, a compromise system has been approached, and is likely to be internationally standardized very soon; speed will then be determined by the resulting agreed test, and the speed, whether expressed in A.S.A. or D.I.N. figures, will have an unmistakeable meaning.

Many standards deal purely with dimensions; these are of interest to a manufacturer but hardly to a user. A selection of (mainly) non-dimensional standards current in Britain, U.S.A., Germany, and France is listed here; these and other standards can be obtained through the British Standards Institution, 2 Park Street, London, W.1, in whose library, open at that address during office hours to all bona-fide enquirers, classified lists of standards from all countries may be consulted.

Book: *Progress in Photography* (2 vols.), ed. by D. A. Spencer (London).

STAND CAMERA. Every type of portable camera which is normally mounted on a tripod. Such cameras are usually of large format—half-plate and upwards—and focus by focusing screen.

See also: *Field camera; Technical camera.*

STAND DEVELOPMENT. Development of films and plates for a long time in highly dilute developers, often in special tanks. This method is not generally popular, as the long times required are rarely convenient.

Stand development requires special developers which do not oxidize readily even at low concentration—e.g., glycin—and which do not readily produce aerial fog.

Dilution is in the region of ten to twenty times normal, and development times range from one to four hours.

Agitation is considerably less important than with orthodox development, as the action of the solution is very slow. Consequently the normal molecular movement in the solution is sufficient to keep the concentration of the active ingredients reasonably uniform throughout the liquid. This applies especially if the film or plate is suspended vertically in the solution, as is normal practice in stand development so that the solution is kept moving by gravity as its density changes on becoming exhausted.

Although highly diluted, the developer solution must still contain a sufficient amount of developing agent per film, otherwise the bath would become exhausted before development reached the required stage. Stand development therefore requires large volumes of solution.

See also: *Finality development.*

STARCH PASTE. One of the adhesives commonly used for mounting prints, made by emulsifying starch in boiling water.

See also: *Mountants.*

STATIC. Abbreviation of static electricity; commonly used to describe an electrical charge produced by friction between certain materials—e.g., glass and silk.

In photography static may be produced on a film by the action of unwinding it in very dry weather. It can be recognized by the sharp cracking sound it makes as it discharges. The discharge may also be accompanied by faint blue sparks which can actually produce a developable image on the film. Ordinary roll films are unlikely to discharge enough static to cause visible marks on development, but cinematograph films can be seriously marked. This is because the faster speed of unwinding and the greater length of the film build up much higher charges and produce brighter sparks.

Static also makes it difficult to get rid of dust on glass surfaces. When the surface of a lens or glass negative carrier is polished with a cloth, the friction builds up a static charge on the surface of the glass. This makes the dust cling tenaciously to the surface and fly back

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

to it after being wiped off. Rubbing the surface harder simply makes matters worse. The remedy is to wipe the glass once, very gently, about five minutes after polishing. There are proprietary dopes and impregnated dusters which are claimed to prevent the formation of static and leave the surface dust-free.

Alternatively, glass negative carriers may be brushed with special anti-static brushes. These contain a strip of faintly radio-active material (such as polonium) which discharges the static electricity.

The above remarks apply equally to dust that has settled on the emulsion surface of plates and films. But radio-active anti-static brushes may fog unexposed films.

See also: *Faults*.

STATUETTES. Figures of statuary and of people, children and pets cut out of photographs and mounted on cardboard or plywood. Cut-outs of this type are used for decorative purposes, table top and model photography, and for attaching to calendars. They are of course used on a large scale for advertising and display material in shop windows and at the point of sale, but for this purpose the pictures are printed from half-tone blocks and cut out in one operation on a machine. They may then be folded in such a way as to be self-standing.

The picture chosen should have a clearly-defined and simple outline, and the tones should be bold and with plenty of contrast. There will be no border to isolate the figure from its surroundings and it must be strong enough to assert itself on its own merits. The enlargement should ensure a figure of at least 4 ins. in height and preferably more. Anything smaller is difficult to work on and the finished product looks insignificant.

Mounting the Picture. The figure is cut out of the print by laying it on a flat surface and going around it with the point of a sharp knife, keeping quarter to half an inch away from the outline.

Just enough of the lower part of the print should be left attached to provide a good base for the cut-out.

The roughed-out portion is then stuck down on to a piece of suitably robust support material. Satisfactory supports may be cut from stiff card, but thin plywood is better. The surface must be clean, dry and free from irregularities. It should be rubbed quite flat on both sides with a piece of fine sandpaper wrapped around a block of wood.

Both the back of the print and the face of the support should be thickly coated with a good cold glue. (The popular tube glues are excellent, but not cellulose glue because this type tends to dry before both surfaces are covered.) Rubber solution and ordinary photographic mountants are unsatisfactory because they do not dry hard enough to give a clean edge when the cut-out is sawn down to the outline.

The two surfaces are pressed together, squeegeed into firm contact and then kept under pressure between flat boards for at least twenty-four hours.

The Support. The outline is now sawn out with a fretsaw—if possible of the treadle type since the faster the speed of the saw, the smoother the edges of the cut will be. All edges are rubbed smooth with fine sand-paper. Grey water colour is then painted all round the edge to tone it down to about the average shade of the print.

Wooden blocks are then glued to the back of the cut-out to form feet. With large figures it is a good plan to drill as large a hole as possible at the back of the feet and pour in melted lead so that the weight prevents the cut-out from tipping forward.

Both sides of the cut-out are then given a coat of clear cellulose lacquer so that it will stand up to handling.

If both sides of the statuette will be visible, it is possible to stick a reversed print on to the back. The reversed print is made by reversing the negative in the enlarger, taking care that the second image is exactly the same size as the first.

Another effective method of mounting a cut-out is to sandwich it between two sheets of glass or Perspex held upright in a slotted block of wood. The outline in this case is cut around with the point of a sharp penknife or razor blade. Here again a left-to-right reversed print can be stuck to the back.

Photographers with a liking for this type of handicraft often produce amusing animated versions and children's toys by articulating the joints of cut-out figures. Others turn straight head and shoulder portraits into miniature imitations of busts, with a pedestal base. F.P

STEINHEIL, CARL AUGUST VON, 1801–70. German astronomer and professor of physics and mathematics at Munich University. Together with Franz von Kobell, Steinheil reported to the Bavarian Academy of Sciences on Talbot's photogenic drawing in April 1839, and at the same time showed their own photographs of views in Munich. These were negatives taken with a cylindrical camera, designed by Steinheil on silver chloride paper fixed with ammonia. Immediately after the publication of Daguerre's process, August 1839, Steinheil began experimenting with the daguerreotype, and in December made the prototype of the first miniature camera, producing pictures 8 × 11 mm. (half the size of a sixpence) which had to be viewed through a magnifying glass. In 1855 Steinheil founded in Munich the optical works which still bears his name. Biography by Rudolf Loher (Munich 1937).

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

STEINHEIL, HUGO ADOLPH, 1832–93. German designer and manufacturer of lenses, younger son of Carl August von Steinheil. Father and son patented in 1865 the Periskop lens which gave a field of 100° free from distortion. In 1866 purchased his father's optical works and produced his Aplanat, an achromatic rectilinear lens for landscapes, reproduction work and interiors. Later produced wide-angle lenses for cartographic reproductions, an Ahtiplanat (1881) and a telephoto lens (1891).

STELZNER, CARL FERDINAND, *c.* 1806–94. German miniature painter in Hamburg. Became a daguerreotypist in 1842 and for a while worked in collaboration with Hermann Biow, taking the earliest news photographs of the ruins after the Hamburg fire, May 1842. Stelzner opened his own studio, 1843, which was run by an employee after his sight failed in the mid-50s.

STENGER, ERICH, 1878–1957. German professor of photographic chemistry and director of the photo-chemical laboratory at the Technische Hochschule, Berlin, for nearly two decades, in succession to Adolf Miethe. Professor Stenger is best known as an historian of photography. For over fifty years he collected everything appertaining to the history of photography, and published several books, of which *Die Photographie in Kultur und Technik* (1938) is his main work. The Stenger Collection was bought by Agfa, Leverkusen, Germany 1955, with the intention of establishing a museum.

STEP AND REPEAT. Method of photographing or printing a large number of identical images side by side on one film.

Used mainly in photo-mechanical reproduction for preparing printing plates (for example of postage stamps) but also for making printed circuits, etc.

The process is more or less automatic, being carried out by a step-and-repeat camera. This moves the film or plate through a set distance after every exposure, to place the successive images side by side, row after row until the film is full.

See also: *Photo-etching.*

STEP WEDGE. Optical wedge in which the density increases in a series of regular steps from the transparent to opaque or at least to a high density.

The steps are usually chosen so that the light passing through any particular section is twice that passing through its denser neighbour. This requires the density to increase by 0·3 at each step.

Step wedges are used in sensitometry and for determining exposures in enlarging.

See also: *Wedge.*

STEREO-MICROGRAPHY. Except at a very moderate degree of magnification it is normally impossible for the eyes to look through a magnifying glass at a small object and view it stereoscopically. This is because to do so they would have to converge at such an angle that a single magnifying lens would not serve both eyes at the same time, and because the separation between the two viewpoints would be so great that the picture seen by one eye would be quite different from that seen by the other and it would be impossible to fuse them into a single stereoscopic impression.

Enlarged stereoscopic views of small objects can only be obtained by scaling down the separation between the viewpoints of the eyes in proportion to the magnification of the image. This is done in the stereoscopic microscope by a system of prisms which in effect allow the eyes to look through the magnifying system from viewpoints separated by a fraction of an inch instead of normal interpupillary distance.

The same effect can be produced by taking two consecutive photographs of the object through the microscope and either rotating the object, or sliding it sideways between exposures. The extent of the change in position (corresponding to the reduced interpupillary separation) is arrived at by simply dividing the normal separation of the eyes ($2\frac{1}{2}$ ins.) by the magnification—e.g., if the object is magnified 50 × life size, then the shift between exposures will be $2{\cdot}5 \div 50 = {\cdot}05$ in. When the resulting negatives are printed and viewed as a stereoscopic pair, the effect will be as though the object had been magnified to fifty times life size and moved fifty times farther away. At that apparent size and distance it would be seen in stereoscopic relief exactly as though it were an enlarged model being viewed normally with two eyes.

See also: *Stereoscopic photography.*

STEREO PROJECTION. Projection of stereo pairs of images to convey an effect of depth by presenting to each eye slightly different images which correspond to the views seen separately by the two eyes. Stereo projection methods may be applied both to still and to cine pictures.

See also: *Projection practice; Stereoscopic photography.*

STEREO-RADIOGRAPHY. Technique of obtaining a three-dimensional impression of the internal structure of an object by X-ray recording. For this purpose two radiographs of the same object are taken in succession at two different positions of the X-ray tube. If measurements in space are to be carried out, the displacement of the tube should be of the order of the interpupillary distance, i.e. approx. 6·5 cm.; otherwise a ratio of tube shift to focus-film distance of 1 : 10 also reveals a good stereoscopic impression.

Change of film cassettes and immobility of

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

the object between exposures are essential. The latter condition is easily achieved in industrial radiography of castings and similar objects, but is more difficult in medical radiography because of involuntary movements of the patient. In this case the exposures have to be taken preferably by means of rapid cassette changers and the exposures should follow in quick succession, e.g. by using two X-ray tubes.

The two radiographs thus obatined can then be viewed with, for instance, a Wheatstone mirror stereoscope or with a binocular stereoscope. With both instruments a three-dimensional view is obtained. In the Wheatstone type stereoscope distance measurements in space can be carried out. Some people are capable of viewing two such radiographs stereoscopically even without the aid of special instruments.

In stereo-fluoroscopy the object is screened alternatively from two X-ray focal spots at a distance apart and the images on the screen are observed in rapid succession so that the left eye sees the image caused by one focal spot and the right eye that by the other focal spot.

The accurate localization of defects or foreign bodies in the field of industrial radiography can be achieved by taking two exposures (using the tube shift method) on one single film. In another technique two small lead markers are used, one in contact with the upper surface of the specimen, the other in contact with its base. The distance of the tube shift need not be known with accuracy in this case. As the displacement of the image of the defect will lie between that of the images of the upper and lower marker, the position of the defect can be determined from a graph relating the distances of the markers (i.e. thickness of the object) and the image displacement. R.H.H.

See also: *Medical radiography*.

STEREOSCOPE

Special type of viewer designed to accept a stereoscopic pair of pictures so that they can be viewed as a single image in three-dimensional relief.

There are two principal requirements:

(1) Each eye must see in the stereoscope the picture that it would see if it were looking directly at the subject—i.e., the left eye must see the print from the negative taken with the left hand lens of the stereoscopic camera (or with the camera at the left hand end of the stereoscopic slide) and the right eye must see the picture taken from the right-hand side.

(2) The eyes should preferably be focused and converged as though they were looking at the actual object. This condition is not always strictly observed in the design of stereoscopes and any departure from it results in eyestrain after a time.

Unaided Viewing. Some people can manage after a little practice to look at a stereoscopic pair and merge them into one stereoscopic image. To do this, the two pictures are placed side by side with their principal points separated by the normal interpupillary distance of the eyes.

There are then two ways of looking at the pictures:

(1) The observer looks at the pictures from a distance of about 10 in., seeing the left-hand picture with the left eye and the right-hand picture with the right eye. (A piece of black card held between the pictures helps to keep the eyes from wandering.) To see the picture stereoscopically under this condition the eyes must be directed as for an infinitely distant object—i.e., without convergence—and focused as for a near object.

(2) The pictures are transposed from left to right and the observer looks at them with each eye seeing the picture on the opposite side. If the pictures are far enough away, the convergence of the eyes is reasonably near normal, even although the axes are crossed, and the effort called for is not as great as when the axes are parallel.

Both these methods require special practice first and involve considerable eyestrain. Some people are unable to fuse the images at all successfully. They are not suitable for continuous viewing.

Elliot's Stereoscope. In 1839, James Elliot produced a stereoscope based on the second method of unaided viewing described above. It consisted of an oblong box with eye holes spaced at the interpupillary distance at one end and a single hole at the other. The observer, with his eyes to the eyeholes, looked through the hole in the end of the box at a suitably arranged stereoscopic pair of drawings set up at a distance outside the box.

Under these conditions each eye looking at an angle through the end opening could see the picture on the opposite side, but it could not see the picture on its own side. This enabled the

ELLIOT'S STEREOSCOPE. Contains no optical system; the left and right eye rays cross over, so that each eye sees only its own picture and not the other one.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

picture for the right eye to be set up where only the right eye could see it, and the left picture where only the left eye could see it; the result was a single stereoscopic image. (In practice the pictures were set up side by side, but with the left picture on the right side and the right on the left; the viewing box was then moved about until the required condition was achieved.)

The Elliot viewer was easier to use than the unaided methods above, but it still called for an unnatural visual combination of focusing and convergence. So only a few specially gifted people could use it and even then its use inevitably produced eyestrain sooner or later.

Wheatstone's Stereoscope. In 1832 C. Wheatstone invented and had prototypes constructed of the reflecting and the refracting stereoscope. In 1838 he fully described to the Royal Society the reflecting type that is still used in modified forms today.

The basic arrangement of this consisted of

WHEATSTONE'S STEREOSCOPE. Uses two mirrors; each stereo picture must be reversed left-to-right. Suitable for prints of any size, since they can be at any distance from the mirror necessary to include the whole picture.

two mirrors set facing outwards at 45° to the line of sight. The mirrors were arranged to reflect the pictures of a stereoscopic pair of drawings (later photographs) held upright on either side, and facing inwards parallel to the line of sight. Because of the inverting effect of reflection from the mirrors, the pictures had to be printed with the negative reversed if the resulting stereoscopic image was to show left and right in their correct relationship. This was an inherent disadvantage, but even so Wheatstone's stereoscope was the first really practical instrument.

Because the pictures are parallel, there is no limit to their size as there is in side-by-side arrangements. So the Wheatstone principle is still employed for viewing large images like those of X-ray film stereoscopic pairs.

Cazes's Stereoscope. A similar type of viewer to the Wheatstone was made by L. Cazes in 1895. In this, two extra reflecting mirrors are introduced so that pairs of any size may be observed side-by-side in one plane. Converging or diverging lenses can be combined with the

BREWSTER'S STEREOSCOPE. Two prisms or half-lenses allow the eyes to converge naturally, though the pictures are appreciably separated. Principle of many modern stereoscopes.

eye pieces to alter the scale and apparent distance of the image. Such viewers have adjustments for arranging the separation of the pairs and the viewing distance to give natural convergence of the eyes no matter what the magnification or reduction of the optical system. Instruments of this type are used for giving magnified stereoscopic images of aerial reconnaissance photographs.

Brewster's Stereoscope. In 1849 Sir David Brewster introduced a refracting stereoscope based on the principle of Wheatstone's second stereoscope of 1832. Originally it consisted of a side-by-side viewer in which each eye viewed its own picture through a plane prism. The two prisms were placed, base out, across the line of sight; after refraction, the bundles of rays coming from each picture were bent away from each other, thus appearing to come from a point. So the respective right and left image rays, instead of appearing to come from two spaced pictures, seemed to come from a single stereoscopic picture at the meeting point of the two converging bundles of rays. This arrangement allowed the eyes to converge naturally on the single virtual image. It went into production in 1851 for viewing daguerreotypes.

An immediate improvement on this system was to substitute lenticular prisms for the plane prisms, thus giving a magnified image. By making the prisms to a suitable angle (in

SINGLE MIRROR STEREOSCOPE. Little more than a primitive viewing aid, it permits the eyes to converge naturally. One of the prints must be reversed left-to-right

STRAIGHT 35 mm. STEREO VIEWER. Designed for viewing untransposed transparency pairs taken side by side on one 24 × 36 mm. frame with the aid of beam splitter lens attachments working on a similar principle.

practice they are formed by a pair of half lenses) it is possible to view palrs separated by as much as 3 ins. without discomfort. This enables larger pictures to be viewed than are possible with the normal interpupillary separation of about 2½ ins.

This type of stereoscope is the one commonly used for amateur stereo photography and for all portable and compact viewers. In its most popular form (at least up to about 1940) it consisted of a frame with a pair of hooded eyepieces at one end of a base carrying the print holder. The separation of the print holder from the eyepieces could be adjusted to focus and merge the pair. More elaborate stereoscopes of this type had the units mounted in a closed box with a reflector at the top for illuminating prints. There was an optional opal glass at the end opposite the eyepieces which could be pointed at a light source for viewing transparencies.

Some of the more complex models included an adjustment for varying the separation of the eyepieces and for correcting focusing disparities between the right and left eyes.

The above principle is the one incorporated in the familiar machines on piers at coastal holiday resorts.

A fundamental requirement of this type of stereoscope is that for natural stereoscopic

TRANSPOSING 35 mm. STEREO VIEWER. Designed for viewing transposed transparency pairs taken with twin-lens stereo unit in interchangeable-lens 35 mm. cameras. The viewing rays cross over in centre prism.

presentation of the subject, the effective focal length of the viewing lenses should be identical with that of the taking lenses. This requirement is difficult to meet in practice, particularly with stereoscopic pairs made on 35 mm. film in miniature cameras. The cost of short focus prismatic lenses, suitably corrected, is out of proportion to the cost of the rest of the equipment, so that it is customary to use lenses of longer than the ideal focal length. This results in over-emphasis of the foreground, but the worst of the distortion can be removed by incorporating additional meniscus lenses in the eyepieces.

Highly developed stereoscopes on this principle, with their own illuminating lamp and battery, are now widely used for viewing stereoscopic colour transparencies taken on miniature cameras with stereo attachments. One of the commonest applications of such instruments is as a sales aid carried by commercial travellers to display goods—e.g., machinery, furniture, motor cars—too large to take around to show to the buyer. But this

TRANSPOSING 35 mm. STEREO VIEWER. The transposed transparency pair is viewed from the back; the prism system for each eye reflects the image three times, resulting in a right-way-round picture and correct stereo view.

kind of visual demonstration has become virtually obsolete, in view of the more impressive procedures of demonstration cine films.

Other Systems. Several variations are based on the method of viewing in which, say, the left eye looks directly at the left picture while the right eye converges on to an image of the right-hand picture which is displaced towards the centre by either a pair of mirrors or a refracting prism of suitable shape.

A variation on this method requires the pair to be set at an angle like the sides of an almost fully opened book. One eye looks directly at one page, while the other, converging naturally on the line of sight of the first, sees the second image reflected in a mirror. This method lends itself to the examination of stereo pairs bound in book form.

In this case the side which is viewed in the mirror must be printed in reverse since the image is reversed on reflection. F.P.

STEREOSCOPIC CAMERA

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

A stereoscopic camera is normally designed to take two simultaneous photographs of the scene in front of it. The photographs are taken from viewpoints separated by the same distance as a pair of normal human eyes. When the subsequent positive prints are looked at through a suitable stereoscopic viewer they combine to give a three-dimensional reproduction of the original scene. The first binocular stereoscopic camera was put on the market in Paris by A. Quinet in 1853.

Some stereoscopic cameras are made to fold, but the most popular type is simply a rectangular box in which the essential parts of two box-type cameras are mounted side by side. The axes of the two cameras are 2½ ins. apart—2½ ins. being the normal separation of the human eyes. The camera may be designed to take pictures on either pairs of plates, pairs of films, separately wound, or on alternately spaced frames of a single film.

The earliest roll film stereo cameras produced 2¼ × 2¼ inch images; hence a stereo pair could consist of neighbouring film frames which were automatically separated by the required 2½ ins. Roll film cameras for smaller film widths—such as size 127 roll film—were at one time made, yielding interlaced stereo pairs.

A more modern attempt to produce stereo pictures on roll film consists of a camera with the two lenses arranged side by side across the width of the film. The film there runs vertically up or down. This automatically reproduces two adjoining stereo images, though the separation of the optical axes is not the normally required 65 mm. The images on the film are transposed when viewed upright and right way round; prints made from negatives therefore need re-transposing, while transparencies have to be viewed in an appropriate transposing viewer.

Miniature Stereo Cameras. Stereoscopic photography gained a new lease of popularity with the introduction of camera models taking perforated 35 mm. film. This also brought colour within the range of the stereo photographer and made it an economic proposition.

Stereo cameras using 35 mm. film take pairs of either 23 × 24 mm. vertical pictures or 24 × 30 mm. horizontal ones. In the first case the two corresponding images are separated by two frames, and in the second case by one frame. This leads to two distinct film transport systems.

In cameras which produce 23 × 24 mm. pictures the film is advanced by two frames for every exposure. The arrangement of images on the strip of film is therefore:

1a. 0. 2a. 1b. 3a. 2b. 4a. 3b. 5a. 4b. 6a., etc., the space between 1a and 2a being blank (1a, 2a, 3a are the right-hand images, 1b, 2b, 3b the left-hand ones). The stereo pairs are thus interlinked throughout the whole length of the film which cannot be cut without splitting at least one stereo pair. A complete 36-exposure load of film yields 27 or 28 stereo pairs.

Where the camera takes 24 × 30 mm. pictures, the film is advanced alternatively by one and three frames for every pair. The images are arranged in a different fashion:

1a. 2a. 1b. 2b. 3a. 4a. 3b. 4b. 5a. 6a. 5b., etc.

Each set of four frames constitutes two complete stereo pairs. A full 36-exposure film yields 21 to 22 stereo pairs. Usually the single and triple frame advance are controlled automatically with the transport knob geared to advance four frames at one revolution. Two film locks, spaced one-quarter revolution apart, then yield the interval of one and three frames alternately.

Many miniature stereo cameras can be used for single shots if desired. One of the two film apertures is then blanked off by means of a built-in masking plate (or one of the lenses covered) and the film transport locks reset to advance the film frame by frame.

Optical System. The lenses must be accurately matched because any discrepancy would mar the stereoscopic effect. Matching wide aperture lenses is an expensive business, so very few stereoscopic cameras have lenses of aperture greater than *f* 6·3. In the miniature formats

MINIATURE STEREO CAMERA SYSTEMS. Left: 23 × 24 mm. stereo frames. The two images of a pair are always separated by two frames; the second frame of the film is thus blank. The film transport advances the film by two frames every time. All pairs continuously interlinked. Right: 24 × 30 mm. stereo pairs, separated by one frame. Only alternate pairs interlinked; film transport advances one frame and three frames alternately by use of special transport lock.

however, some cameras are made with lenses of aperture $f3{\cdot}5$ and even $f2{\cdot}8$. The iris diaphragms of both lenses are coupled to a common control.

CC-0. Tagore Centre for Digital Preservation Foundation, Chandigarh

A brilliant type of viewfinder is mounted on the top of the box mid-way between the lenses. One advanced type of stereoscopic camera is built on the twin-lens reflex principle and has a viewing lens and focusing screen in place of the viewfinder.

If the finder is mounted between the lenses, parallax correction is simple; the finder area is masked vertically to include only the field covered by both lenses. The masks may be fixed (for all subjects beyond 3–5 feet) or movable (for close-up work).

Some cameras have their lenses fitted in screw focusing mounts, coupled to a single lever which indicates the distance of sharp focus on a calibrated scale. In others, the lenses are mounted on a focusing panel racked forward by a thumb wheel on the side of the camera.

A number of miniature stereo cameras incorporate a coupled rangefinder. As the camera itself has a comparatively long body, the rangefinder can have a base length of up to 6 ins. or thereabouts without difficulty.

Shutter Units, The simplest stereo camera shutter consists of a long metal plate with two apertures, spaced the appropriate distance apart, and moving horizontally behind the lenses. This automatically ensures perfect synchronization of both exposures as well as identical exposure times. The speed range and accuracy are, however, as limited as with box camera shutters. More versatile models may feature better behind-lens shutters (which still have the advantage of permitting a reliable direct linkage) or between-lens shutters of advanced design. With these accurate matching at all shutter speeds is important, for the two images of a stereo pair must be equally exposed. With high-speed action subjects precise synchronization of the release of both shutters is also essential, otherwise the two stereo pictures show the subject in different phases or stages of movement.

Stereo Attachments. Normal 35 mm. cameras giving 24 × 36 mm. images can also be used for stereo work with the aid of a stereo attachment. This splits up the 24 × 36 mm. image area to produce two 18 × 24 mm. images forming a stereo pair. There are two ways in which this can be done, giving differently orientated pairs.

The first method uses a straightforward beam splitter in front of the camera lens. This consists usually of a double reflector unit, possibly with a prism, which takes in the same view from two viewpoints separated by the interocular distance of about 65 mm. The beams from the two halves of the beam splitter cross over on going through the lens (following the usual optical laws) so that the right hand side of the beam splitter produces the right eye image upside down on the left-hand half of the film

STEREO ATTACHMENTS. Left: *Beam splitter to fit in front of normal camera lens, produces two untransposed images side by side on the normal negative area. The prism unit ensures correct separation of viewpoints.* Right: *Twin-lens attachment for interchangeable lens cameras. The images are inverted (as with beam splitter) and also transposed. Can be used with a prism unit, or, for very near subjects, without it.*

frame (as seen from the back of the camera). Similarly, the left-hand beam produces the left-eye image on the right-hand half of the frame. If the complete frame is turned upside down (for example after processing) and viewed so that the images are right-reading, the left-eye half of the stereo pair is on the left- and the right-eye half on the right. The miniature stereo pair, if taken on reversal black-and-white or colour film, can be mounted in standard slide frames and viewed in a straight (non-transposing) viewer.

Beam splitter attachments of this kind have been produced at various times for a number of cameras; usually they are specially tailored to a camera model, but do not have to be. As long as the beam splitter is correctly centred in front of the lens and close to it, it will work with any miniature camera.

The second way is only suitable for cameras with completely interchangeable lenses. Here the normal camera lens is replaced by a pair of short focus lenses mounted side by sidef forming their images on the left- and right-hal, respectively of a standard 24 × 36 mm. negative. Since the separation between the lens axes is usually of the order of 15 to 17 mm., a prism stereo attachment is also used. This is not a beam splitter, but a pair of prisms which shifts the effective viewpoint of each lens of the pair outwards to obtain the correct interocular distance. For close-up photography the

STEREO PRECISION MINIATURE CAMERA. This model takes up to 21 pairs of 24 × 30 mm. stereo frames on a standard 36 exposure load of 35 mm. film. The matched lenses are mounted on a common lens panel for simultaneous focusing, while aperture and shutter controls are coupled for both. The individual images of a stereo pair are separated by one frame; the film transport therefore advances the film alternately by one and three frames, with a complete turn of the knob corresponding to a cycle of two stereo pairs. The camera will also take about 42 single frames. Top left: *General view of camera against 1 in. square grid.* Top right: *Top view.* Centre right: *Front view.* Bottom right: *Rear view.*

stereo lens pair can be used without the prism attachment; in that case even close-up lenses can be placed over the entire lens pair.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Since each lens forms it image separately, there is no cross-over; hence the two 18 × 24 images on the 35 mm. film are transposed left to right when viewed upright and right-reading from the back of the camera. Transparency slides made with such an arrangement therefore need viewing in an appropriate transposing viewer.

In both cases the left- and right-eye views of a pair are immediately adjoining; the whole film can thus be cut up into self-contained stereo pairs. Stereo shots can be mixed with normal full size 24 × 36 mm. frames by removing the beam splitter (or replacing the twin lens system by the normal camera lens). The image sequence with the beam splitter on the single camera lens is: 1a. 1b. 2a. 2b. 3a. 3b—and so on.

With the twin-lens attachment the sequence is: 1b. 1a. 2b. 2a. 3b. 3a. 4b. 4a., etc.

STEREOSCOPIC PHOTOGRAPHY

The word stereoscopic is derived from two Greek words stereos and scopeo, meaning "to view solid". From early times attempts were made to simulate stereoscopic vision by providing artificial stimuli in the form of drawings made from slightly different viewpoints. The first successful stereoscope, designed by Wheatstone in 1832, used such drawings, but photography soon replaced drawings, for Wheatstone's friend, Fox Talbot, suggested stereoscopic pairs of calotypes in 1841 and Collen made the first ones for Wheatstone in August, 1841. Stereoscopic photography did not, however, really begin until ten years later, when the refracting stereoscope was put on the market.

BINOCULAR VISION

The ability to assess the mass and distance of objects depends to some extent on their light, shade, and colour contrast, and on perspective, but it results mainly from the fact that the two eyes and the brain form a human rangefinder. When the eyes are directed from a distant object to a near one, two things happen: they rotate inwards slightly in their sockets (this movement is known as convergence); an adjustment of focus takes place (this adjustment is known as accommodation).

The most distant plane in which the human vision can distinguish relief is around two hundred yards, although for all practical purposes the limit is closer. The nearest plane in which objects can be viewed comfortably without optical assistance is about ten inches, below which convergence and accommodation are difficult, and may cause discomfort.

The approximate separation of the human eyes when fixed on infinity is assumed to be $2\frac{9}{16}$ ins. (65 mm.). This figure, known as the interpupillary distance, is important in the design of stereo cameras and viewers.

The Stereoscopic Slide. A stereoscopic slide consists of a pair of positive prints or diapositives made from negatives taken from two slightly different viewpoints. Normally the separation is equal to the interpupillary distance, but it may be increased or decreased when photographing distant or near objects.

Modern practice is to mount positives so that the separation of corresponding infinity points does not exceed 65 mm.: this point is important because the eyes do not easily diverge. This fact imposes a limit on the width of stereoscopic positives. At one time, positives up to $3\frac{1}{2}$ ins. wide were used. So that the eyes would not have to diverge, prismatic lenses were fitted to old-time stereoscopes; they were cut from the transposed halves of a bi-convex lens. There are still many of these old instruments in use.

BINOCULAR VISION. As the two eyes occupy distinctly separate positions when viewing a scene, they also see slightly different views. The difference is particularly apparent in a relative displacement (parallax) of near objects against their background (e.g., the candle against the corner of the room). This gives the scene its appearance of depth.

CC-0. Digital Preservation Foundation, Chandigarh

Distortions. Stereoscopes are fitted with lenses so that the slide can be brought close to the eyes, and fill the field of view more or less completely. The focal lengths of the camera and stereoscope lenses should theoretically be equal, but in practice viewing lenses of increased focal length are commonly used: these cover the field more easily and with less marginal distortion, and some people prefer the effect they give. In practice, the error introduced by an excess focal length of as much as 30 per cent may escape detection.

If the viewing lenses are of longer focal length than the taking lenses, the subject will appear more distant, and elongated in a direction away from the observer. The picture will in addition appear rather small. Conversely, if the taking lenses are of longer focal length than the viewing lenses, the subject will appear to be nearer, and compressed. The picture will be over-magnified, and the corners may not be covered.

If the stereo negatives are taken from viewpoints spaced wider apart than the normal interpupillary separation, the subject appears nearer, and relief is exaggerated. Conversely, if the taking separation is reduced, the subject appears more distant, and the impression of relief is diminished. Excessive separation should be avoided: it may cause difficulty in viewing and is unnecessary—in fact many stereoscopic cameras have been made with less than normal separation.

STEREOSCOPIC EXPOSURES

Any ordinary camera can be used for making stereoscopic negatives—even a simple box camera. The size of negative should preferably be less than $2\frac{1}{4} \times 3\frac{1}{4}$ ins. If the negatives are made with a smaller camera, and the prints are intended for use in a large viewer, the viewing conditions can be improved by making small enlargements up to 65 mm. wide.

Stereoscopic negatives may be made in two different ways: by sequential exposure or by simultaneous exposure.

Sequential Methods. In sequential methods, the negatives are exposed one after the other in the same camera, from viewpoints separated by the normal interpupillary distance. With this method, several seconds may elapse between one exposure and the next, so it is only suitable for still subjects. (In simultaneous methods, both negatives are exposed a the same time, so the subject may be moving as quickly as for normal photography.)

(1) Hand held exposures. It is possible to make a stereoscopic picture with an ordinary camera held in the hand in this way:

Stand with the feet apart, and the weight of the body on one foot. Make an exposure, wind the film, transfer the weight to the other foot, and make a second exposure. With luck and good judgement the result will be a stereoscopic pair of negatives. By moving the body in the same direction as the film is moved for the next exposure, the pictures will be taken in the correct relative positions for viewing, but probably at an incorrect separation. The camera may be tilted up or down, but it must be kept level from side to side, and the same area should as far as possible be included on both negatives.

STEREO-PHOTOGRAPHIC METHODS. Two photographs of a subject, separated by the interocular distance, can be made either with a twin-lens stereo camera, or by successive exposures with a normal camera.

(2) Tripod attachments. A suitable stereo slide can be made from a shallow wooden tray, 65 mm. wider than the camera. It should have a bush on the under side for attaching it to a tripod. This enables two exposures to be made with certainty from the correct distance apart. Exposures are made with the camera first at one end and then at the other. The camera may be lifted off the tray when setting the shutter and winding the film. Commercial attachments are available for many of the better makes of roll film and miniature cameras.

(3) Moving the object. This method is useful for small objects and has the same effect as moving the camera. The subject must be taken against a plain background; the movement between exposures should be $\frac{1}{4}$ in. per foot distance from the lens (2 cm. per metre). The lighting must be diffused, or must move with the subject.

(4) Rotating the object. A small object can be stood on a turntable and rotated about four degrees between exposures. The lighting must be diffused, or rotate with the subject.

(5) Rotating the camera. This method is suitable for use when taking small objects with a plate camera. A piece of black card is arranged inside the camera back so as to obscure half the plate. After the first exposure, the card is changed to the other side, and the camera is rotated on its support so as to bring the image to the other side of the plate. This method gives a pair of exposures on one plate.

(6) Displacing the lens. The body of a plate camera can be divided by a central partition, and the lens, mounted on a long panel, is moved from one side to the other between exposures. Alternatively, it can be fitted to one side of its panel, and the panel inverted between

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

STEREO SLIDE. For stereo photography by successive exposures in a normal camera, the camera displacement and positioning have to be accurate. The stereo slide moves the camera by the exact distance required between exposures, while a spirit level helps to check that it is truly level. In use the whole slide is mounted on a tripod, and the camera on the sliding part.

exposures. The slide must be closed during the change unless the camera has a focal plane shutter.

Simultaneous Methods. These methods may give two separate negatives or a pair of negatives on opposite halves of a single plate.

(1) Using two cameras. Two identical cameras can be fixed together at the required separation, the shutters being released together. Commercial attachments for this method are made for some miniature cameras, and many workers find an economical way of making stereos is to mount two cheap box cameras side by side.

(2) Using a stereoscopic camera. A stereoscopic camera resembles two cameras in one body. The lenses are matched, and the diaphragms, shutters, and focusing movements are coupled, so as to ensure that the negatives are identical except for the separation of the viewpoints.

(3) Using beam splitters. Two pairs of surface silvered mirrors, or a similar arrangement of surface treated prisms, are arranged in front of the lens in such a way as to impress two images on opposite halves of one frame of film. The resulting negatives are of rather a narrow angle; and exposures must be increased from 50 to 100 per cent because light losses take place.

In another pattern, now obsolete, a pair of mirrors fixed at an obtuse angle was placed at 45° in front of the lens, and the picture was taken with the camera at right angles to the subject. Commercial beam splitters are available for most of the better miniature cameras. One such instrument incorporates a pair of short focal length lenses and includes a normal angle of view.

Subject and Exposure. Subjects should generally be selected for their depth, but a distant background should not be included with a close-up subject. Apart from difficulty with depth of field, eyestrain is likely to result when such pictures are viewed.

The lighting should preferably emphasize roundness although *contre jour* subjects make attractive slides. Since stereoscopic photography is essentially the photography of foregrounds, a foreground of some kind should always be included. Even a fence will often make the difference between success and failure.

Good definition is necessary over the whole picture area, so the depth of field must be adequate. Generally the apertures should be small and a tripod should be used if possible. The exposure must be generous enough to give printable detail in dark foreground objects: at least double the exposure necessary for a normal photograph should be given. Areas of solid black that can be tolerated in a normal photograph will ruin a stereo picture.

Special Techniques. Objects more than about 200 feet away do not possess stereoscopic relief, but the normal separation between the exposing positions can be increased by moving the camera to provide relief in objects at any distance. The separation of the camera stations can be calculated on the basis of one-fiftieth of the distance to the nearest plane to be included, or it can be estimated by changing the camera position until a noticeable displacement occurs between the foreground and background on moving from one camera station to the other. This technique is known as hyperstereoscopy.

Separation is sometimes increased to provide extra relief in such subjects as worn coins or inscriptions.

Objects under the microscope may be photographed in stereoscopic relief either by taking two photomicrographs from slightly separated viewpoints or by tilting the stage.

A stereoscopic impression of the X-ray image can be created by taking two radiographs from separated viewpoints. This technique is used principally in medicine, to determine the depth of organs or foreign objects in the human body.

When taking close-ups with a single lens camera, the separation can be adjusted to the subject, and if necessary the lens can be converged to keep the subject central on the film. With a stereoscopic camera, the separation can be varied from the normal by capping each lens in turn, and making sequential exposures, moving the camera the required distance.

NEGATIVE MATERIAL AND PROCESSING

In the long history of stereoscopic photography, many formats for taking or viewing have been used. They vary from frames on 16 mm. film up to 5 × 7 ins., and the total number so far tried is in excess of twenty. Current formats for negatives include the 35 mm. film sizes, 45 × 107 mm., and 6 × 13 cm., and viewing formats include the above, 41 × 101 mm., and the standard card mount for prints, which measures 3½ × 7 ins. The complete list of formats includes a numbe

CC-0. Agamnipam Digital Preservation Foundation, Chandigarh

of obsolete sizes, and apparatus for some of these is still in circulation. For example, 7 × 13 cm. and 3¼ × 6¾ ins. cameras are still used, but supplies of plates or film are difficult to obtain. These sizes, however, are equally effective in viewers of correct design.

Plates, sheet film, roll film, and 35 mm. film are all currently used, and at one time film packs were popular. The positives are not only viewed under magnification, but they receive closer scrutiny than any enlargement of equal magnification, and for this reason grain must be avoided. Fine grain material should be used whenever possible: certainly for small sizes.

Monochrome reversal material can be used with success; it is becoming increasingly popular, and some workers use reversal processing methods with normal negative material.

A normal developer can be used for sizes above 45 × 107 mm., but for smaller sizes fine grain processing is best. Below full size 35 mm. frames, fine grain technique is essential, and processing must be carried out with great care. Over-development, leading to blocked highlights, must be avoided; there should be printable detail in all parts of the negative.

In stereo photography it is always easier to prevent blemishes than to cure them; even the spotting of paper prints is difficult, and it is practically impossible to retouch a blemished transparency. For this reason, cleanliness is important. Dust must be avoided at all stages, all processing solutions must be filtered, and sensitive material should be handled as little as possible, so as to reduce the risk of mechanical damage. The camera itself should be carried with the lenses pointing downwards, so that dust tends to fall away from the plate or film. Airbells should be avoided by using a wetting agent in the developer.

Making Positives. The aim should be to produce a print or transparency with a full range of tones, and with detail in every part. Areas which are devoid of detail appear either as meaningless dark patches, or as holes in the picture through which the grain of the diffuser in the viewer is visible.

On the other hand, a slide which appears dull and flat when held in the hand, and which would be quite unsuitable for use as a normal photograph, may look quite satisfactory when viewed in the stereoscope. This is because points which are scarcely to be distinguished from others by contrast occupy different positions in space. It is in fact common for a dull slide to brighten up in the viewer.

Prints on Paper. Daylight paper (P.O.P.), contact, bromide, and chlorobromide papers are all suitable for making stereoscopic prints. Many workers still favour daylight printing for its long scale of tones and for the beauty of the toned image.

It is essential to use a glossy surface, but the prints need not be glazed: some people consider that the reflections from a glazed print are distracting. Opinion generally favours a warm tone, as black tones appear unnaturally cold.

Transparencies. Transparency plates are obtainable in the 45 × 107 mm. and 6 × 13 cm. formats coated with emulsions which correspond to contact, bromide, and chlorobromide papers. Sheet film coated with a fine grain ordinary or a process emulsion can also be used. These materials provide a range of contrasts which enables a reasonably good slide to be made from most negatives, with warm or cold tones, which can in turn be toned to provide a further range of image colours.

Colour Material. Colour film may be used in the form of sheet film, roll film or 35 mm. film. Some of the additive processes are satisfactory in sizes above 45 × 107 mm., but the reseau on which these processes depend becomes annoyingly visible under high magnification. However, 45 × 107 mm. slides made by the additive processes appear satisfactory if a viewer with lenses of abnormally long focal length is used.

Slides of exceptional beauty can be made in all sizes including 35 mm. on subtractive colour film because of the absence of reseau or grain.

Transposition. If a negative made in a stereoscopic camera is held up to the light with the emulsion facing away, it will appear the right way up and the right way round, but the left hand image will be on the right hand side, and vice versa. The reason for this is that the image

TRANSPOSITION. Each image produced by a twin-lens stereo camera is upside down; on inversion, the left-eye image is on the right hand side of the negative, and the right-eye image on the left. Before they can be viewed correctly in a normal stereoscope, these images must be transposed so that each is on its own side for viewing by the correct eye.

was upside down in the camera: inverting it has brought the frames to the wrong side of the plate. As it is essential that each eye should view the picture made from its own corresponding viewpoint, it is necessary to transpose the pictures. Negatives on film can be cut and transposed. and at one time apparatus for cutting and transposing glass plates could be obtained. (There was a risk of damaging the plate in cutting it.) Similarly, if the positive is on paper or sheet film, the two frames can be cut apart, and mounted in their correct positions.

For making positives on glass, it is usual to use a special type of printing frame called a transposing frame. Several types are made, but the most usual has a central opening of the correct size, surrounded by an opaque mask.

The positive and negative plates overlap at the central aperture, and extend at each side, their positions being governed by a rebate. After the first exposure, their positions are reversed, and a second exposure of the same duration is made.

The length of the rebate is calculated to ensure that the separation of corresponding points on the positives does not exceed 65 mm. in the case of 6 × 13 cm., and 63 mm. in the case of 45 × 107 mm.; but as a small tolerance is allowed in cutting the plates, it may be necessary to adjust the length by gluing thin cards in the end rebates.

TRANSPOSING FRAME. Used for contact printing the images of a transposed stereo negative. 1. The left-eye (right-hand) negative is printed first on the left-hand side of the printing paper. 2. By sliding the negative and paper in opposite directions, the right-eye (left-hand) negative is then printed on the right-hand side of the paper, yielding a correctly oriented stereo pair for normal stereo viewing.

VIEWING METHODS

CC-0. Jangamwadi Math Collection. Digitized by eGangotri Digital Preservation Foundation, Chandigarh

Many experienced workers are able to view slides stereoscopically without apparatus, having trained themselves to dissociate convergence from accommodation. The eyes are fixed on infinity, and the slide, held about eighteen inches from the eyes, is raised into the line of sight. If all goes well, the pair of pictures will fuse, and will be seen in full stereoscopic relief. This technique calls for special ability.

Viewers. Normally correct reconstruction can only be realized with specially designed viewing apparatus. The following are the main types of viewer.

(1) Brewster type viewers. These are box type viewers used for transparencies. They have a pair of lenses at one end, and a slot for the slide at the other. Daylight types have a diffuser behind the slot, but modern miniature types are usually self-illuminated. In some viewers an opaque slide can be illuminated through a window in the top.

(2) Holmes viewers. These are open type viewers, having at one end a pair of well-hooded lenses, which are frequently prismatic. The carrier that holds the slides is adjustable for focusing along a horizontal rod. Viewers of this type are used almost exclusively for opaque slides mounted on standard 3½ × 7 ins. cards.

(3) Cazes viewers. This type of stereoscope, designed by L. Cazes, closely resembles a beam splitter of the four-mirror type, and is used for the examination of stereoscopic pairs taken from the air. The same principle, on a smaller scale, is used in viewers designed for the examination of stereoscopic pairs made on 35 mm. film with a beam splitter, and mounted as 5 × 5 cm. slides. In this case, the mirrors produce images with the required interpupillary separation from positives printed side by side on a single frame of 35 mm. film.

(4) Cabinets. The need for changing the slide by hand is avoided by using a cabinet type viewer. The early types carried a number of slides (usually thirty or more, but models were made which held 300) attached to a continuous chain or band. This was operated by turning a handle, which caused the pairs of prints to appear one after the other in the viewer.

Cabinets of an improved type carry the slides in groups of twenty-five in grooved plastic trays. By operating a handle, each slide in turn is raised vertically into the viewing position, and the eyepieces are obscured during the change.

(5) Special viewers. A number of special viewers exist. Among these is one for using uncut filmstrip. This has an internal prismatic system, which renders transposition unnecessary. Another interesting viewer is made for use with discs which carry seven pairs of positives. These are changed by operating a lever,

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

the eyepieces being obscured during the change.

Other Methods of Viewing. Auto-stereoscopic methods are becoming popular for advertising and publicity. As many as six or more exposures are made with special apparatus, and from the resulting negatives a positive is made which consists of a number of narrow vertical picture elements. This is displayed behind a screen which may either consist of vertical grid elements, or of moulded vertical lenticular prisms. The grid or lenticular elements enable only one aspect to be seen at a time by each eye, and the person viewing can obtain a satisfactory impression of relief at near or distant points within a wide arc.

Photographs made by these systems are sometimes known as parallax stereograms.

Anaglyphs, originally popular in the first quarter of this century, have recently appeared again in magazines. In making an anaglyph, a pair of images printed in ink of complementary colours (usually red and green), is superimposed. When these are viewed through spectacles of similar colours one image becomes invisible to each eye while the other appears in dark grey tones. In this way the correct images for the right and left eyes can be presented as they would appear when viewed normally, and the result appears in monochrome. Carbro, dye imbibition processes, photogravure, and half-tone are all suitable processes for the production of photographic or printed anaglyphs. This method dates from 1891.

A vectograph consists of a pair of stereoscopic transparent images located on each side of a plastic polarizing support, which is backed by a reflecting metallic surface. When viewed by reflected light, the images are polarized in two separate planes at right angles to each other. A pair of polarizing spectacles is worn when viewing, the eyepieces being so arranged as to select only the image appropriate to each eye.

TRIMMING, MOUNTING AND MASKING

Positives on paper are usually mounted on dark toned card of size 3½ × 7 ins. Prints made from a stereoscopic negative must be cut apart, trimmed, and transposed, but before doing so they are first marked. This is best done by reversing the print, and drawing a light pencil line from the centre of one print to the centre of the other. When separated and correctly transposed, the line cuts the outer edges of the prints.

Care must be taken to trim the prints square, and to mount them at the correct separation. It is important also to see that the prints do not slope at an angle. Inaccuracy will be evident in what is called a "floating edge"—the sign of careless work.

In order to obtain the correct separation, a millimetre rule is used to set a pair of distinct homologous points in the background to the

WINDOW EFFECT. Making the separation of the picture edges the same as the separation of two near point images produces an effect of a picture window located at the same apparent distance as the near points. D, distant image points. F, frame separation. N, near image points. NN must be the same as F, and E_1 as well as E_2 must be the same for each image. Making F equal to DD locates the stereo window in the plane of the distant subject points, behind the foreground.

normal distance apart. A centre line and a base line are ruled on the mount as a guide, using a white pencil, which is easily erased.

Window Effect. It is the customary, but not universal, practice to mount prints or to make transparencies so as to produce the effect of looking at the subject through a thin opaque window. This is done by making the separation of the edges of the mask or prints equal to the separation of a point at the distance at which it is desired to locate the imaginary window. The distance chosen is usually 3, 6 or 9 feet, and the separation can be calculated.

In practice, it suffices when trimming prints to do it by a method of trial and error. The rule is as follows:

Trim a little more from the right-hand edge of the right-hand print than you trim from the right-hand edge of the left-hand print, then place the prints together and trim them to the same size. Experience soon shows how much to trim off to give the effect of the distance required.

Masking Transparencies. The following are the main methods of masking:

(1) The mask may be cut from thin black paper with a steel straight edge and a razor blade.

(2) Or a mask may be built up on the slide or cover glass with adhesive black binding

tape. (It should be noted that cover glasses will not enter the grooves of some types of automatic viewers.)

(3) Masks can be ruled with a draughtsman's ruling pen, using an opaque quick-drying black varnish.

(4) Masks may also be printed photographically by giving a second exposure under a masking negative made by sticking opaque black paper over the picture area on the face of a cover glass.

Titles can be printed in white ink on the back of card mounts, or on the central space of the mount in the case of transparencies.

Mounting 35 mm. Pairs. 35 mm. pairs are usually mounted with self adhesive tape on cut-out mounts or on commercial card mounts. As an alternative, there are commercial metal or plastic mounts on which the films are correctly located by means of projections moulded or pressed in the material of the mount.

The adjustment of the small pieces of film over the apertures of a cut-out mount must be carried out with precision: it is difficult to do so without mechanical or optical assistance, and it is an advantage to use a special mounting jig sold for the purpose.

This holds the films in the correct position during mounting.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

STEREOSCOPIC ACTIVITIES

The interests of the stereoscopic photographer are rarely catered for by the average photographic society, but there exist in Britain, France, Canada, Australia, and America, societies devoted to the subject.

British. The oldest is The Stereoscopic Society, with headquarters in London. Founded in 1893, it circulates print and transparency portfolios in Britain, America, Australia, New Zealand, and Canada, and has also a local transparency folio circulating only in Britain. The Society also holds meetings, and organizes reunions and outings.

Foreign. In America, there is an active branch of The Stereoscopic Society, and also The Stereo Guild, which circulates 35 mm. transparencies. A number of local societies either specialize in or cater for stereoscopic interests.

In France, the Stereo Club Francais holds monthly meetings in Paris, and circulates an illustrated monthly bulletin.

Two major exhibitions in Great Britain, and several in America, have classes for stereoscopic slides. K.C.M.S.

Book: *Stereo Photography*, by K. C. M. Symons; *Stereoscopy*, by N. A. Valyus (both London).

STERRY PROCESS. Forebath for producing a soft print from a contrasty negative. The exposed print is immersed in a 1 per cent solution of potassium bichromate or ferricyanide. After about a minute, it is drained and transferred to the developer for normal processing.

While the process softens the gradation of the print it tends to change the image colour from pure black to warm black with a greenish tinge.

Potassium ferricyanide or bichromate both tend to make the developer inactive and may cause stains, so the developer must be changed frequently.

STIEGLITZ, ALFRED, 1864–1946. American photographer, editor of *Camera Work*, 1903–17. Studied engineering and photography in Berlin 1882–90, then worked for five years in the family photo-engraving business in New York. Stieglitz condemned artificial picture making and advocated straight photography of life, opened up by the hand camera. Founded the Photo Secession, 1902. Exhibited pictures of *avant-garde* artists as well as photographers in his New York gallery "291". A prominent exhibitor at international photographic exhibitions and influential leader of American photography for forty years. Received Progress Medal of the R.P.S. 1924. Biography by Waldo Frank (New York, 1936).

STILB. Photometric unit of brightness (luminance) of a light source or illuminated object in terms of intensity per unit area, equal to one candle (candela) per square cm.

See also: *Light units.*

STILL LIFE. To the photographer, still life subjects offer opportunities for experiments in composition, lighting, colour arrangements, studies in texture reproduction and so on. They have the advantage of requiring little space, and a wide variety of effects can be achieved with simple lighting equipment.

The basic essential of all still life work is a satisfying, self-contained arrangement of shapes. From this point of departure the photographer can branch off into a number of directions. He can use shadowless lighting technique so that all the emphasis falls on the tones of the subject, or he can employ strong lighting to present his subject in terms of shadow patterns or contrasted surface texture. He can project the shadows of his subject on to the background or foreground so that the shadows themselves become a part of the subject, or he can light the background to kill the projected shadows so that the whole interest is once more framed within the subject.

The best type of camera for still life work is undoubtedly a technical camera of at least quarter-plate size, with a focusing screen and a selection of lenses.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

A reflex camera is excellent, but whatever the camera, it must be possible to examine the image full size on a focusing screen.

A long focus lens is essential so that the subject can be photographed from a fair distance, to ensure good perspective. A wide-angle lens is useful for special effects, such as deliberately distorted perspective. The maximum aperture of the lens is unimportant since the exposure can be of any duration without fear of subject movement. It is frequently desirable to stop the lens well down, in order to achieve overall sharpness.

The only props of any importance are one or two large sheets of thick paper of various tints to use as background material. As a rule the background should be unobtrusive, and for that purpose it is always safe to stand the subject on a large sheet of paper and curve the paper up behind to form the background.

Books: *Camera Close-up*, by O. R. Croy (London); *Creative Table Top Photography*, by E. Heimann (London).

STIRRING ROD. Glass or plastic rod used to stir solutions while dissolving chemicals. Some stirring rods have a thick disc at one end for crushing tablets, crystals, etc., to make them dissolve quicker. Some photographic thermometers also have a thickened end for use as stirring and crushing rods.

STOCK SOLUTION. Processing solution which needs only to be diluted with another chemical or to be mixed with another stock solution to be ready for use. Developers which will not keep in normal solution are often stored as two separate stock solutions which will keep indefinitely apart and be always ready for mixing when required.

See also: *Solutions.*

STOP. Originally, the term referred to a metal plate with a hole in it which was inserted through a slot in the mount of early lenses to act as a fixed diaphragm. Stops with holes of different sizes could be interchanged to alter the working aperture of the lens. Each metal plate was associated with the corresponding *f*-number, and nowadays it is customary to refer to the diaphragm settings as stops whether they are formed by a perforated plate or a variable iris diaphragm.

See also: *Diaphragm.*

STOP BATH. After a negative or print has been developed, it is usual to rinse it in clear water for a minute or so before transferring it to the fixer. In these circumstances development does not stop completely for some seconds.

Normally the slight amount of extra development that takes place is not important but there are times when it is desirable to end development decisively with a special stop bath. A solution of 2–5 per cent acetic or citric acid, or potassium metabisulphite is commonly used for this purpose. It immediately neutralizes the alkalinity, and thus the activity, of the developer.

Commercial stop baths sometimes incorporate an indicator dye to show at a glance whether the acidity is still sufficiently high. When the stop bath is exhausted, it changes colour.

An acid stop bath should always be used after a high speed developer and for hot weather processing.

An acid hardening bath acts as a stop bath and also hardens the gelatin.

See also: *Hardening bath.*

STOPPERS. Ordinary corks are unsuitable for bottles of photographic processing solutions because they rapidly become soggy and disintegrate. They can be made to last longer by being soaked in hot paraffin wax, but even then they are never completely reliable for more than short-term use.

Glass stoppers are not affected by processing liquids, but they are by no means ideal. Their greatest drawback is that they tend to stick stubbornly if the bottle has been left for any length of time and the liquid has crystallized around the neck.

A smear of vaseline applied evenly around the stopper will prevent it from sticking, but it is apt to make the fingers greasy and cause finger marks on any sensitized material handled afterwards.

A glass stopper that has become jammed in the neck of the bottle can often be freed by tapping it smartly on the side with the handle of a table knife.

Another popular method is to wrap a cloth soaked in hot water around the neck of the bottle to expand it away from the stopper.

Rubber is by far the best material for stoppers for photographic solutions. It is not affected by any of the normal chemicals, and it cannot become jammed in the neck of the bottle. Encrusted solution can easily be washed off the surface, and the resilience of the material means that the stopper gives a completely air- and solution-tight seal. Rubber stoppers can be bought in all sizes, and many photographic chemicals are sold in rubber-stoppered bottles which, when empty, can be used again for stock solutions.

For some purposes, plastic screw caps may be better than rubber stoppers; they can be screwed on tightly without any fear of them coming undone again.

Plastic stoppers are now also being made and possess the same advantages as rubber stoppers.

See also: *Bottles.*

STOPPING DOWN. Decreasing the size of the lens aperture—i.e. using a smaller stop. This may be done either to increase the depth of field covered sharply by the lens or to control exposure.

With field cameras, single lens reflex cameras, and all other types in which the image formed by the taking lens is focused visually on a ground glass screen, it is always easier to focus on the principal plane with the lens at its widest aperture. Focusing done at wide aperture is the most accurate, since the acceptable depth of field at a wide aperture is comparatively small, and hence the transition from sharpness to unsharpness is most noticeable. Afterwards the lens aperture is reduced to a value (found either by actual inspection or by referring to a depth of field table) which gives the required depth of field.

If the lens has to be stopped down considerably, the image becomes difficult or impossible to see. In numerous reflex cameras this problem has been solved by a pre-selecting mechanism. This enables the user to focus at full aperture and then press the shutter release normally. Before the shutter actually operates, the diaphragm is automatically stopped down to a pre-selected value.

Stopping down the lens also reduces the amount of light passing through, and together with the shutter speed controls the effective exposure.

When taking flash photographs with open flash technique the usual way of controlling the exposure at a particular flash-to-subject distance is by stopping down the lens. In fact the flash exposure is expressed in terms of a guide number which is constant for any one film speed, and any one type of flash bulb or flash unit, and which is the product of the distance and aperture number.

Stopping down may also be necessary in enlarging, after focusing the image visually at the full aperture, to increase the exposure to a manageable length. If the exposure is made at full aperture, it may be too short to be estimated accurately, and leaves no time for "dodging" and other forms of control during printing. Stopping down also assures better overall sharpness of a print in the case of an enlarger which may not be aligned quite accurately. It becomes essential when the planes of the paper and negative are deliberately tilted with respect to each other to correct converging verticles.

STORAGE OF SENSITIZED MATERIALS. All kinds of light-sensitive material tend to lose speed and deteriorate in the course of time. There are many reasons for this. Some are beyond the control of the purchaser—e.g., the effect of impurities in the emulsion support—but the conditions under which the materials are stored have a great bearing on how long they will keep in good condition. In general, if films, plates and papers are stored in a cool, dry, dark cupboard, away from the fumes of gas or open fires, or—most deadly of all—sulphide solutions, they will lose none of their original speed or quality at least up to the expiry date given by the makers, and generally for very much longer.

See also: *Filing negatives and prints; Film storage; Keeping qualities of materials; Polar photography; Tropical photography.*

STREAK CAMERA. Special type of high-speed cine camera which records an image as a continuous spread-out picture rather than as a series of separate frames. This image needs special viewing equipment to analyze it and reconstitute individual pictures.

See also: *High-speed cinematography.*

STRESS MARKS. Streaks and other areas of density on a developed photographic image caused by pressure or friction on the emulsion before development.

This form of pressure can quite easily render parts of an emulsion developable just as if they had been exposed to light.

See also: *Faults.*

STRIKE CAMERA. Special cine camera mounted in aircraft to record "strikes" or hits during aerial gunnery practice. There are two main types: (a) 16 mm. cameras with a long focus lens mounted alongside the guns of an aircraft to record the target during bursts of firing; and (b) 35 mm. cameras with wide-angle lenses mounted in radio-controlled target aircraft to photograph projectiles or missiles approaching the target. The latter type of strike camera often works at high framing rates and may need special protection to permit recovery of the film if the target aircraft crashes.

See also: *Aircraft camera; Air force photography; Gun camera.*

STRIPING. Process of applying a narrow strip of a magnetic oxide layer to a cine film for subsequent sound recording. This narrow strip, commonly known as the stripe, may be coated direct on the emulsion surface of the film during manufacture (pre-striped film) or after processing (post-striped films). Alternatively, the stripe may be coated on a very thin plastic support and the latter applied to the film.

Dimensions and positions of magnetic stripes on different types of film stock are laid down by various standards.

See also: *Sound recording; Sound synchronization.*

STRIPPING. There are times when it is useful to be able to remove the film from a glass plate or celluloid support and retain the negative image intact. If the glass of a plate

negative or lantern slide is cracked, the emulsion can be stripped off and transferred to another plate.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

When large numbers of plate negatives or slides are to be stored for reference, it is more convenient to store the emulsion film without its glass support.

Stripping film, which could be peeled off the glass plate, was mentioned by Frederick Scott Archer in his communication of the collodion process in March 1851. Other methods of stripping the negative from its glass or paper support were put forward by Alexander Parkes (1856), C. M. Ferrier (1857), Leon Warnerke (1875), Thiébault (1883), Georges Balagny (1883). George Eastman introduced stripping film for use in the Eastman-Walker roller-slide in 1886.

Some printing processes reverse the image, left to right. In such cases it may be more convenient to strip the film off the plate and put it back reversed so that the print appears the right way round.

There are several ways of removing the film. The quickest methods rely on hydrofluoric acid which is dangerous to handle because it attacks glass and calls for special containers and processing vessels.

It is generally wiser to avoid using this acid. The methods described below may be slower, but they are completely safe and can be carried out with the normal darkroom equipment.

Methods. The simplest method is as follows:

(1) Prepare a solution of:

Potassium carbonate	90 grains	5 grams
Glycerine	100 minims	5 c.cm.
Formalin	100 minims	5 c.cm.
Water to make	10 ounces	250 c.cm.

(2) Filter off the precipitate.

(3) Soak the plate for 30 minutes in the solution.

(4) Drain, wipe, and allow to dry slowly for at least 12 hours.

(5) Cut through the emulsion all round with a sharp knife about ⅛ in. from the edge.

(6) Raise one corner of the film with the point of the knife and peel the whole film layer off the glass.

The following method is suitable for either plates or films but it has one disadvantage: it increases the dimensions of the film by about 3 per cent.

(1) Soak the negative in this solution:

Caustic soda	100 grains	5 grams
Formalin	¼ ounce	6 c.cm.
Water to make	10 ounces	250 c.cm.

(2) When the emulsion begins to leave the support, transfer the plate or film to the following solution:

Hydrochloric acid	½ ounce	12·5 c.cm.
Glycerin	½ ounce	12·5 c.cm.
Water to make	10 ounces	250 c.cm.

(3) Float off the emulsion and squeegee lightly down on to the new support while still wet.

A suitable adhesive for sticking the film down on to the new support is made as follows: soak 0·25 grams (4 grains) of gelatin in 50 c.cm. (2 ounces) water, dissolve by heating, and add about 10 drops of formalin. Coat the glass with this solution immediately before applying the wet film.

The following method allows the dried emulsion to be stripped off a glass plate:

(1) Soak the negative in water for at least an hour.

(2) Transfer it to a saturated solution of potassium carbonate in water and leave for 5 minutes.

(3) Wipe off the surplus solution and cut through the film ⅛ in. from one edge.

(4) When dry, insert the point of a knife in the cut and the film will peel away.

Stripping Materials. There are also several photographic processes which rely on stripping the emulsion from the support. For this purpose special transfer or stripping materials are available.

These sensitive materials usually have a specially hardened emulsion, coated on top of a layer of unhardened gelatin. When the material is soaked in warm water, the soft gelatin dissolves and allows the emulsion layer to be stripped away from the film or plate support with ease.

The surface of the final support may have to be prepared to receive the emulsion by being coated with a layer of gelatin or other suitable adhesive.

In the process of being transferred from one support to the other, the image is reversed from left to right. If it is to appear the right way round, it is transferred twice: first to a temporary support of non-adhesive plastic or waxed celluloid, and then to the final support.

Negative transfer emulsions are mostly used in photomechanical work. In the form of positive materials they are used in three-colour photography.

With processes like Carbro—where the three colour images have to be brought together on one support the stripping (by transfer to a temporary support) takes place during the development procedure.

Silver halide stripping films have also been used for producing the etching resist of photogravure cylinders as one alternative to the traditional carbon tissue.

Transferred positives are also used for decorating walls, ceramics, and other surfaces with photographic images. The emulsion may in certain cases even be transferred to the final support first and then exposed and processed in position.

This method is used in making templates and similar industrial work. L.A.M.

STROBOSCOPIC FLASH

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Electronic flashes fired repeatedly at high frequencies of hundreds to thousands of flashes per second. This method has various applications in speed photography and motion study.

Technically a stroboscopic flash unit is based on an electronic flash discharge circuit, with certain modification to permit a high flashing rate.

Historically, electronic flash lighting is almost as old as the negative-positive photographic process, since W. H. Fox Talbot used both about one hundred years ago. True, he covered only a small subject with flash, but his writings prophetically describe the modern electrical flash equipment, as used in photography today.

Theory of the Single Flash. Light is produced when electrical energy stored in a charged condenser is discharged into the flash tube. During the discharge, the instantaneous power is very large (it may be as much as several million watts). However, the practical criterion is the light energy or exposure—i.e., the integral of the light power in candle power during the flash time in seconds.

Possibly the most important component in a flash unit, other than the flash lamp, is the condenser (or capacitor). This accounts for most of the weight, volume and cost, of the usual equipment. The capacitor is the energy storage component of the circuit. It can take in energy at a slow rate over a period of seconds or even minutes and then discharge it into the lamp in a fraction of a second at the required megawatt rate. Many of the advances in modern electronic flash equipment design have been concerned with improved capacitors and further improvements are expected.

Electronic flash tubes are made in many sizes and forms, such as straight, U, or spiral shapes, as required for different applications. The gas pressure and electrode spacing are arranged so that the tube will not flash by itself in most applications. But when a triggering pulse is applied to an external electrode, internal ionization results, and the tube flashes.

Most of the flash tubes used today are filled with xenon gas at a pressure of a fraction of an atmosphere. A series of 1 microsecond exposures of the arc in a typical tube made with a magneto-optic shutter shows that the arc starts as a narrow filament adjacent to the flash-tube wall on the side of the external triggering electrode. Soon, if the energy is sufficiently large, the arc filament enlarges to fill the entire flash tube.

Flash duration for a specific flash tube and circuit is best defined by plotting the light as a function of time. This shows the initial delay, the initial rise, the peak, and the decay of the light. From a practical standpoint, the actual duration is negligible, if the motion of the subject is effectively stopped. One practical way to indicate duration is to define it as the time between the initial and final instants when the light is 1/3 of the peak.

The output of a flash tube is the integral of the light against time. An approximate value can be obtained by taking the product of duration by the peak light. If the peak light is measured in candle power, and time in seconds, then the output will be in units of candle-power-seconds. The lumen-second output is greater by a factor of 4π, or about 2·5, when the angular asymmetries of the flash tube are considered.

The electronic flash tube has a most unusual volt-ampere characteristic, At the start of the discharge, the resistance is infinite, since no current is flowing. Then, as current starts to flow, the resistance drops rapidly to a value of a few ohms for the main portion of the discharge. Finally, the current again becomes zero, and the resistance infinite. During most of the flash, the volt-ampere curve is similar to that of a resistor and the circuit transients can be calculated approximately. Extrapolations to other lengths and diameters of flash tubes can be made as though the tube were a resistor of uniform conductivity. Then flash duration can be estimated from the equation:

$$\text{Flash duration} = \frac{RC}{2} \text{ seconds.}$$

where C = capacitance in farads.
R = resistance.

There is a large variety of electronic flash tubes available for the equipment designer to consider. For any specific case important factors are:

(1) The shape of the tube—linear, spiral, U-shaped, etc. A concentrated lamp is more effective in a reflector, where control of the light is required.

MERCURY POOL CONTROL CIRCUIT. The mercury tube in series with the main flash tube sharply starts and interrupts the current for the flash, and handles high power rates. Permits several thousand flashes per second. C, main capacitor.

CC-0. In Public Domain. Digital Preservation Foundation, Chandigarh

(2) The efficiency at the required energy input. Each lamp has its maximum efficiency for a particular input. The designer should attempt to use the lamp at or near this maximum efficiency point, although in practice it is generally necessary to work at a lower value of efficiency to prevent the tube from overheating and to prolong its life.

(3) The flash duration is a function of the tube and the circuit. If a specific duration is required, the design is usually fixed.

(4) The voltage at which the flash is desired. Item (2) above needs to be reconsidered in terms of voltage, since the efficiency usually drops when the tube is used at low voltage.

There are many times when the most efficient flash tube cannot be used—particularly in stroboscopic work, at high frequency and high power—because of heat storage and heat conductivity problems.

Stroboscopic Photography. The name "stroboscopic" photography has come to mean multiple-flash exposed photographs. Some of the earliest exploiters of this general system are Muybridge, Marey, Cranz, Bull, etc., whose excellent pictures of horses, people, and bullets are still used as examples today. The first multi-exposure photographs were made on a single, moving plate using a slotted disc as a shutter or on separate plates with a series of cameras. The modern method is to use a succession of electronically produced flashes of light separated by accurately controlled intervals of time.

Two practical problems arise when an electronic flash tube is required to run as a stroboscopic source:

(1) The flash tube becomes so hot that it does not function properly—e.g., it may miss occasional flashes, due to not starting properly.

(2) The flash tube fails to de-ionize, thus preventing the capacitor from building up a charge for the subsequent flash. A low value continuous current flows in the flash tube. This condition is called "hold-over".

A hot tube may fail for several reasons: such as, puncture of the glass by the external sparking circuit, short circuiting of the triggering spark by the conduction of the hot glass, or actual collapse of the glass wall of the tube. Failure of a tube to de-ionize results in the continuous arc hold-over condition, where the capacitor charging current flows continuously into the lamp. A further difficulty may result when the tube self-flashes, as the capacitor recharges, due to the lowering of the hold-off voltage by residual ionization or temperature.

Any or several of the difficulties mentioned above are soon experienced when a flash tube is operated at a fast rate of flashing with high energy per flash.

Tubes of quartz are better than glass tubes at high power rates, since quartz has the higher melting temperature.

Several special circuits have been used to operate flash tubes at high rates. Examples are the series mercury-arc rectifier of the pool type, and the hydrogen thyratron, as used in radar modulators.

Mercury-pool Control Tube Circuit. The only new element added to the conventional electronic flash operating circuit is the mercury tube. This mercury tube is connected directly in series with the main discharge current path of the capacitor to the flash tube. Thus the mercury tube must be designed to handle adequately these high-valued peak currents. Immediately after a discharge, the mercury tube de-ionizes quickly, due to its low-pressure, and thereby prevents the previously mentioned hold-over current from flowing in the flash tube.

The mercury tube connected in series is also beneficial in starting a flash tube, because the igniting spark circuit from the mercury cathode goes directly between the two main electrodes. This circuit makes it possible to start flash tubes at very low voltages on the flash capacitor.

Operation at several thousand flashes per second with an input of 1 kilowatt are practical with the mercury-connectron tube.

Hydrogen-thyratron Tube. The thyratron serves as a switch to discharge the capacitor energy into the flash tube. This thyratron has a very quick de-ionization time, thus enabling the starting of the flash tube to be controlled at high frequency, far above rates where the frequency is limited by the slowly de-ionized high-pressure gas in the flash tube. High-pressure (10 to 70 cm.) of xenon gas is required for efficient light production in the xenon flash tube.

The circuit with the hydrogen thyratron is similar to that used in radar transmitters, except that the flash tube is replaced by a magnetron. In either application, the function

HYDROGEN THYRATRON PULSING CIRCUIT. The quick deionization time of the thyratron tube permits higher flashing frequencies. C, main capacitor. T, thyratron tube.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

is the same: namely, to pulse the lamp or magnetron with high-voltage and high-power energy. One of the properties of the hydrogen thyratron is the ability to supply large peak currents without change to the thyratron cathode.

A typical commercial high speed stroboscope using a hydrogen thyratron control tube operates at the following electrical conditions: lamp voltage, 8,000 volts; capacity, 0·01, 0·02, or 0·04 microfarads; frequency, 6,000 max. per second (0·01 microfarads); flash duration, 1 to 3 microseconds; energy per burst, 1,500 watt seconds (limit set by lamp heating).

The flash tube in such equipment must be designed with high resistance to reduce the peak-current requirement of the hydrogen thyratron. This is accomplished by the use of a small diameter (of the order of 1 mm.) and a long arc length (up to 4 ins.). A small percentage of hydrogen gas is mixed with the xenon to reduce the afterglow in the discharge.

The stroboscopic light can also be synchronized with the motion of the film to produce framed pictures for projection. This is commonly done with 16 mm. high-speed cameras. Magnetic pickups are used to trigger the flash lamp at the correct instants of time.

Multi-capacitor Circuits. There is another general type of multiflash equipment that is capable of great speed and flexibility, and which has utility when a limited number of photographs can be used. Each flash for this method is powered by a separate capacitor into either separate lamps or a common lamp. This circuit becomes bulky when a large number of flashes are desired, since each flash requires a separate storage system, as contrasted with a single storage capacitor discussed in the previous method. There is a frequency limit set by trigger-tube de-ionization for these last two circuits, even if one operation is used. Control air-gaps with three electrodes triggered by a time-delay element can be used.

MULTI-CAPACITOR CIRCUIT. A series of separate capacitors are discharged in turn into the same flash tube. Unit is flexible but bulky. C, power capacitors. G, controls gaps. T, time delay units for triggering the successive flashes.

Applications. Stroboscopic flash has two main applications: analysing a rapid movement by photographing successive phases on one film or plate, and arresting a rapid cyclic or other periodic movement for visual observation and photography.

Examples of the first kind are multiple photographs of dancers, hurdlers, etc.; the classical one was a shot of a golfer driving off. For this two flash tubes were used, each driven by a mercury pool tube. Each flash tube was operated from a 10 watt-second charge at 100 flashes per second. The power into each lamp was about one kilowatt. Normally, such a lamp will soon overheat unless it is artificially cooled, but this tube did not overheat, since the operation time was only half a second.

A bullet in flight was taken by multiflash photography with a xenon tube operated at 6,000 flashes per second, with about half watt second per flash for a brief period. The bullet was photographed against a background of reflecting material to reflect the light of the lamp which was mounted directly above the camera lens. The film was a strip of 35 mm. film. The flashing frequency was controlled by an electronic oscillator. There was no blur on the continuously moving film, since the exposure was only about one microsecond in which time neither the bullet nor the film had moved appreciably. In this method there is no need for synchronization between the film motion and the frequency of flash, it is only necessary to move the film so fast that the photographs do not pile up on top of each other.

For the second type of application the flashing frequency is matched to the frequency of the cycle of the movement. As a simple instance, a machine component rotating at 5000 revolutions per minute may be illuminated by one or more stroboscopic tubes flashing at 5000 flashes per minute. If both rates are accurately matched the flash will illuminate the same phase of the movement every time and the component will appear stationary. It can then be observed or photographed in that way —a useful procedure in industrial photography where it is not practicable to stop a machine for picture taking.

By slightly shifting the phase of the flash between successive exposures a whole picture series of complicated movement cycles is obtained permitting the study of motion that would be impossible to observe in any other way.

STUDIO

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Room equipped and set aside for photography—in particular, for portraiture. By extension the term is also applied to any business in which photographs are taken in a studio on the premises—e.g., portrait studio, commercial studio.

Size. There is no upper limit to the size of a studio. Commercial studios may be big enough to accommodate large objects like motor cars and well spaced groups of people. At the other end of the scale it is possible to be more specific. It is desirable for the studio to be long enough to permit full-length portraits to be taken with a normal angle lens. So assuming a maximum subject height of 6 feet and allowing another 1 foot clearance above and below—i.e., 8 feet altogether—the distance of the lens from the subject can be obtained by simple proportion. If the lens is, say, of 6 ins. focal length working on a quarter-plate ($3\frac{1}{4} \times 4\frac{1}{4}$ ins.) negative and D is the distance from lens to subject, then

$$6 : 4\tfrac{1}{4} = D : 8$$

and $D = 6/4\frac{1}{4} \times 8 = 11{\cdot}3$ feet approximately.

This is the bare distance between the lens and the subject. To this must be added the focal length of the lens (in this case, 6 ins.), at least 3 feet space between the subject and background, and another 2 feet behind the camera for the photographer. So that, no matter what the size of the studio camera, if it is equipped with a lens of normal focal length the studio must be at least 17 feet long to give full length portraits with a reasonable amount of elbow room for the photographer and subject.

For normal operations, the studio should be half as wide as it is long and the ceiling, overhead cables or roof girders should all be over 10 feet from the floor. All the above dimensions are the least that should normally be accepted in choosing or planning a studio. It is of course possible to work in a smaller space with smaller subjects or with a greater amount of inconvenience.

Daylight Studio. In the early days of photography there were no suitable forms of artificial lighting, and the photographer who wanted to work indoors had to use a specially constructed or adapted room which admitted the maximum amount of daylight (but not direct sunlight) and was equipped with some means of controlling it. Daylight studios are still in use today in out-of-the-way places without an electricity supply.

The majority of daylight studios have a glass roof facing north (in the northern hemisphere) and sloping at an angle of not less than 60°. This minimum angle ensures that the direct rays of the sun will not shine into the studio. It applies only to latitudes around 50°; towards the equator the angle must be increased and eventually it becomes impossible to keep out the direct rays and they must be diffused with a curtain of fabric or by white-washing the glass. In addition to the roof, the wall away from the sun should be glazed down to a height of about 3 feet.

Roller blinds are fitted directly under the roof and over the glazed part of the wall to allow the light to be controlled. There should be two sets of blinds—one of opaque fabric to cut off the rays completely, and the other of light diffusing muslin or similar translucent cloth. Each set of blinds should consist of a separate roller and blind at the top and bottom of the glazed area so that the light can be cut off at either end.

One type of daylight studio was glazed at one end only—immediately over the sitter—while the other consisted of a low unlighted annexe in which the photographer could focus the image without the need for a focusing cloth.

A favourite method of constructing a daylight studio extension to another building is to make it in the form of a glass lean-to against the side of a wall facing away from the sun.

The great objection to daylight studios is the unreliability of the daylight and its variation from hour to hour and season to season. For this reason daylight studios have now been almost entirely superseded by those entirely lighted by electricity.

Professional Studios. In professional studios there is a wide variation in design, size and equipment, but the basic furnishing conforms to a regular pattern. There is a camera with interchangeable lenses (or a range of such cameras) mounted on a substantial camera stand which can generally be moved about or locked in position at will.

Lighting consists of banks of overhead and side floodlights for general illumination of the subject area; one or more high power modelling lights; spot lights for background lighting and effects, and various white reflectors and mobile screens. The background may be provided by roll-up fabric back-cloths, by portable "flats", or there may also be a translucent screen with space behind for projected background scenes. In addition to normal lighting, many modern studios are now equipped for multiple electronic flash lighting.

If the studio has any ordinary windows, these can be completely blacked out by roller blinds or shutters so that the lighting is limited to the controlled electric sources.

The studio is usually lavishly wired, with socket outlets at many points in the floor or suspended from the ceiling. The object of this is to reduce the number and length of trailing wires to a minimum.

"Props" vary according to the nature of the work undertaken, from comfortable chairs for a portrait studio to comprehensive kitchen

fittings for a studio specializing in food photography, recipe illustration and the like.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Amateur Studios. Few amateurs are fortunate enough to be able to set aside a room exclusively to serve as a studio and even camera club studios have to revert to normal use after the club night. So the problem is to equip the studio with lighting and other props that can be quickly brought out and arranged and just as quickly dismantled and packed away.

Clubs usually have no difficulty in finding a room of the right size, and they can nearly always count on having a cupboard where the equipment can be stored from one club night to the next. The worst problem is apt to be the electricity supply. Too often the room has only a single power plug which is neither conveniently placed nor of a high enough rating to take the lighting load. It is of course possible for the club to have the necessary extra points installed, but the expense can be considerable.

Where this is out of the question, the best plan is to connect a heavy cable from the nearest power point to a portable box fitted with a number of outlets up to the maximum load on that particular circuit—e.g., a 15 amp outlet on a 230-volt supply would safely provide for a load of 3,000 watts consisting of four Photofloods (1,200 watts), two 500 watt spotlights (1,000 watts) and a number of 150 watt tungsten lamps for effect and focusing lights. The cable and portable distribution box enable all the lights to be kept on short leads and avoid numbers of trailing cables between the power plug and the subject position.

Backgrounds and light reflectors in such circumstances must be either sheets of fabric tied on to collapsible frames, or arranged like roller blinds and hung from the picture rail. Other properties must be limited to the furniture normally in the room supplemented or disguised by draped fabric. An effective method of providing unusual backgrounds is always available in the club projector; if this is quite powerful, it can be used for projecting made-up transparencies of a suitable nature from either in front of or behind a suspended sheet of white or translucent material.

Home Studio. The amateur who works indoors at home must be prepared to improvise and compromise to a much greater degree. His studio is usually the living-room or a bedroom which can only be spared from its normal functions for an hour or two at most. The room itself is usually not long enough and there is insufficient space to accommodate lighting equipment on safe, broad bases.

The best way of solving the problem of the length of the room is to shoot through the open doorway and have the subject on the far side of the room. This adds 3 or 4 feet at least to the camera-to-subject distance and gives a much better perspective.

Everything should be cleared away from the studio end of the room, leaving it completely bare. If the carpet has an assertive pattern, it should be covered over with a plain, neutral-tinted sheet and a similar sheet should be suspended from the picture rail—preferably on a batten—to form the background. It is sometimes convenient to use a piece of background material long enough to cover the floor under the subject as well. This gets rid of the horizontal line at the floor level, but it also makes the background bulkier to handle and store.

If there is a fireplace at the only convenient end of the room, it is better to arrange to let the fire go out for the evening and heat the room with a portable heater. The background can then be hung so as to cover the fireplace, leaving the whole of the end of the room clear for the subject and lamps.

The portable distribution point described earlier is the best method of supplying the electricity for the lighting, and it should always be connected to a 15 amp outlet if more than one Photoflood bulb is being used. It is certain that the room lighting will be wrongly placed to provide any useful light on the subject, so if possible it should be switched off and the subject arranged by the photographic lighting only. One of the best aids to this is a series-parallel switch enabling two Photofloods to be connected in series for continuous lighting and switched on to full brilliance in parallel for the duration of the exposure only.

In the average living-room there is not enough floor space for more than two lighting stands in addition to the subject and the normal furniture. It is generally best to use these stands for the main (modelling) light and the back light, as these generally are used at a reasonable height. For the remaining lights, the type of lamp reflector that stands on a table or a chair or on the floor or that can be clamped on to any handy piece of furniture or on to the edge of a door at any height may be used. This type of support is much more rigid than the folding telescopic stand, and it calls for no extra space.

A typical amateur studio set-up would consist of a background sheet suspended from the picture rail along one end of the room and lighted by a Photoflood lamp in a reflector standing on the floor or on a chair. Main lighting would be provided by a Photoflood lamp in a reflector and on a stand. Another Photoflood lamp in a reflector for fill-in lighting would be clamped on to the back of a chair or other suitable item of furniture. Back lighting, or rim lighting, to highlight the hair, etc., is generally given by a spotlight, but a flood in a reflector, and on a stand, can do the same job provided the lamp is placed so that it does not shine straight into the camera lens.

This basic set-up would be satisfactory for head and shoulder portraits, but would have to be considerably boosted for full-length figures. The most desirable additions would be a spotlight and an adjustable light reflector—e.g., a square of plywood painted white on one

side and mounted on a universal clamp-on tripod head.

A set-up of this kind can be stored in an ordinary cupboard; it will transform a normal living-room into a studio in about a quarter of an hour and take no longer to clear away.

CC-0. Anannigam Digital Preservation Foundation, Chandigarh

The amateur who is lucky enough to have a room that he can reserve exclusively for photography has no conversion problems. He can afford to have his lamps mounted on adjustable stands, and permanent wiring run to conveniently-sited points not only along the floor but along the picture rail. In such circumstances it is a great convenience to have one perfectly plain wall to serve as a background. If the skirting board can be removed and the wall plastered and distempered or papered right down to floor level it will get rid of a perpetual distraction. In addition to the wall surface (which gives a background free from folds and creases) there should be a roll-up background mounted on brackets near the ceiling and long enough to curve forward under the subject. All wall and ceiling surfaces should be light cream or off-white.

The electric wiring should allow for room heating as well as photographic lighting: it should not be necessary to use the heating point for any of the lamps.

Finally, the floor should be covered with plain unpolished lino or drugget.

Power Requirements. The total amount of electric power consumed by the studio will depend on its size, the type of work undertaken, and whether heating as well as lighting is provided by electricity. The average amateur equipment can usually be connected to the normal lighting and power outlets of the room without overloading the distribution system of the whole house (in case of overloading the fuses of the individual lighting or power circuits will blow first).

On the other hand, the maximum demand of a professional studio is apt to exceed the capacity of the average distribution system and may call for special provision in the form of heavier supply cables, metering and wiring. In any case it is advisable to add up the individual consumption of all the apparatus likely to be switched on at one time and make sure that the supply arrangements are adequate.

A typical commercial studio undertaking some film photography will require about 10 kilowatts (i.e., about 45 amperes at 200–250 volts) for lighting alone and double that figure if sub-standard cinematography is included. A purely portrait studio can operate on 5 to 10 kilowatts, while the amateur will have to be satisfied with a maximum of about 2½–3 kilowatts (i.e., 10–15 amperes at 200–250 volts) if he wishes to run all his lighting off the normal room wiring (e.g., 15 ampere power plugs). The consumption of any heaters, motors, dry-mounting presses and other equipment must be included in the above totals.

Wiring. Modern studios are wired on the ring main system whereby a number of 13-amp. socket outlets are supplied by a closed loop of power cable. Current to any socket can travel around the loop in either direction, thus doubling the current-carrying capacity of the system. In Great Britain, the main fuse supplying the ring is rated at 30 amps. so that it is only likely to blow if a short-circuit occurs on the distribution cable itself. Each separate piece of equipment carries its own correctly rated cartridge fuse in a holder, inside the plug connecting it to the mains. The result is that a short circuit in the equipment simply blows the fuse in the plug and leaves the rest of the system unaffected.

Ring mains outlets are designed to take standard 13-amp. fused plugs which have flat pins so that there is no danger of inserting an ordinary round pin plug. This type of circuit is particularly advantageous in a professional studio since it allows further power socket outlets to be connected straight on to the ring instead of having to be wired all the way back to the main distribution panel.

A large studio may require more than one ring to carry the total load, but a single ring should be adequate for an amateur set-up.

To be on the safe side any commercial or professional set-up should be installed—or at least checked over—by a competent electrical contractor. The amateur can always get the representative of his local electricity authority to tell him if his lighting arrangements are likely to overload the supply equipment. F.P.

STUDIO PHOTOGRAPHY

Even the smallest town nowadays has at least one professional photographic studio which caters for the photographic needs of the general community. It is an essential part of the make-up of a typical township, and although businesses of this type vary in size and scope, they conform to a fairly regular pattern. There is usually a retail shop with a photographic studio attached, and facilities for taking portraits, weddings, etc., and a certain amount of industrial and commercial photography both on and away from the premises.

Premises. In the days before electricity became available for lighting photographers had to depend upon daylight and the photographic studio of the past was constructed largely of glass. The roof faced north to secure even, shadowless light and it was usual for one or more of the walls to be in the form of a large window. Because of these vast expanses of

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

SIMPLE SMALL-TOWN STUDIO. Scale about 1 in. = 18 feet. O, office. F, finishing room. S, studio space. DR, darkroom. CR, changing room (situated near darkroom for easy plumbing). R, reception room. E, entrance. The arrangement is rather crowded, especially as far as processing is concerned (a single darkroom serves for developing, printing, chemical mixing, and chemical storage), but it frequently is dictated by the facilities and space available in small premises. Display shelves are fitted in the reception room which sometimes also serves as a shop, at least for selling films and materials and for accepting developing and printing orders of customers' films.

glass it was difficult to keep the place warm in winter and cool in summer; it was also difficult to make it waterproof. The essential equipment included an enormous camera with its black focusing cloth, a rose-garden background and an assortment of decorative furniture. This was the photographer's workroom.

The studio of today is a very different proposition. Daylight can be dispensed with altogether, backgrounds are plain and easily interchangeable, furniture is comfortable, lighting units are efficient and portable and the camera for many assignments can be small and compact. Modern heating and ventilating appliances help to make clients comfortable and the style of decoration is chosen to impart a feeling of restfulness and security.

Although a studio may be intended primarily for portraiture it is usual (particularly in the country and small-town businesses) for all kinds of photographs to be taken in it. These include copying, photographing paintings and taking photographs for catalogue illustrations, as well as photographing many other small objects and collectors' pieces. Only a few exclusive specialists can afford to keep a studio solely for portraiture.

Planning. The planning, organization and running of a studio and workrooms are essentially matters of economics. It is of little use building up a fine connexion if by mis-management and lack of organizing ability the money earned is wasted by general inefficiency of the supporting departments. Whatever the reason for which photographs are taken, the basic functions of making a photograph are always the same: negatives have to be processed, prints and enlargements have to be made and subsequently washed, dried, mounted and finished. Even a small studio will be severely handicapped if all these jobs are carried out in one or even two rooms. It is much wiser to plan or rearrange the premises so that each section of the work can be conducted in a separate room, and not interfere with the next.

In addition to the studio, office and reception rooms, there should be a small room or cubicle where negative materials are unpacked and loaded into slides, a negative processing room and a printing and enlarging room with separate accommodation for washing and drying.

There should be a separate room set aside for mounting, finishing and retouching. In the darkrooms, provision should be made for wet and dry areas and they should be kept solely for these purposes. This avoids trouble from spotty negatives and prints. It is also worth while, whatever the size of the studio, to set aside a small room solely for mixing chemicals —a job which should never be done in darkrooms or in draughty places.

The layout of darkrooms and benches in all departments should be on the continuous chain principle so that as materials go from one dish or tank to the next they do so without passing over solutions or benches previously used. Every studio layout should be checked by a little time/motion study to analyse the separate movements involved in doing specific jobs and to see that wasteful walking about and reaching up and down are reduced to a minimum. No studio is complete without one or two toilet rooms and cloakrooms a pleasant and comfortable waiting room and a lock-up stockroom where a careful check can be kept of all materials consumed.

A business, artistic or otherwise, can never make healthy progress by neglecting matters such as costing, fixing prices and assessing profits. If the photographer cannot attend to them himself then he should employ someone who can.

EXCLUSIVE PORTRAIT STUDIO. Typical layout for a larger city location. Scale about 1 in. = 32 feet. N, negative processing room. P, printing room. F, finishing room. O, office. OP, private office. CR, changing rooms. SC, special children's studio. S, main studio. Y, waiting room. R, reception room. The finishing and printing rooms are easily reached by the receptionist. Separate negative and positive processing rooms increase the flow of work and the capacity of the business. This type of studio can handle advertising orders (using hired models), as well as normal portrait photography.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

UNIVERSAL STUDIO IN SMALL TOWN. Upstairs location. Scale about 1 in. = 22 feet. R, reception room. E, entrance. S, studio. Y, storage room. CR, changing rooms. P, printing room. DR, general darkroom for loading, film storage, etc. L, laboratory for mixing and storing chemicals, etc. N, negative processing room. PS, photo-finishing printing room. F, finishing room. T, toilets. X, framing room. The studio handles portraiture, commercial work, photo-finishing, framing, etc., for the town as well as for a wide surrounding district. The reception room can also be used as a retail shop.

Photography is now largely a manufacturing process and as such the prices charged for the finished product must bear a fair relationship to the raw materials used, the processes involved and overhead expenses including salaries, depreciation and rents.

The husband-and-wife studio is a combination which has brought success to many enthusiastic workers. In practice, the wife is receptionist/secretary/retoucher/colourist and finisher while the husband takes on the operating, processing and getting business. With one general assistant to handle routine jobs of washing, mounting, making up solutions, etc., this type of studio can profitably undertake work of all kinds.

Studio Layout. The layout and equipment of a photographer's studio should be dictated as far as possible by the kind of work he mainly practices. Whatever type of work is undertaken, it is essential to interpose a small room between the studio itself and the outside world, which can act as a reception-place. Privacy is essential to portraiture, and careful studio work of any kind demands a degree of concentration which necessitates insulation against the voices and eyes of chance visitors.

Except for the most simple passport studio, the portrait studio should be at least 15 × 12 feet in size, with a 9 foot ceiling. Full-length shots require at least 20 × 15 feet of floor-space and a ceiling of 10 to 12 feet is the minimum needed for overhead lighting of standing groups. It is difficult, however, to establish a personal atmosphere for portrait work in too large a studio and a degree of intimacy might be introduced by partially cutting-off a small area decorated in a more domestic fashion. In setting up a studio for the first time, the owner may be unsure of the channels through which his future work will come, so it is wise to install equipment which is adaptable to several different kinds of photography and to avoid apparatus

SUBURBAN PORTRAIT STUDIO. Scale about 1 in. = 11 feet. W, display windows. E, entrance. CR, changing room. R, reception room. S, main studio space. LD, special loading darkroom for reloading plate holders and storing films and plates. DR, general darkroom; used at night and in the early morning for developing, during the day for printing. RT, retouching room, also negative filing room. T, toilet. F, finishing room for washing and drying of prints as well as trimming, mounting, etc. DS, dispatch and mailing room. The studio uses studio and reflex cameras, as well as a roll film twin-lens reflex for child photography

CC-0. Agamnigam Digital Presevation Foundation Chandigarh

which is firmly attached to walls or ceiling until the real need for these is proved.

Backgrounds. As part of the decor, a number of differently textured wall panels may be installed, using genuine materials or some of the excellent replicas offered by display specialists. Brickwork, rough and textured plasterwork, timber weatherboarding and stone-walling are available in simulated form. A panel 8 feet high by 6 feet wide in each is a minimum for general background use, though smaller pieces can be used for head and shoulder work. A realistically painted sky may be used like a theatre cyclorama, when exterior settings have to be built. Rolls of background paper, 9 feet wide, may be suspended from the farthest studio wall, to be pulled down when required. Black, white and middle grey are satisfactory for black-and-white, but many colours are available for colour work. The paper is cheap enough to be readily discarded by the yard, as it becomes dirty or buckled at each use.

Cameras. The general practitioner in photography will need two or more cameras, each with its own set of accessories. However wide the intended scope, it is wise to restrict the number of different formats which are used, if only to avoid need for an impossibly large collection of processing tanks, racks and other darkroom gadgets. The particular choice will depend on the nature of the work itself. Action and ballet photography, reportage, identity portraits, etc., may require 35 mm. equipment, and the ideal choice will be a really sound precision instrument, preferably a single lens reflex, taking inter-changeable lenses.

Some photographers might prefer 120 roll-film as their smallest format, and a single-lens or twin-lens reflex as their most portable instrument.

For portraiture, however, the $2\frac{1}{4} \times 2\frac{1}{4}$ ins. frame is really too small for good quality negative retouching and the old type studio camera on its massive stand is too clumsy for the lively kind of portrait favoured today. A modern technical camera, as used for the bulk of commercial and industrial work, is also quite suitable for portraiture. The 4×5 ins. format is most convenient, and if a roll film adaptor is available the equipment becomes all the more versatile. Lenses of several focal lengths should be part of the outfit, and the camera should have a double extension. General work may be exposed on rollfilm, specially critical portraits may be made with sheetfilm.

For commercial, advertising and technical photography a technical camera with front and rear focusing, all movements, and a triple extension is required. This may be of the range-finder type, rapidly convertible to use as a press-type camera, but with a focusing back into which may be inserted sheet film holders, film magazines, Polaroid adapters and rollfilm holders. Each lens on its own panel is coupled to the rangefinder and includes its own synchronized shutter. More suitable for most studio work is a technical camera of the monorail type. This has more extensive camera movements, but is less useful for action shots.

Whichever of these kinds of technical camera is chosen, it should be mounted upon a sturdy stand, preferably with separately controlled side-tilting and forward-tilting head adjustments. A ball-head is unsuitable. Ideally the studio stand will permit the camera to be placed firmly and securely at any height from ground-level to at least 7 feet above that. Either of them may be pressed into use for coping work, if a separate copy-camera is not installed.

Copying. Even where the amount of copying work does not justify a permanent set-up with its own camera, the work is greatly assisted if a copyboard is fixed to a wall, illuminated by two or four pearl lamps in reflectors, with a pair of rails squared up to it upon which a carriage is arranged to take the technical camera. Alternatively an old studio camera can be adapted and used as permanent copying equipment. Ordinary work may be done with a lens from one of the studio cameras, but for really critical reproductions it is worth obtaining a lens especially made for the job.

Lighting. The small studio should install adaptable lighting equipment which may also be taken to the homes or factories of clients. Equipment must be good and sturdy, and quality should come first, even if it means limiting the number of units which can be afforded. Excellent portrait and simple still-life photography is possible with only a couple of 500 watt spotlights, two diffused floodlamps and one or two 500 watt photopearl reflectors. All should be on well-balanced wheeled stands which can be lowered to within 24 ins. of the ground and raised to 6 feet or more high. If these are fed from loose distribution-blocks with 3-pin sockets, properly earthed, drawing their current from heavier 3-way cables from one or more wall-points, any part of the studio may be rapidly used when working. The cabling serves as feeders on the outside jobs as well, with one or two adapter-plugs to match the local installation.

A single 13-amp ring socket or 15 amp power point will safely feed the above collection of lighting equipment, but it is more convenient and safer still to split the load into two. For more complex projects one or two more spotlights, a couple of the smallest 100 watt "inkie-dinkies" for catch-lights and perhaps one or more "broadsides" of banked 500 watt photopearl lamps, in a trough holding 4, 6 or 8 such lamps together, might be added. A further higher-powered spotlight to simulate sunlight, ceiling battens and troughed rows of photopearl lamps at floor level would make fully competent fashion photography a possibility. Installation should be carefully executed to the highest safety standards.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

In addition to the above tungsten lighting, some kind of flash equipment will sometimes be required. A portable electronic unit, with one extension lamp can deal satisfactorily with child portraiture; but if fashion in colour, food-products and fast-moving subjects are to be photographed, a heavy-duty studio electronic unit with several lamps containing their own modelling-lights, will be needed. Synchronized flash bulb illumination from two or three flash heads is also useful for many varied types of work.

Commercial Photography. The small-town studio will have to undertake a certain amount of commercial work and, if space is limited, some careful planning is necessary to allow both types of work to proceed at the same time. That does not mean that two operators will ever be using the studio at the same time but that it should be possible for sitters to be taken without disturbing a complicated set-up of a subject and without their being distracted by its presence.

For instance, a local engineering firm may require a number of photographs to be taken of a small mechanism or perhaps a layout of tools for a catalogue and because such work cannot be hurried it may occupy the studio for several days. For normal portraiture to be done at the same time, therefore, it must be possible to divide the studio by a temporary partition. In addition, as the lighting of these subjects is usually straightforward, the work can often be done with portable units at the opposite end of the studio.

COMMERCIAL AND ILLUSTRATIVE STUDIO. Designed by owner. Scale about 1 in. = 19 feet. E, entrance. R, reception room for props (used largely in advertising and illustrative work). T, toilet. DS, dispatch room. K, storage room. CH, chemicals rooms; one is intended for storage, the other for mixing solutions. ES, service entrance. Y, film loading room. N, negative processing room. KF, filing room for negatives and prints. P, positive processing rooms. F, finishing room. PS, special printing room for contact prints. The two main processing rooms feed prints from the fixing bath direct to the finishing room by means of service hatches. The frontage of the studio is taken up by display windows.

If it is at all possible, however, commercial operating should be carried out in a separate room because it is essential that sitters should be allowed complete privacy while being photographed. In addition, this work often involves the use of numerous wooden blocks, supporting stands, etc., which it is impossible to keep tidy.

In addition to commercial work on his own premises, the photographer must be prepared to undertake work outside the studio. This will include architectural photographs for estate agents and surveyors, etc., shop windows, local views and factory installations. A progressive worker who is the only photographer in the district will also be expected to attend local functions, photograph people and children in their own homes and, in fact, to record any event or scene for all manner of private, business or official clients.

Wedding Photography. A professional studio undertaking wedding photography should formulate a policy regarding this work and stick to it. The soundest principle is to attend a wedding only when specifically commissioned to do so, with a deposit or understood charge for the service. It is not uncommon for a certain type of freelance photographer to appear uninvited at the ceremony, to take pictures which are rapid-processed and brought back to the reception as proofs by young ladies who hawk them among the guests. What is first seen is often purchased in such circumstances, and unless one meets this method with a similar approach or is covered by agreement with the client, it is doubtful whether wedding photography can be profitable.

Side-lines. It is usual for all but the most exclusive portraitists to sell a range of films and photographic goods and to stock a limited number of side-lines. These include frames of all kinds, coloured miniatures and often pottery and artists' materials. In addition, the small-town photographer will accept amateur films for developing and printing. It is a mistake, however, for the processing to be attempted by a one-man business. Developing and printing business is a specialized branch which, to be conducted economically, must be operated on a large scale by a highly skilled fast working team of operators in workrooms equipped specially for the purpose. If a studio proprietor wishes to handle developing and printing because it brings people into his shop, then the processing should be put out to one of the many firms specializing in the work. The same thing applies to retouching, colour-

ing, framing and perhaps copying. These all represent routine work which, for a start, it is better to pass on to specialists.

CC-0. Panjab University Digital Preservation Foundation, Chandigarh

Colour Photography. So long as daylight can be excluded, there is little difficulty in taking colour photographs with normal studio lighting, particularly if the nature of the work requires the use of negative colour film. Although, ideally, all kinds of colour film should be exposed only by illumination which matches that for which the film is balanced, negative colour film is more adaptable to different kinds of lighting. But all the lamps used must match each other in colour temperature.

The C.P. range of projector and floodlamps covers all reasonable needs from a modified Photoflood of 275 watts, which costs only a few pence more than the common Photoflood lamp, to giant projector lamps used in film and television studios. All are designed to produce light at a nominal colour temperature of 3,200° K. for which the present-day studio colour films are mostly balanced. As they are equally suitable for black-and-white photography, there is no reason why this kind of lamp should not be fitted by a studio which anticipates colour work as part of its business. If the demand will be small, then a set of C.P. lamps can be stocked for use only when required, for the cost of ordinary lamps is slightly lower.

Reflectors should be white or neutral silvered and kept clean. When C.P. lamps become blackened by use, they should be replaced for colour photography, though they can be kept in use for some time for monochrome work.

Reversal colour films which produce transparencies must be exactly matched to the illumination. It is advisable to use either films specifically intended for 3200°K studio lamps, or possibly the type which is balanced for Photofloods (3400°K) with a suitable filter on the camera.

Alternatively, daylight colour film may be used with electronic flash.

Except for deliberately unusual effects all colour subjects must be illuminated with lamps of uniform colour quality. The normal room lighting of the studio should be extinguished, especially fluorescent tubes. Blinds or curtains should be drawn tightly and any areas of brightly coloured walls which are not a feature of the picture itself are best covered with white or neutral cloth or paper.

Colour Processing. When the volume of colour work is great, processing and printing of colour negatives might be carried out on the premises, but good colour prints require a skilled hand and it is advisable for a small studio to send out this work to a trade laboratory. Transparency films in roll and miniature sizes are processed by the manufacturer with the processing cost included in the price of the film. Sheet films are charged separately for processing and this is again worthwhile carrying out on the premises where the volume of work is sufficient.

A further advantage of user-processing is that the results are available much sooner. However, it requires an appreciable outlay on equipment, including temperature control gear.

Book: *The Business of Photography*, by C. Abel (London).

STYLE. Any medium of artistic expression must allow a certain amount of control. The peculiar combination of methods favoured, and the variation of degree in applying them, produce a particular style. The more flexible the medium, the more pronounced the style possible, because the artist is allowed greater scope in selection and emphasis.

When the style of an artist is well developed it shows consistent tendencies—his choice of subjects, the particular range and hue of colours he favours, his special manner of applying the paint, the effects of lighting he chooses—and so on. Any one of these things on its own would not give him style. But the very particular combination of effects he favours and the emphasis he gives to each, add up to a unique and singular arrangement. Alter or vary one of the effects and the sum no longer gives the same answer. That is style.

The medium of photography does not allow the same amount of individual control that is possible, for instance, in painting. But some control is possible; so the photographer can achieve a certain degree of style.

Personal Treatment. There are several ways in which the photographer can influence the final result of his work and thus create an individual style. The first is his choice of subject. He may have a liking for portraiture or he may find a peculiar attraction to landscapes. He may even narrow his outlook to special subjects like trees, or yachts, or flowers.

Next, a tendency to emphasize certain features of the subject may equally be something individual and singular. One photographer may strive to show Nature in his landscapes as rugged and fierce. With the same scene before him, another may—by choice of viewpoint and careful emphasis—depict Nature as delicate and beautiful. This tendency of the photographer can be evident no matter what subject he chooses.

He can regulate exposure to concentrate interest on the highlights in a picture; or on the shadows.

He can vary or at least select the effect of lighting to give the picture depth and shape. Or he can go to the other extreme and display the subject flatly with no differentiation of

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

planes. (Interest then would be concentrated on outline rather than form, pattern rather than shape.) In the same way he can emphasize or play down texture.

By suitably adjusting both exposure and lighting he can introduce predominantly high or low key tones with their attendant effects.

He may arrange the composition to make a picture appear graceful and passive. Or he can vary it to suggest vigour and movement.

By selective focusing he can concentrate interest on only one plane, or give an over-all sharpness to the picture. Or he can use diffusion to give the whole picture softness.

Even blur caused by camera shake or subject movement can be exploited to give a picture spontaneity or a feeling of action.

The photographer who has matured and developed a style will use devices such as these. But it is his actual selection and combination of methods, and the consistent adoption of this pattern, that creates his style. It may not be the result of a conscious effort indeed it seldom is.

Style is dependent on the photographer's background, training and outlook. Generally, the more distinctly individual the photographer's character is, the more consistent and easily recognizable will be his style.

But while style itself is the result of the combination of a mass of details, the final product can only be general. This special pattern of method can only be seen by a broad, over-all examination of a photographer's work. In fact, it is only its constant repetition that makes it style at all.

Style however should be individual. It is an intricate pattern, peculiar to the photographer. Copy it and it becomes unconvincing and lacks the vitality of sincere art. Its development must be spontaneous and not forced, its growth natural and unhurried.

Schools of Style. Just as the individual can have style, so can nations or communities. The style then is no less individual, but rather are the people who contribute to it less individual in their outlook. Such a unity of style among people is known as a school.

Photographs from certain countries will often show this tendency to a common style. It may be the result of national characteristics. Or it may be a changing outlook reflecting economic and social conditions.

When just a group of people share a common style—although often still with personal differences—it is usually the result of a conscious and organized effort. This kind of common purpose inspired many of the great schools of painting. More often than not it begins as a revolt against convention or tradition in art. The unified outlook of the group then favours the natural development of a style.

Natural development—that is the essential condition of style, whether of the group or the individual. And style can only come naturally by forgetting about it.

In a photograph, such a style makes the work original, belonging to one photographer and not any photographer. It is the stamp of the artist that renders a signature unnecessary. Indeed, style is frequently the very means by which unsigned work is identified. J.D.C.

SUBJECTIVE PHOTOGRAPHY. Self-chosen name of a contemporary school of creative photographers with distinct leaning towards non-representational patterns. Initiated by Prof. Otto Steinert in Germany after the second World War and allied in outlook to the Bauhaus after the first World War. The earlier trend arose among amateurs and was more original; the later among young professionals and is more mature in its products.

See also: *Abstract photography.*

SUB-MINIATURE. Alternative name for ultra miniature camera, i.e. still cameras taking pictures 12 × 17 mm. or smaller on 16 mm. or narrower film.

See also: *Ultra-miniature.*

SUB-STANDARD CINE FILM. Obsolescent term for narrow gauge film (8, 9·5 or 16 mm. wide) for amateur cinematography, as distinct from the standard 35 mm. cine film used for professional motion picture work.

See also: *Cine film.*

SUBSTRATUM. Binding layer which helps the emulsion to adhere to the glass or film base.

See also: *Sensitized material manufacture.*

SUBTRACTIVE SYNTHESIS. Method of reproducing colours in which white light passes successively through, two or more coloured filters each of which absorbs (subtracts) a region of the visible spectrum which is transmitted by the others. The colour produced depends upon the quantity of light absorbed by each filter. Usually filters of the colours cyan, magenta and yellow are used, and these are often termed minus red, minus green, and minus blue since they absorb the colours red, green and blue respectively. When those filters are in the form of dye images superimposed in register on a transparent support, the result is a colour transparency.

See also: *Colour synthesis; Additive synthesis.*

SULPHIDE TONING. Method of changing the colour of the normal bromide print to give brown or sepia tones instead of black.

See also: *Toners.*

SULPHURIC ACID. Oil of vitriol. Used in reducers and clearing baths.

Formula and molecular weight: H_2SO_4; 98.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Characteristics: Corrosive oily liquid. Evolves a great deal of heat when mixed with water. The acid should always be poured into the water while stirring the mixture, never the water into the acid.

Solubility: Mixes with water in all proportions.

SUNK MOUNT. Type of lens mount in which the major part of the lens lies behind the lens panel instead of projecting in front. Sometimes also applied to print mounts with plate markings.

See also: *Lens mount; Mounts.*

SUNRISE AND SUNSET. Light at sunrise and sunset is richer in red and orange rays than in the middle of the day.

Photographs of the sky at sunrise and sunset are apt to be disappointing when seen in black-and-white as the main attraction about such a scene is its colour. At the same time much of the beauty of the sky can be reproduced by careful technique. Generally the exposure should be kept to the minimum value; anything like a full exposure gives a dense negative and a print that lacks the necessary feeling of luminosity. For the same reason the negative should be processed in a soft-working developer to preserve the delicacy of the tone rendering in the highlights.

Panchromatic films are always best for black-and-white photographs taken early or late in the day because they are sensitive to red light.

A sunrise or sunset is best photographed in colour. Exposures should be kept to a minimum, otherwise the scene will be colourless and have a washed-out appearance. A daylight colour film without filter should generally be used, as such a scene would lose considerably if its characteristic red quality were removed. When photographing scenes illuminated by a low sun, and not the sunrise or sunset itself, however, it will often become necessary to use a correction filter to render the scene less red.

At such times of day the light changes quickly from minute to minute and any special effects need to be anticipated and photographed without delay.

See also: *Daylight; Sunshine.*

SUNSHADE. Alternative name for lens hood, current in the U.S.A. Its use is not limited to sunshine, though it is of course most effective then.

SUNSHINE. Sunshine is nature's light source Being a point source of light, it requires reflecting surfaces which will illuminate shadow areas; this applies to all photography, and to colour work in particular. Reflectors may be clouds, light coloured walls, a sandy beach etc.

Tone Range. The correct use of reflecting surfaces ensures that the ratio of the highlight intensity to that of the shadows is within the acceptable latitude of the photographic emulsion, the resulting photograph having detail in both the highlights and shadows.

Instead of reflectors, flash may be used as a fill-in for shadows. Where it is not practicable to employ any of the above means, it is wise to use a fast emulsion negative material, which yields softer results. Further reduction of contrast may be obtained by over-exposing the negative and under-developing it. Unless one is aiming for special effects, exposures should be based on the more important shadow areas, and not the highlights, in black and white photography.

It is not always necessary to reduce the extreme contrast of a scene in direct sunshine. The photographer sometimes aims deliberately at making a print where the shadows are black shapes. He may do this to emphasize the brilliance of the sunshine, or simply to create a black and white pattern in which intermediate tones would spoil the effect.

Generally speaking, the direct light of the sun is bad for portraiture, and should be particularly avoided when high in the sky and shining down almost vertically.

Variations in Quality. Sunshine varies in quality and strength according to time of year and day, and the locality. In Britain it seldom reaches the brilliance and high colour temperature that it does in many other countries. These inconsistencies produce great differences in contrast, exposure and, in the case of colour films, of colour.

Early and late in the year and/or day, sunshine is weaker in actinic value. Its red-content is apparently greater in the evening and in the morning, although in fact it is the blue content which is lower at those times, and this, too, influences colour film to a marked degree.

Between 11 a.m. and 3 p.m. in June, July, and August, sunny scenes should be avoided. The sun is then too overhead, giving downward, short shadows, devoid of modelling or pictorial interest. Sidelighting at angles of 45°–80° to the line of vision is admirable for depicting texture on sides of buildings, scenes, and objects of all kinds. Oblique back-lighting (coming from slightly behind the subject at angles of 100°–160° to the line of vision) is excellent for isolating the subject from its background and "glamorizing" mundane objects. It is sometimes difficult to prevent it striking the lens from this position, and a lens hood is therefore necessary.

Artificial Sun Effects. Sunshine may be simulated outdoors by means of flash held to one side of and well above the camera. The flash and daylight must be carefully balanced, so that the background does not reproduce unnaturally dark. The same can be achieved indoors by judicious placing of lights, with a plain medium-grey backcloth or painted cloud-scene if expertly executed and rendered out-

of-focus. No shadows must be allowed to fall on this and so reveal the artifice.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

A sunny atmosphere can be strengthened by using a diffusion disc on the camera lens, thereby spreading the highlights into the shadows and softening definition with its halo effect. P.J. (V.G.)

See also: *Daylight; Sunrise and sunset.*

SUPERCOAT. Many sensitized materials have a coating of unsensitized gelatin on top of the sensitive emulsion. This supercoat is added to protect the sensitive layer from physical injury, in particular, from abrasion and stress marks (visible marks produced on development due to pressure on the sensitive emulsion).

With special materials, like transfer stripping films, where the image is to be transferred to another support, the supercoat may also serve as adhesive layer upon transfer to attach the emulsion to the new support. Stripping materials are not always manufactured with such an adhesive layer.

High resolution materials and films and plates intended for photographing ultra-violet radiation never have a supercoat; in the latter case it absorbs ultra-violet.

See also: *Negative materials.*

SUPER-8 mm. Type of 8 mm. film with a 50 per cent larger image area as compared with traditional 8 mm. film. The Super-8 mm. film also has an increased frame height and perforation pitch, so that there are only about 72 frames per foot (instead of 80). The perforation size itself is smaller. The film can only be used in appropriately designed cameras and projectors.

See also: *Cine film; Perforation.*

SUPPLEMENTARY LENS

Extra lens used to change the focal length of the camera lens. Usually fitted in a mount to slip, clip, or screw on to the front of the camera lens like a filter.

Positive Supplementary Lenses. A popular way of photographing close-up subjects is to shorten the focal length of the camera lens by using a positive supplementary lens in front of it. When the focal length of the lens is shortened in this way, the camera must be brought closer to the subject to focus it sharply, and this automatically gives a bigger image of the subject.

There are two methods of focusing with positive supplementary lenses:

(1) If the camera lens is set at infinity, adding a supplementary lens focuses it on objects at a distance equal to the focal length of the supplementary lens. A 50 cm. supplementary lens added to any camera lens focused on infinity will focus the camera on objects 50 cm. in front of it.

This method of focusing does not require a focusing screen, so it is a popular method of extending the range of fixed focus cameras and those which focus by scale alone. It is a simple device for adapting fixed focus cameras for portraiture, and supplementary lenses sold for this purpose are called portrait attachments.

So long as the subject is at a distance exactly equal to the focal length of the supplementary lens, the image will be sharp. The disadvantage of working close to the subject in this way, however, is that it tends to distort the proportions of the subject.

(2) With screen focusing cameras (including single lens reflex types) the supplementary lens may be used over a range of subject distances. In this case the camera is focused by examining the image on the screen in the usual way, the only difference being that it now works closer to the subject and gives a bigger image than with the normal taking lens alone.

Used in this way the greatest subject distance is given with the camera lens set at infinity, when the subject distance is equal to the focal length of the supplementary. The normal focusing extension then enables the camera to be focused for distances less than this.

Even if the camera is not equipped with a focusing screen, its normal focusing extension can still be utilized for close-ups at distances less than the focal length of the supplementary. Under these circumstances the distance focused sharply for any point on the focusing scale is given by the expression:

$$d = \frac{us}{u + s}$$

where d = the actual distance focused on
s = focal length of supplementary lens
u = scale setting of camera lens.

Example: if the camera lens focusing scale is set at 3 feet (36 ins.) and the supplementary lens has a focal length of 24 ins., adding the supplementary lens will enable the camera to focus on $(36 \times 24)/(36 + 24)$ ins.—i.e., $864/60 = 14{\cdot}4$ ins.

A positive supplementary lens can also be built up of several converging and diverging units. If the separation between these units is adjustable, the complete system can act as a variable focus supplementary lens. In other words, the power of the combination in dioptres depends on the actual separation between the elements, and the supplementary lens can therefore cover an appreciable range of continuous close-up distances. This has obvious advantages over the use of a number of simple supplementary lenses, each of which covers only a narrow range of subject distances.

Variable power supplementary lenses usually have their adjustment calibrated to show both magnification and required subject distance at different settings; they are, however, best used

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

USE OF POSITIVE SUPPLEMENTARY LENS. Top: At medium subject distances, the image of a smaller subject becomes very small on the film. Centre: The closest focusing distance of most cameras is still in the region of 3–4 feet. At this range the subject may still be too small in the picture. Bottom: A positive supplementary lens enables the camera to approach the subject closer for the same focusing movement of the camera lens. This focusing movement now covers a continuous, but limited range of near subject distances, the farthest of which (with the camera lens set to infinity) is equal to the focal length of the supplementary lens.

with reflex or other cameras that permit visual focusing on a screen.

Wide-angle Conversion. The fact that a positive supplementary lens shortens the focal length of the camera lens makes it suitable as a wide-angle attachment.

Such a combination can of course only be used with a camera where the bellows movement permits the lens to be racked back nearer to the negative. The effective focal length of the combination is $(s \times f)/(s + f)$, s and f being the focal lengths of the supplementary and camera lens respectively.

In practice the optical quality of such a wide-angle combination is not very good, and the image is likely to show appreciable distortion near the edges of the field.

Negative Supplementary Lenses. A negative (diverging) supplementary lens increases the focal length of the camera lens. The new focal length of the combination is given by the expression $(s \times f)/(s - f)$ where s is the focal length of the supplementary lens and f, the focal length of the camera lens.

This means that it is not possible to focus an image sharply unless the lens is moved farther away from the plate. When the lens-plate separation is equal to the new focal length—i.e., $(s \times f)/(s - f)$—objects at infinity will be in sharp focus. For nearer objects, the lens must of course be moved farther out still.

Because the negative lens increases the focal length of the camera lens it automatically reduces the field covered—actually, in the ratio $s : (s-f)$. In other words it sees less of the subject in front of the camera. And since less of the subject now occupies the same picture size, it is presented on a magnified scale.

So, without moving the camera position, a negative supplementary lens can be used to magnify the scale of the image. The increase in image size is proportional to the increase in focal length—i.e., it increases in the ratio $s : (s - f)$.

Example: if the negative supplementary lens has a focal length of $s = 12$ ins. and the camera lens a focal length of $f = 6$ ins., the focal length of the combination will be $(12 \times 6)/(12 - 6) = 12$ ins. And the increase in scale of the image will be $12/(12 - 6) = 12/6 = 2$—i.e., the supplementary lens will double the size of the image obtained with the normal lens alone.

But a negative supplementary lens can only be used to give a bigger image in this way if the camera will extend far enough to allow for the increased focal length. Furthermore, the aberrations introduced by adding an uncorrected lens become serious at magnification over about 2×—i.e., where the focal length of the supplementary lens is less than twice the focal length of the camera lens.

Afocal Attachments. A lens system acting like a telescope presents to the eye, on looking through, a visual image at infinity. Such a

WIDE-ANGLE SUPPLEMENTARY LENS. A positive supplementary lens shortens the focal length of the camera lens. The combination covers a larger angle of view, yields smaller image scale, and needs reduced bellows extension.

The scale of reproduction is the ratio of image size/object size. Thus values smaller than 1 are reductions, larger than 1 are magnifications.

The table holds good for a camera lens set at infinity.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

NEGATIVE SUPPLEMENTARY LENS. Increases focal length of camera lens. Combination yields larger scale images at given distance, covers smaller angle, and needs increased bellows extension on camera to retain sharp focus.

system therefore has no focal length, but still magnifies the scale of the visual image. On placing such an afocal unit in front of a camera lens focused at infinity, the camera records the image on an enlarged scale, as through a telephoto lens. In the same way an afocal system can reduce the image scale, and so increase the angle of view.

The first type of system is used as a supplementary tele-attachment, and the second type as a wide angle attachment, on cameras with fixed (not interchangeable) lenses. This can provide a range of focal lengths, especially for telephoto purposes. The use of suitably designed binocular or monocular units can achieve image magnifications of 8, 10, or more times. Afocal attachments of variable magnification also exist and produce an effect similar to that of a zoom lens.

Effect on *f*-number. For most practical purposes it can be assumed that a positive supplementary lens when used for close-up work with the camera lens set at infinity does not affect the *f*-number of the camera lens. This must be so because the size of the stop remains the same and the lens-plate distance—i.e., the effective focal length—is unchanged. (Neither of these assumptions is quite true, but the error is not normally appreciable.)

But if the combined lens is focused on distant objects, the *f*-number of the camera lens must be divided by $(s + f)/s$ to give the true relative aperture. A camera lens of $f = 6$ ins. used with a supplementary of 20 ins. would thus have its effective aperture divided by $(20 + 6)/20 = 26/20 = 1{\cdot}5$—i.e., at $f8$, the true relative aperture would be $(8 \times 2)/3 = 16/3 = f5{\cdot}3$. In practice, this theoretical increase in aperture is offset by light losses and aberrations.

A negative supplementary changes the *f*-number of the camera lens in proportion to the increased lens-plate separation. So the *f*-number of the camera lens must be multiplied by $s/(s - f)$—i.e., in the example for a negative lens the *f*-number would be multiplied by $12/(12 - 6) = 2$. So that the supplementary lens in this case doubles the *f*-number. Doubling the *f*-number e.g., from $f8$ to $f16$—calls for a 4× increase in exposure which is another limitation of the method.

Definition. Supplementary lenses are generally simple uncorrected elements of the spectacle lens type—i.e., with both surfaces curved. Such additions upset the corrections of the camera lens and introduce most of the aberrations in some degree. So the camera lens must always be stopped down to give a sharp image right to the corners of the plate. Even when stopped down, the definition is never as good as with the camera lens alone.

Meniscus lenses—i.e., with one convex and one concave surface—give distinctly better definition than the spectacle (biconvex or biconcave) type and are generally meant to be fitted with the concave side to the subject.

Since a camera lens is always designed to give its best performance on its own, the use of any form of supplementary lens tends to impair maximum definition and evenness of illumination. In high-quality supplementary lenses and afocal attachments, designed specifically for a given camera lens, the loss of quality can be negligible.

Attachments of the monocular or binocular type used for tele-photography must also be designed with a larger exit pupil to avoid vignetting of the image.

Corrected Supplementary Lenses. Fully corrected supplementary lens assemblies are supplied by some manufacturers for providing a range of focal lengths in conjunction with a permanent rear lens element and shutter system. These give the equivalent of a set of interchangeable lenses of short, normal, and long focal length for the cost of what is virtually a set of three corrected supplementary lenses and a fixed camera lens. To change from one focal length to another, the front component is simply unscrewed and interchanged, leaving the back component, shutter and diaphragm undisturbed.

With some cameras such an interchangeable front component can yield a lens system that is already focused at a close or very close distance. With an interchangeable macro lens of this kind, up to same size copying may be possible at a considerably higher level of lens performance than is normally achieved by adding supplementary close-up lenses to a complete camera lens.

A corrected supplementary lens is also used in an accessory which converts an ordinary camera into a coupled rangefinder focusing type.

The device consists of a supplementary lens assembly with front-cell focusing coupled to a split-image rangefinder. The camera lens is set

at infinity and the supplementary assembly is fitted in front of it. Under these conditions, operation of the coupled rangefinder automatically focuses the camera on the object ranged upon.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Supplementary lens assemblies of the types described above are highly corrected and capable of giving definition equal to that of a normal camera lens.

Use With Twin-Lens Reflex Cameras. Supplementary lenses can be used with twin-lens reflex cameras provided that both viewing and taking lenses are fitted with identical supplementaries so that the image on the viewing screen is exactly the same as the image on the film. Some manufacturers of twin-lens reflex models supply special sets of matched positive and negative lenses for their own cameras.

Scale of Reproduction. The scale of reproduction with supplementary lenses is given by:

$$M = \frac{F}{S}$$

where M = Scale or reproduction (image size-object size)
F = Focal length of camera lens
S = Focal length of supplementary

provided the camera lens is focused on infinity. In this case the focal length of the camera lens must be known; in all other supplementary lens calculations, it is unnecessary.

Both focal lengths must be measured in the same units. Where the power of the supplementary lens is stated in diopters the reciprocal of the number of diopters is equal to the focal length in metres. L.A.M.

SUPPORTS FOR EMULSIONS

Two main types of support are used for negative emulsions: glass plates and celluloid film. Both are transparent and allow the negative to be printed by contact or projection.

Positive emulsions are coated on paper, film and glass plates.

Paper is occasionally also used for making the sensitive material known as negative card because of its cheapness.

Various plastics, transparent and opaque, are also used as support for special sensitive materials.

Glass Plates. Photographic plates consist of a support of flat glass plate coated with the sensitive emulsion. As a rule, the larger the size of the plate, the thicker the glass.

The advantages of glass as an emulsion support are dimensional stability and chemical inertness.

Glass plates do not stretch or curl during processing. They are therefore used in preference to films where high dimensional accuracy is required, as in photogrammetry, aerial survey, and certain types of astronomical photography.

Larger than			
24 × 30	61 × 76	0·13	3·3

Plates are also used when making colour separation negatives where the images are later to be combined in exact register.

The glass support is chemically neutral and unaffected by all solutions used in photographic processing. As glass does not decompose or deteriorate in storage, emulsions coated on it keep better than on any other support.

The disadvantages of glass are its thickness, weight, low adherence of emulsion and the fact that it is easily broken.

Because of the thickness of the glass, it is not possible to reverse the plate in contact printing to give a transposed positive, since the positive image would no longer be sharp. This is a disadvantage in certain transfer processes. When a plate negative is reversed in the enlarger, the plane of the emulsion moves out of focus by the thickness of the glass. This shift must be allowed for if the plate is being enlarged in an automatic focusing enlarger.

Plate negatives are more likely to show halation than films, because the greater thickness of the glass support allows the light reflected from the back surface to scatter over a wider area.

Gelatin emulsions do not adhere as well to glass as they do to celluloid. When the emulsion on a glass plate has been wetted, it is more likely to frill and leave the support near the edges, so glass plates call for more care in handling and processing.

Plates are fragile and relatively heavy so they are more troublesome to transport and store than films.

Because of these disadvantages sheet film is steadily taking the place of glass for general

purpose materials, particularly in the U.S.A. The present tendency is to use plates only where high dimensional stability is of first importance.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Film Materials. Film negative material consists of a sensitive emulsion coated on sheets or rolls of thin, flexible, transparent material.

Advantages of film supports are flexibility, thinness and low weight.

Films can be handled and processed without fear of breakage. They can be bent and rolled, and they lend themselves to film-changing systems which are far more reliable and convenient than any of the methods possible for changing glass plates. Film negatives will bend easily to fit the curved focal plane used on some cheap cameras with the idea of producing reasonably sharp negatives from lenses uncorrected for spherical aberration. They are used in certain special scientific cameras and in panorama cameras where curved focal planes are sometimes necessary for other reasons.

Flexible film is the only practicable material for cinematography.

Film supports are thin enough to be used either way round in the camera or in enlarging or projection apparatus without calling for an appreciable change in focusing adjustment. This is important in such work as colour photography where the negative may have to be exposed through the support.

Film negatives are less affected by halation than plates because light passing through the emulsion and film support travels only a short distance before it is reflected by the back of the support.

Films are so much lighter than the equivalent number of glass plates that they are very much easier to store and transport. This is one of the principal reasons for the greater popularity of films.

The disadvantages of film are low dimensional stability and liability to decomposition.

The commonly used types of film base stretch when they get wet during processing. They do not stretch evenly in all directions, and do not always go back to their original shape when dry. Certain special types of film base with high dimensional stability are, however, made for use in photogrammetry and similar special fields.

Types of Film Base. For many years the main type of film base in general use was cellulose nitrate film. This had the advantages of great strength and comparatively high dimensional stability, but the serious drawback of being highly inflammable and even explosive. Because of its dangerous nature certain legal requirements covered its storage and use in quantity. With the advent of acetate and other chemically more stable film supports, cellulose nitrate gradually went out of use, and is today completely obsolete.

The most important current film bases are the range of cellulose acetate and polyacetate compounds on the one hand, and various polymerized plastics on the other. While these still burn under suitable conditions, they will not do so easily; the fire risk is usually less than for an equivalent weight of paper.

Cellulose tri-acetate is the commonest film base for general use today, forming the support for most roll, sheet, and miniature films, as well as standard and narrow-gauge cine film. While this is not quite as strong nor quite as stable dimensionally as the old nitrate film, it does not lag far behind. Cellulose tri-acetate is the successor of the earlier types of acetate film—originally referred to as safety film to distinguish it from cellulose nitrate—which was inferior in dimensional stability and strength.

Tri-acetate film is made in thicknesses from 0·003 to 0·009 ins. (0·08 to 0·22 mm.).

Graphic arts, photogrammetry, and other special fields require still more stable film bases, and a wide variety of polymerized compounds have been tried.

At present the main supports to achieve success are polystyrene, polycarbonate, and polyester films. The latter in particular surpass nitrate film in toughness, and in certain cases approach glass in dimensional stability. Further advantages of some polymer plastics are increased resistance to creasing, reduced absorption of moisture, and consequently more rapid drying after processing.

Paper. The great advantages of paper as an emulsion support are that it is cheap, flexible and light in weight.

Its principal disadvantages are that it is easily torn and damaged, is apt to change its size and shape when it is processed, and is difficult to free from chemical impurities.

The last objection is largely overcome by the baryta coating which most photographic paper receives in manufacture before being coated with the sensitized emulsion.

Paper has one inconvenient characteristic from the point of view of processing: it is porous. Consequently paper prints require long washing times after processing (since the paper fibres retain harmful soluble chemicals more tenaciously) and also longer drying times. Special waterproof papers are therefore made where the paper surface is sealed by varnishing or similar treatment and becomes impervious to the processing solutions. Such papers dry much more quickly.

Paper bases are available in a variety of thicknesses, according to purpose. Normal enlarging and contact printing papers come as single weight or double weight (card) base. Single weight paper is handier for mounting; the increased thickness of double weight paper gives it greater protection where unmounted prints are handled a lot. Document papers (and others also) are frequently available in an extra light weight base which take up less room in filing. In addition document papers also exist on a translucent paper base which

permits contact printing through the paper. The translucent base is more uniform in its structure, and so does not show up the paper grain so much during printing. Such papers are largely used as masters for mass printing processes such as dyeline.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Other Supports. Although cellulose acetate and polymerized plastics are the commonest bases, other materials, both flexible and rigid, are occasionally used.

Opaque supports, which are printed either by reflex methods or projection, include steel, aluminium—which must have a protective coating to prevent interaction between the emulsion layer and the support—resin-impregnated glass cloth and white plastics used for reversal colour print materials.

For high dimensional stability laminated papers may be used.

These papers contain a piece of metal foil sandwiched between layers of paper which thus cannot stretch or shrink easily during processing and drying respectively.

Laminated papers with an opaque layer between the normal paper layers are sometimes used for special purposes where no light must reach an emulsion layer through the back. This might be the case in transfer-diffusion processing, where the negative and positive sandwich are exposed to ordinary lighting during processing.

Transparent supports include nylon-type plastics for plates. L.A.M.

SURFACE DEVELOPMENT. During the process of development the image may either form first at the surface of the emulsion and gradually penetrate deeper, or it may come up simultaneously throughout the depth of the emulsion layer. The first is surface development, the second, depth development.

The mechanism of the process depends on the composition of the developer.

With rapid acting developing agents (e.g., metol, para-aminophenol, etc.) the developer acts as soon as the solution reaches the surface of the emulsion layer. It therefore builds up a surface image of appreciable density before penetrating deeper.

With slow-acting developing agents (e.g., hydroquinone) the developer begins to reduce the silver halide only after a certain induction period, by which time the solution has penetrated fully into the emulsion layer. The image therefore builds up gradually throughout the depth of the layer.

Because of irradiation, the image tends to be more blurred below the emulsion surface. Provided development is stopped early enough, surface developers largely ignore the blurred deeper image, and therefore yield images of higher resolution than depth developers. In a similar way, surface developers also help to minimize halation (which first affects the deepest areas of the emulsion). On the other hand, the contrast and maximum density obtainable at the surface are limited, so the depth developers yield negatives of the greater density range.

SURFACE AND DEPTH DEVELOPMENT. Left: *Surface developers confine their action largely to the upper part of the emulsion layer.* Right: *Depth developers work in the whole emulsion and may bring out irradiation.*

See also: *Physical development.*
Book: *Developing*, by C. I. Jacobson (London).

SURGICAL PHOTOGRAPHY. Photography is used in hospitals for "before-and-after" records of surgical cases, and both still and moving pictures are taken in the actual operating theatre.

See also: *Dental photography; Medical photography; Medical radiography; Ophthalmic photography.*

SURVEYING PROPERTY. Apart from specialists engaged in map making or mining, the bulk of surveyors are concerned with land in its broadest sense. "Land" in its accepted legal meaning includes not only the ground but all buildings or erections thereon. In general the professional surveyor is concerned with land and what is on it, its location, value, design, construction, condition and use.

Photographic Records. Since he is invariably occupied with on-the-spot recording of facts, it is not unnatural that the surveyor finds a great deal of use for the camera as a means of making records to supplement his written notes. With few exceptions he uses either a folding roll film camera or a 35 mm. miniature, and there are times when the Polaroid type of camera, yielding a finished print within seconds of the exposure being made, is invaluable.

On arrival at the building to be surveyed he will probably walk round the outside to get a general idea of the property and take photographs of the exterior elevations. He will not trouble much about the lighting; his concern is simply to make records in accordance with a

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

set routine. The survey invariably starts with the roof and works down. The surveyor writes down a description of each part of the building he visits and notes dimensions, condition, features and defects, and uses the camera to augment his notes—e.g., he will probably photograph the roof, taking one or two general views, and will take close-up pictures of any defects such as fractures to the chimney stacks. In this way he then goes through the building from the attic to the cellar recording data.

On all interior pictures he uses a tripod and gives a time exposure or, alternatively he might use flash, because auxiliary lighting is bulky to carry (and, in any case, many buildings will be vacant and have their electricity disconnected).

When the survey is finished it is usual to take an exterior "prestige" picture to show the building to best advantage.

Presenting the Information. At the office the film is developed. Roll films are generally contact printed, and 35 mm. films enlarged to quarter-plate. Then, from his written notes and his photographic prints, the surveyor compiles his report. This report, a typed, bound and signed document, is handed to the client requesting the survey. It is supplemented with drawings and plans, but generally includes only one "prestige" photograph. The other prints are indexed and dated and filed with the written notes, and are not shown to the client unless for some specific reason. This is because the report deals with all the factors affecting a property and an odd photograph of one part might mislead rather than help the client. The "prestige" picture, however, precedes the written matter in the report folder and helps the client to understand the written part.

Shop premises often depend for their value more on their location than any other type of property, so it is usual to include in the survey photographs of both sides of the street. With a miniature camera using a short focal length lens it is possible to include about four shops in each oblique shot and a thirty-six exposure cassette usually holds enough to cover most thoroughfares. The film can then be printed as a positive film strip by contact or better still, by projection. The leader strip can be marked with the date and the name of the road.

This film strip can be run through a projector to show the whole of the main shopping thoroughfare to a prospective buyer of the property offered. M.H.T.

SUTCLIFFE, FRANK M., 1859–1940. English professional portrait photographer in Whitby, England, from 1875. Mainly known for his landscape and genre subjects. Prominent in the Naturalistic school of photography and founder member of the Linked Ring, 1892.

SUTTON, THOMAS, 1819–75. English writer on photography. Encouraged by Prince Albert and partnered by Blanquart-Everard, he established a photographic printing works in Jersey (1855). Founder and editor of the periodical *Photographic Notes*, 1856–67. Invented a fluid globe lens, 1859, used in his panoramic camera 1861; patented the first reflex camera in 1861. Published the first Dictionary of Photography in English (1858).

SWAN, SIR JOSEPH WILSON, 1828–1914. English inventor, chemist and photographic manufacturer. Perfected the carbon process for printing photographs in permanent pigment, 1864 (introduced 1866) and applied it also to a mechanical form of carbon printing from an electrotyped copper mould-photomezzotint, 1865. Discovered the ripening process by heat in making gelatin emulsion, 1877, when his firm Mawson & Swan in Newcastle began producing commercial dry plates. Patented the first automatic plate-coating machine in Britain, 1879. At the same time started the manufacture of gelatin bromide paper. Greatly advanced half-tone printing with his line screen turned halfway through the exposure, 1879. Swan took out over 60 patents, his best known invention being the carbon filament electric light bulb, 1881. Biography by M. E. and K. R. Swan, London 1929.

See also: *Carbon process.*

SWEDEN. It is only in recent years that photography has really made its presence felt in Sweden. A great interest in photography had always existed and, as in other lands, it entered into all spheres of human activity. But not until after World War II was photography acknowledged as an essential cultural factor.

The Past. Photography arrived in Sweden soon after its discovery. In the autumn of 1839 the description of Daguerre's invention was published in a Swedish translation. The first portrait studio in Sweden was opened in August, 1841 by J. A. Seven. At the beginning of the 1840's Sweden was visited by many foreign photographers and among them was the Frenchman Derville, photographer of King Oscar I who came to the throne in 1844. The picture of the king embossed on the coins of the day was a copy of one of Derville's photographs.

The oldest portrait studio now in existence, the Studio Jaeger in Stockholm, was founded by the German photographer Johannes Jaeger in 1853. Under the direction of court photographer Herrman Sylwander (1883–1948), the studio was especially popular with royalty and society. In Gothenburg, Studio Jonason celebrated their 100 years jubilee in 1964.

Another internationally known photographer, Ferd. Flodin (1865–1935) was for a large number of years one of the foremost

SGPC. Agamnigam Digital Presevation Foundation, Chandigarh

champions of artistic portrait photography. One of the greatest fighters for the cause of the professional photographer was court photographer Ernest Florman (1862–1952), a founder of the Swedish Photographers' Association in 1895, and its president for thirty-six years.

The best-known names in Swedish photography were Henry B. Goodwin (1878–1931) and Jan de Meyere (1880–1950). Henry B. Goodwin was born in Munich and for several years was lecturer on German at Uppsala University. He first became interested in photography as an amateur but he later opened a portrait studio in Stockholm and attracted a lot of attention through the excellence of his portraits. Dr. Goodwin published several books and often gave lectures; he spoke before the Royal Photographic Society in London and was a member of the London Salon of Photography.

Jan de Meyere was a Dutchman and came to Sweden in 1914. At first he was concerned only with painting, sculpture and handicrafts, but eventually photography took his whole interest and during the 1930's he was the best-known portrait photographer in Stockholm. He was the first in Sweden to work in high key and his pictures soon became known throughout the world. He took part in nearly all the international exhibitions, and he too was a member of the London Salon of Photography.

Present-day Activities. Today photography is accepted as a means of artistic expression, a view supported by the big daily newspapers, where mention is made of exhibitions and newly published books—by foreign as well as Swedish photographers—and by the principal museums of art, where permanent collections of photographs are being built up.

Since 1945 a leading newspaper, *Svenska Dagbladet*—Sweden's *Times*—has presented a gold medal and a large money prize for the year's best photography. The authorities have also taken notice of photography and photographers were included among those entitled to art and cultural scholarships presented by State and Municipal authorities. Previously only artists, composers, actors and authors received such scholarships. Numerous publishing houses and the Swedish Photographes' Association also award valuable scholarships each year.

In 1954 scholarships worth £500 were given to two photographers, and the Sweden-America Foundation awarded a photographer $1,500 to study in America. Other institutions and associations and the Swedish Photographers' Association give scholarships to professional photographers.

There are several municipal training schools for photographers and the Swedish Photographers' Association arranges courses at the National Institute for Handicrafts in Stockholm.

Many of the Swedish news-photographers cover the whole world and their work is published internationally. The production and appreciation of good photographs is also helped by the large number of books on photography published every year.

Exhibitions and Collections. The Swedish photographers often arrange their own exhibitions and participate in the various international photographic exhibitions with great success. Special attention has been paid to the work of the younger photographers, and when Edward Steichen gave his exhibition of European post-war photography at the Museum of Modern Art in New York in 1953 Swedish photographers were well represented.

The Modern Museum in Stockholm, the Art Museum in Gothenburg, and the Värmlands Museum in Karlstad all have fine collections of modern photography.

The Royal Institute of Technology in Stockholm has a large and modern institution for scientific photography. This scientific institution was previously under the direction of John Hertzberg (1871–1935), who became world famous in 1930 when he developed the negatives from S. A. Andrée's polar expedition of 1898. All the members of the expedition perished and for thirty-two years the films lay in the expedition's last camp. Thanks to John Hertzberg's achievement a great and unique collection of photographs was made available to the world.

At the Museum of Technology in Stockholm there is a large historical collection, both of photographic apparatus and pictures, among which are included several photographs by Hill and Talbot. In Stockholm City Museum and in several others too there are large photographic collections.

Industry and Professional Photography. Sweden imports photographic material and apparatus to the value of about £12 million yearly. The country's only factory for the manufacture of photographic material is Ceaverken, in Strängnäs. The factory, which was started in 1939 manufactures chiefly X-ray film, but also produces a certain amount of photographic paper. A world-renowned 2¼ in. sq., single lens reflex camera, the Hasselblad, is manufactured at Gothenburg.

There are a large number of photographic organizations in Sweden. The professionals' organization is the Swedish Photographers' Association; the country's 173 photographic clubs come under the National Association of Swedish Photography, which has 8,000 members; there is a Press Photographers' Club, founded in 1930; and there is also a special organization for the picture agencies that sell photographs to the press. The photo-dealers have an association, and the importers have their Photo-Contractors' Union. The Scandinavian professional photographers' organizations are united in the Nordic Photographers' Association.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

There are three photographic magazines, *Foto*, *Popular Photography* (Swedish edition), and *Nordisk Tidskrift för Fotografi*, which mainly cover amateur and pictorial photography, but also include technical news and reviews. *Fotonyheterna* is a journal on professional, technical and industrial photography and *Svensk Fotografisk Tidskrift* is published by the Swedish Photographers' Association. K.S.

SWING BACK. Back of a screen-focusing camera hinged so that it can be turned at an angle to the vertical—and often the horizontal—axis of the camera to improve the perspective of the image and extend the depth of field covered sharply by the lens.

See also: *Camera movements.*

SWING FRONT. Lens panel of a camera hinged about its vertical—and sometimes horizontal—axis so that it can be used, in conjunction with the swing back, to control perspective and, independently, to control depth of field.

See also: *Camera movements.*

SWINGING THE CAMERA. Technique for photographing objects moving more or less across the line of sight. The camera is moved to keep the subject in the same position in the viewfinder as the shutter is released. The resulting image of the subject is sharp while the background is blurred, thereby increasing the impression of motion.

The term "panning" is sometimes used to indicate swinging of the camera. Panning, however, is a motion picture expression that refers to a slow horizontal swing of the camera to take in the whole sweep of a stationary scene.

See also: *Movement.*

SWITCHES. There are switches of two main types; single- and double-pole. A single-pole switch disconnects one wire only; the double-pole disconnects both. Single-pole switches are always connected in the live wire so that when they are in the off position, the live wire goes no farther than the switch. If a switch is connected in the neutral wire, even when it is off, the live wire is still left connected to the equipment. Double-pole switches cannot be incorrectly wired up in this way; they are generally stronger than the single-pole types and are used for more responsible work.

Switches are normally of the "single way" type; they complete a circuit in the "On" position and break it in the "Off" position. However, there are also two- and three-way switches which will connect, say, a live wire to any one of two or three separate circuits according to the position of the switch dolly. A two-way, double pole switch with a centre "Off" position can be used for a number of complicated switching duties—

ON-OFF SWITCHES. Top: *Single-pole switch.* Bottom: *Double-pole switch, completely isolates circuit from electricity supply by breaking both sides of the connexion*

e.g. to switch a pair of Photofloods (or groups of Photofloods) from series connexion (in which they run at half voltage) to parallel (in which they run at their full voltage and brilliance at the expense of shorter burning time). This arrangement allows the lamps to be run economically while the subject is being arranged and only switched to full brilliance for the actual exposure.

There used to be only one type of switch for both A.C. and D.C., but now there are special switches that are made for A.C. only. These switches are simpler, cheaper, and quieter than the traditional tumbler switch, but they cannot be used in D.C. circuits. Switches of this type are always marked "A.C. only".

Foot Switches. A foot-operated switch is often the most convenient form of control for electrical equipment in the darkroom and studio; it leaves both hands free and allows the power to be switched on and off near the equipment instead of at the outlet on the wall or skirting board.

All the various types of foot-operated switch conform to the same general pattern. A heavy metal box houses the switch and is connected to the supply socket outlet by a length of cable and a plug. On the side of the box is a socket outlet where the lead from the equipment is plugged in. The equipment is switched on or off by pressure on a pedal mounted on the box. Some foot switches are made with more than one socket outlet so that, for example, alternative lighting may be switched on by foot pressure on a second pedal.

Time Switches. Time switches automatically switch off the electricity supply to any piece of equipment at the end of any chosen interval of time. The switch has a length of flex and a plug for connecting it to the mains, and the equipment is plugged into a socket outlet on the switch.

In principle, the switch resembles an ordinary alarm clock. There is a dial, marked in hours and minutes, or minutes and seconds, a hand or hands that show how long the mechanism has been running, and a movable hand that can be set to the time when the switch is to open.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

TWO-WAY SWITCHES. Appliance can be switched on and off from either switch. Top: Switched on, either switch breaks circuit. Bottom: Switched off, either switch closes circuit.

Switches that cover periods of more than a minute are ordinary pieces of clockwork mechanism, but the type of switch used for controlling enlarging and printing lamps is a more elaborate affair. Printing times may be as short as half a second, and it is costly to design clockwork for such intervals. Instead of using clockwork, switches of this type are operated by an electronic device and a relay. The electronic circuit measures the passing of time in terms of the time taken to charge a condenser.

Thermal Switches. Thermal switches are designed to open or close when the temperature rises or falls to a chosen level. In photography they are used to switch off current to room, tank, or dish heaters when the temperature reaches the working temperature.

Switches of this type are generally built into the equipment they control, but some are manufactured as separate accessories which can be connected to a warning light or bell, or individual pieces of processing apparatus.

Most thermal switches utilize the unequal expansion of a bimetal strip or spiral to open or close a pair of contacts. Where the switch is required to break a heavy current, the first pair of contacts merely breaks or makes the circuit of a relay. It is the relay that does the real work of switching the main circuit.

Photo-electric Switches. A photo-electric switch is operated by a change on the level of the illumination falling on it.

A photo-electric cell is connected in the grid circuit of a thyratron valve which is biased to pass no current under normal conditions. When the strength of the light falling on the cell changes, it changes the potential applied to the grid of the valve, and current flows in the plate circuit. This current is made to operate a relay which makes or breaks the main circuit.

Photo-electric switching is used for certain kinds of photography in which the subject automatically releases the shutter—e.g., nature photography and crime detection. For such work the photocell is illuminated by a beam of invisible infra-red light, and interruption of the beam releases the camera shutter and fires a synchronized flash.

One of the most interesting applications of the photoelectric switch in photography is in the operation of electronic flash "slave units." These are electronic flash units consisting of a portable power supply, tube, and reflector, with a photocell circuit operated solely by light from the master flash.

Any number of slave units can be set up to illuminate the subject, and when the master flash is fired, it operates the slave flashes with a delay of no more than a few microseconds. This system cuts out any wires between the master and slave units.

Two-way Switching. Two-way switches are designed to give control of a piece of equipment —generally a lamp—from more than one point. A room with a door at each end may have a switch by each door to control the same room light, or a bank of floodlights may be controlled at will by switches at each side of the studio. In each case, either switch will put the light on or off without reference to the other.

Ceiling Switches. Lamps over darkroom sinks are best operated by ceiling switches. These are simply ordinary make and break switches incorporating a toggle action worked by pulling on a hanging cord. The switch is fixed to the ceiling and all contact with wet hands is avoided —giving safety to the operator and longer life to the switch.

Miscellaneous Types. A number of other switches are used in photographic lighting and power circuits.

Three-position tumbler-type switches may be employed to connect either of two circuits to the supply—e.g., a yellow safelight (left), enlarger lamp (right), and both off (centre).

Two tumbler switches coupled by a bar may be used for series-parallel switching of lighting circuits—e.g., two Photofloods: in series (at half brilliance for arranging the subject); in parallel (at full brilliance for making the exposure).

Switch fuses are heavy duty multiple outlet switches for controlling a number of circuits in the permanent wiring of the building. They are generally fitted in iron boxes attached to the wall near the incoming supply and contain a set of fuses, one of which is associated with each out-going set of cables. The switch is connected directly to the meter and is operated by an external handle that can only be placed in the "On" position if the door of the fuse box is closed.

Ratings. The rating of a switch is the current in amperes that it will safely carry and break without overheating or arcing. This safe current is clearly marked on every switch designed to be connected to a public electricity supply. The total current that the switch will have to carry when all the equipment connected to it is switched on should never exceed the rating. Overloading a switch is dangerous and in time renders it useless. F.P.

SWITZERLAND

In the past Swiss scientists have made notable contributions in the optical and chemical fields of photography, and today there is a thriving Swiss photographic industry.

Historical. Even before the invention of photography, Swiss experimenters had shown an interest in photo phenomena. Jean Senebier (1742–1809), a clergyman turned librarian, studied the visible change caused by the action of light on silver chloride. He established that it was the blue and violet rays that had the strongest effect (five years earlier the Swedish chemist, Scheele, working independently had discovered the same thing).

Pierre Louis Guinard (1748–1824) improved the manufacture of optical glass; his methods are still used today.

Shortly after the publication of Daguerre's invention by the Académie Française in 1839, the painter Johann Baptist Isenring (1796–1860) introduced the process into Switzerland, and held a large exhibition of his own daguerreotypes (including portraits) at St. Gall in the following year (August 1840): he improved the method by the introduction of retouching and colouring with fast and indelible pigments.

Half a century later the photographic process, which had in the meantime made considerable progress, was put on a firm scientific basis by the introduction of sensitometry—an advance in which Swiss workers can claim considerable credit. The Swiss Ferdinand Hurter (1844–98), together with his friend Vero Charles Driffield (1848–1915), laid the foundations by formulating the conceptions of transparency, opacity, and density, and by defining the characteristic curve (1891).

At Zürich, in 1907, the chemists J. H. Smith and W. Merkens developed a process for obtaining coloured paper prints from colour-transparency originals, under the name of Utocolor Paper. This had a black layer which was bleached by irradiation and assumed the colour of the incident light. This very elegant method of colour reproduction, which others had tried before without success, pursued the same end, although by different means, as the modern colour reversal processes.

In 1912, W. R. Hess, 1950 Nobel Prize Winner in medicine, published an ingenious process for the production and viewing of stereoscopic pictures by means of a lenticular screen film. The results could be viewed without any optical accessories and were so pleasing that for a time the process was very popular.

Industry. Switzerland is the home of a considerable industry for the manufacture of photographic products and accessories.

Heerbrugg, in the extreme north-east of the country, possesses a large factory producing high-quality aerial cameras equipped with lenses which combine high speed and excellent resolving power. The same plant makes the whole range of photogrammetric equipment necessary for the evaluation of aerial photographs, such as first-order autographs as universal units, second-order stereo-mapping apparatus for single-pair evaluation, police autographs for forensic purposes, and rectifiers.

About 1945, at Balzers-Liechtenstein, a plant was set up for coating optical glass surfaces, both for the purpose of reducing internal reflections, and for the production of interference filters for all wavelengths.

High-vacuum coating machines to carry out these processes are also mass-produced and sold at Balzers.

A further project has been developed at Mauren, Liechtenstein, for the manufacture of 8 mm. cine-cameras. A plant in Schaffhausen, with a subsidiary branch in Murten, produces a technical camera which is widely exported.

Zurich is famous for the manufacture of cameras, and as early as 1880 the first miniature camera, made of wood and taking 40 mm. roll film, was made there. Today Zurich is the home of two manufacturers of note. One produces automatic reproducing machines and photographic registration equipment and the other makes large format mirror reflex cameras.

The town of Aarau has an efficient optical precision engineering industry manufacturing microscopes, photographic lenses and various optical instruments for medical and other uses.

St. Croix is a centre of the precision engineering industry. Here, in addition to the famous Swiss watches, is made a range of world-famous, narrow gauge cine gear.

In the centre of Switzerland, at Schwyz, there is a factory for film supports and magnetic recording tapes.

A well-known miniature reflex camera is made in Ballaigues, and in Lugano, in the south, there is a comparatively new company producing sub-miniature cameras.

At Burgdorf, not far from Berne, the federal capital, sensitized photographic materials for various types of technical photography are manufactured, including X-ray films and materials for photocopying and typographical and photomechanical reproduction processes. The factory is unique in having been the first in the world to specialize in this field.

Another plant, at Fribourg, produces photographic contact and enlarging papers, and has finally taken up the manufacture of colour materials. Recently this firm was amalgamated with a very large chemical concern in Basle, which is beginning to build up a world-wide photographic industrial organization.

At Baden, an industry is engaged in a patented process in which silver salts are deposited in an oxide layer electrolytically produced on aluminium plates, on which mechanically and chemically resistant pictures can be reproduced.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Lastly, there is a well known company at Winterthur making photographic gelatin.

In addition there are in Switzerland many young companies making high quality apparatus for varied photographic purposes, not to mention the numerous Swiss firms which act as representatives for foreign products.

Professional Organizations. There is no institute of photographers—i.e., an organization representing photography on a national level—in Switzerland. The commercial interests in the photographic field, however, are organized in the Verein der Photoindustrie (Federation of the Photographic Industry and its representatives) in Switzerland, with offices at Zürich. The federation covers both Swiss manufacturers and the numerous representatives of foreign interests.

The Verein der Photo-Industrie und deren Vertretungen in der Schweiz (Union of Photographic Manufacturers and Representatives in Switzerland) provides an organization for the phographic retail trade, and the Schweizerische Photographenverband (Swiss Photographers' Union), represents the intrests of professional photographers and also takes care of professional training. The Schweizerische Verband für Photohandel und -gewerbe (Swiss Photo-dealers' Association), acts in a similar manner on behalf of the dealers. The Schweizerische Fotografen Bund (Swiss Photographic Federation) represents photographic employees. The amateur photographers are united in the Schweizerische Amateur-Photographen-Verband (Swiss Amateur Photographers' Association).

Education. Photographers receive their training either by serving a normal apprenticeship, which may be followed by gaining a master's diploma, or by taking a course at the photographic section of the technical college (Ecole des Arts et Métiers) at Vevey, Lake of Geneva.

The Kunstgewerbeschule (Art School), in Zurich also has a photographic department.

Scientific photographers with a special final certificate are taught at the Photographic Institute of the Eidgenössische Technische Hochschule (Swiss Federal Institute of Technology). This institute, founded in 1886, is remarkable in being one of the very ew establishments in Europe offering photography on an academic level within the framework of the college teaching programme. It covers theory and practice as well as conducting scientific research. There are regular lectures and photographic symposia by well-known scientists and Swiss and foreign experts. These lectures, in which the various experts report on the nature of their work, enable the Photographic Institute of the E.T.H. to maintain permanent contact, on a technical as well as a personal basis, between the circles interested in the scientific and technological aspects of the profession.

The first world exhibition of photography, covering practically every field of pictorial work and photographic applications, was held in Lucerne in the summer of 1952.

Photographers. Mention has already been made of the daguerreotypist, Isenring. Johann Baptist Taeschler (1805–66) was another pioneer in this field. He made a name for himself in the early stages of photography, opening a photographic studio at St. Fiden near St. Gall in 1846, where he produced work of high artistic merit; he gained awards at the first international photographic exhibitions. His four sons took over the business under the name of Taeschler Bros.

Fred Boissonas (1858–1946) was one of the first and most outstanding Swiss landscape photographers. At Paris, in 1891, he was awarded a Gold Medal for the first telephotograph of Mont Blanc ever produced; it was a masterpiece, exposed through a telephoto lens on a home-made orthochromatic plate. He derived his main fame from his pictures of Greece. The mountain and landscape photographs by Emil Meerkämper (1877–1948) and Jean Gaberell (1887–1949) are also world-famous.

In those days photographers would frequently also be active in a technical capacity, as for example Carl Koch (1845–97) who was a mountain photographer and also manufactured dry plates for the Company of Tronel & Koch, Schaffhausen. Other technicians to be mentioned in this connection are Emil Suter (1850–1936) who made cameras and lenses as well as other optical apparatus, Gottileb Zulauf (1871–1959) and Carl Pfann (1869–1929),, both well known producers of cameras from Zurich.

As an aerial photographer, the pilot Walter Mittelholzer (died 1937) not only produced captivating alpine landscapes of his own native country, his aerial photographs of other continents are to this day acclaimed as some of the best pictures of their kind. A number of outstanding specialists in this field are still to be found in Switzerland.

The pictorial journalists Paul Senn (died 1953) and Werner Bischof, who met with a fatal accident in the Andes in 1954, were of the same outstanding calibre in their own special branch of pictorial journalism. Examples of their work have appeared in all important illustrated journals the world over.

Camill Ruf (1872–1939) was perhaps the greatest Swiss portrait photographer. He was the author of excellent group pictures and many exquisite examples of bromoil and gum-printing techniques.

The work of other great portraitists of that time, such as Francis de Jongh (1864–1928) and Boissonnas deserve mention here.

Switzerland has also produced some eminent advertising photographers—a branch of photography which gives scope to the special abilities of Switzerland's professional workers.

The photomechanical industry in Switzerland has reached a standard of high quality. Striking

examples of this are the excellent ordnance maps of the country, produced by the Federal Ordnance Survey by a special photomechanical process. Swiss posters offer the most impressive evidence of the fruitful application of photography and graphic art in the field of advertising. International poster competitions, such as those held for the Olympic Games, have repeatedly been won by Swiss designers.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Magazines. The main Swiss publications for professional photographers are the *Schweizerische Photo-Rundschau* (Swiss Photo Review) which is the official publication of the Schweizerische Photographen-Verband (Swiss Association of Professional Photographers), and the *SFB Mitteilungen* (Reports of the Swiss Photographic Union). There is also a dealer's magazine, *Der Schweizer Photo-Händler* (Swiss Photo Dealer), and a semi-professional periodical *Camera*.

The main professional cine periodical is *Schweizer Film* (Swiss Film) and *Schweizer Schmalfilm* is a monthly publication for cine-amateurs. A number of religious organizations also issue their own cine magazines.

Amateur photographers are served by a number of club magazines, the main one being *Photo-Amateur* (of the Schweiz. Amateur-Photographen-Verband), and *Foto-Rundschau* (Photo Review), the official publication of the Arbeiter Fotovereine (Working Mens's Photo Clubs). There are also a few amateur cinematographers' magazines sponsored by amateur cine associations and clubs, as well as one or two minor independent publications.

J.E. & K.P.

SYMMETRICAL LENS. First of the true anastigmats, made possible by the discovery of the new Jena optical glasses at the end of the nineteenth century.

A symmetrical lens consists of two identical, or at any rate closely similar, sets of glasses with a stop between. Up to five glasses may be used in each set. The distortions introduced by one half of the combination tend to be cancelled out by the same distortions of an opposite nature introduced by the other half.

But this obliging characteristic depends on the object-lens-image distances. Where they are roughly the same, as in copying, an exactly symmetrical lens will serve, but where there is a big difference, as in camera lenses, the designer has to make changes in one half of the combination to balance matters. For this reason a symmetrical lens designed for copying or small amounts of enlargement is of no use in an ordinary camera.

Symmetrical designs nowadays are used mainly for wide angle and process lenses although a few modern camera lenses are derived from the symmetrical type.

Two distinct types of symmetrical lens are commonly used in cameras.

One is intended as a long focus lens for 35 mm. cameras. In this type, the centre of the field is highly corrected for the small area it has to cover. The second type is for use in normal cameras and is corrected to cover a bigger area. So it is possible to have two lenses of the same focal length and aperture, one for use as a long focus lens on a miniature camera, and the other a normal lens on a larger camera.

See also: *Lens history.*
Book: *Photographic Optics*, by A. Cox (London).

SYMMETRY. Effect of similar or identical arrangement of subject matter on each side of an imaginary central dividing line or point. Aesthetically symmetry is rarely pleasing because it looks too formal and studied. It is occasionally effective where the intention is to draw the observer's attention specially to the perfect symmetry of a particular subject.

See also: *Composition.*

SYNCHRO-FLASH. Technique of flash photography in which the firing of a flash bulb is initiated by contacts which are generally in the shutter mechanism, but at other times externally connected to it, so that the useful part of the flash illuminates the subject at the instant the shutter is open. For very short exposures the timing of the flash in relation to the shutter opening is arranged so that the exposure starts and finishes during the peak brilliance of the flash. With electronic flash, which fires almost instantaneously upon contact being made, and which is of very short duration, the flash circuit is closed at the instant the shutter is wide open.

See also: *Flash synchronization.*

SYNCHRONIZER. Mechanical device for firing a flash bulb in synchronism with the opening of the camera shutter. A synchronizer usually incorporates the following parts—a release button, a pair of electrical contacts which can be connected to the flash head and flash battery through a flexible lead, a plunger for operating the shutter. Finally there must be an adjustable coupling between the flash contacts and the shutter release plunger so that the contacts can be timed to allow the flash to rise to peak brilliance before the shutter opens.

Synchronizers of this type have mostly been rendered obsolete by internally synchronized camera shutters.

See also: *Flash synchronization.*

SYNCHRO-SUNLIGHT. Balanced combination of sunlight and synchronized flash used for taking photographs.

See also: *Flash technique.*

T

TABLE TOP

There are three different branches of photography open to the photographer who chooses to work within the limits of a table top studio: still life studies, photography of small scale models and creative composition. The last is the true "table top photography", and it offers the greatest scope to the photographer with imagination and artistic ability.

Still Life. Still life arrangements are best if kept simple. Whether the subject is a flower study, a group of porcelain, or a pile of nuts and bolts, the effect is strengthened by straightforward presentation.

The still life photographer is fortunate in having complete control over the background of his picture. Generally a plain background is to be preferred as it helps to concentrate interest on the picture material.

A plain background is easily contrived from a large sheet of off-white, or grey paper which covers the top of the table, hangs over the edge at the front, and curves gently upwards and out of the picture at the back.

Shadows cast on the background by the lighting can be exploited to make an important contribution to the composition. At the same time, unless they are carefully watched, they can ruin the whole effect.

Back lighting can be attractive in throwing useful shadows that help to fill the foreground and unify the composition. Other shadows may be introduced from objects outside the picture.

In straightforward still life studies of this type there is no attempt at deception; the aim is simply to arrive at a pleasing piece of decoration, using recognizable objects suitably arranged and lighted. In flower studies, however, the lighting and background may be deliberately arranged to give the effect of a natural outdoor setting by using shaped masks and cut-outs in front of the background light to cast shadows, suggesting sky and clouds.

Scale Models. In dealing with a scale model, the aim is generally to make the finished print look like a photograph of the real thing. This is done by using a suitable lens and viewpoint, and by careful attention to the details of the model and its setting.

The height of the viewpoint is best chosen to correspond with eye-level on the actual full-sized object. A doll's house, for instance, would be photographed with the lens at the eye-level of an imaginary figure standing in the doorway. And the natural viewing distance is reduced in the same proportion—i.e., if the actual object would be viewed from, say, ten feet away, and the model is 1/10 scale, then ideally the model should be photographed from 1 foot away and with a 1 in. lens.

In practice these conditions cannot always be achieved, but it is possible to get a more natural perspective by using a short-focus lens.

Whereas a 6 ins. lens on a quarter-plate is satisfactory for the average still-life and table-top shot, a lens of 3 or 4 ins. focal length will be found more suitable for scale models. If such a lens is not available, the camera should be brought nearer to the subject. The illusion can be strengthened by using a viewpoint below table level, with the aid of the rising front of the camera.

The effect of perspective can be further increased in the building of the set. If the model is to be shown in a landscape, any foreground trees or buildings are made large, and the others are arranged to decrease in size as they recede into the distance. The foreground may be built of small stones, the middle distance of fine gravel and the far distance of sand.

Creative Effects. True table top photography is not concerned with merely reproducing facts.

It can be a source of amusement or a useful medium for book illustration and advertising· and at its best it is a branch of creative art.

Much of the interest of this branch of photography lies in building up scenes with all manner of odds and ends. Pieces of paper, Cellophane, cotton wool, glass shapes and other materials, when seen by the camera out of focus, can be made to assume the appearance of mountains, water, icebergs and so on. For instance, it may be more effective to represent

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

a forest by a few simple alternating lines of light and shade, than by using actual twigs.

Interior Sets. Interiors are built like stage sets, with three sides and open at the top. Thin strawboard covered with paper with a small pattern (or the back of a piece of wall paper whose pattern is not too obtrusive) serves admirably for walls. Furniture may be made to scale from cardboard or plywood, although it is generally easier to buy suitable ready-made toy furniture. The fewer props and pieces of furniture there are the better; suggestion is more effective than actual portrayal.

Exterior Sets. Sand and assorted stones can be used to form the basic shapes for most landscape scenes. Pieces of velvet will do for valleys and hills, large stones or coal for mountains, and moss and felt with a rough nap for bushes and grass. Snow can be made from cotton wool, salt or flour; Cellophane over a light or dark base can suggest water, and walls can be made from modelling clay or children's building bricks.

Small trees, carefully pruned branches, or roots of heather, can be used as trees. Trees in leaf are difficult to suggest, but small pieces of ornamental shrubs, ferns, or asparagus plants will often give the desired effect.

Figures. Those with sufficient skill can make their own solid figures from plaster, plasticene or modelling clay. Adjustable figures can be made from bent wire padded with cotton wool and dressed. Often, suitable figures can be bought from toy or fancy goods shops, and blown glass figures are especially attractive. But whatever form they take, they must be well finished because at such close distances any faults or blemishes stand out and destroy the illusion, particularly if the final enlargement shows the figures larger than actual size. Dolls of foam rubber or neoprene, having wire skeletons enabling them to be bent into any pose, are very useful for table-top work.

Models made of glazed china or finished in glossy paint may have to be dabbed with putty to deaden surface reflections. Average figures should measure 4 to 6 ins. in height, and though smaller ones can be used, any extra accessories—like umbrellas or sports equipment—will be correspondingly smaller and more difficult to make.

Treatment. A table top photo can be made to express an idea, tell a story, illustrate a quotation, or put over a topical skit. It offers the photographer a completely flexible medium of expression for humour, fantasy, drama, or pure decoration. Space and gravity can be defied in the world of the table top, and the photographer is free to portray the supernatural and the impossible with equal ease.

In any set-up the subject matter should be simple and all fussy detail avoided. Most table-top pictures fail either because they include too many items or because they try to represent the subject accurately and in detail instead of simply suggesting it in a broad effect.

As an example of correct technique, a desert scene might be constructed on the following lines:

A pool of water is suggested by a piece of creased Cellophane and some sand. (A piece of mirror would give unbroken reflections.) Two or three toy camels and a cardboard palm are arranged around the pool. The foreground can be a piece of draped cloth or creased paper, and the background a sheet of translucent paper.

The camera is focused sharply on the pool at a wide aperture. This throws everything in front and behind partly out of focus, and emphasizes the principal item. The lighting is arranged to show only the pool and its immediate surroundings. Shadows can be cast on the background from the back and be made to suggest clouds and receding distant hills.

This method of treatment does not attempt to disguise the nature of the subject material, but softens it and presents it in the pleasing light of fantasy.

Glass-top Technique. A technique which might be called glass-top photography offers even wider scope. This calls for some means of holding sheets of glass horizontally at different levels. The objects to be photographed are laid on the glass, each glass sheet representing a different plane in the picture. The camera looks down vertically on the glass, and the subject is lighted principally from the sides.

This method presents figures and objects as though they were suspended in mid-air without any means of support.

The Camera. No matter what camera is used, it should have a strong, steady tripod, with a tilting top or a universal head.

All forms of table top photography call for a camera with a focusing screen. If possible, it should also have double extension, a drop

GLASS-TOP PHOTOGRAPHY. Some subjects are best built up on layers of glass against a suitably illuminated background. This permits wide excursions into realms of fantasy.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

TABLE TOP SETS. Near, medium distant, and distant objects in a table top set-up have to be built to different scales. This is to give an effect of reality to the subject and to simulate the perspective recession of a life-size scene within the confines of the set-up. For the same reason, the actual proportions of model buildings must also be distorted to exaggerate perspective.

and rising front, and a swing back. Front side swing is useful for subjects (e.g., a toy train) which recede at an angle. For photographing scale models the camera lens should be capable of being stopped down to at least *f*64.

The creative branch of table top photography demands a wide-aperture lens. All-over sharpness is not always required because many effects depend upon differential focusing.

Lighting. Table top photography does not call for elaborate lighting equipment. Exposure times should, however, be kept within those limits where the reciprocity law applies, as reciprocity failure will lead not only to incorrect exposure, but also to incorrect colour rendering. The instruction leaflet supplied with each film should be studied carefully.

Light sources of varying colour temperatures should not be mixed when using colour, unless special effects are wanted.

A great deal can be done with ordinary table lamps fitted with ½-watt pearl or opal bulbs. Small spotlights are invaluable, especially in glass-top photography, and there should be at least one focusing spot in which the aperture can be adjusted to throw a narrow beam.

In the simplest form of lighting the principal light is placed to one side of the camera at an angle of about 45° to the subject. The fill-in light to give shadow detail should be diffused, or it can be indirect light produced by shining the lamp on to a white wall, a piece of card, or even the ceiling. This light should not throw any noticeable shadows, but if it does, they should be weak enough to be killed by the principal light.

The beginner should start with one light only, placed slightly to one side, with white cardboard reflectors adjusted to throw light into the shadows. Pieces of mirror or shiny silver paper can be employed to provide local spots of reflected light, but they need careful adjustment to avoid throwing patches of light of their own shape. Lamps must be screened off so that no stray light reaches the lens. The direct light from the lamps should be prevented from falling on the camera, and the lens should, in any case, always be protected from stray reflections with an efficient hood.

Exposure. If a photo-electric meter is used readings should be taken of the darkest and lightest areas to be rendered in detail. This will give the contrast range of the subject. If the range is found to be excessive it should be reduced by using a more powerful fill-in light or extra reflectors. An exposure should then be selected which will not leave the shadow areas under-exposed nor the brightest lights over-exposed. This procedure is very necessary with colour film.

In any case, a few test exposures should be made. They will always provide a useful basis for future work because, on the whole, conditions do not vary greatly with artificial lighting. It is always worth while to make a note of all exposure details, together with rough diagrams of the set-up.

Where extension tubes or bellows, or extended camera extensions, are used, allowance must be made for the change in the effective aperture of the lens, and an accordingly longer exposure must be given.

Sensitive Material. Almost any type of sensitive material can be used for table top work because speed is unimportant, but a medium speed panchromatic emulsion may be preferred for its more correct rendering of colour values. It is a wise precaution not to dismantle the set before the film is processed, if this is at all practicable. E.H.

TAKING PHOTOGRAPHS

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Certain basic steps are common to every field of photography outside the laboratory.

The minimum equipment required is: a camera, sensitized material (film or plate), a support for the camera (the hand, or a tripod) some means of measuring the distance from the camera to the subject (rangefinder or tape), some means of estimating or measuring exposure (calculator or exposure meter), some form of lighting (daylight, electric light, or flash).

Basic Steps.

(1) Load the camera with the film or plate.

(2) Sight the subject in the viewfinder and choose the best distance and viewpoint.

(3) Determine the distance from the camera to the subject and focus the lens.

(4) Determine the exposure and choose the stop and shutter speed that will give it.

(5) Tension and release the shutter.

(6) Change the film or plate.

(7) Process the film or plate to a negative.

(8) Print the negative.

Choice of Equipment and Materials. Many normal cameras cover a wide range of subjects. Intelligent photography, particularly when dealing with specific subjects, goes still further and includes selecting the most useful apparatus and the most suitable sensitive materials.

The following tables summarize the requirements from this point of view.

In the case of equipment the specifications are the ideal ones. With some subjects special apparatus is virtually essential. With many others, the ideal camera type will do the job best—and is the obvious choice for photographers specializing in that subject. But most average or better outfits will usefully tackle such subjects occasionally, often with special accessories, though perhaps not as conveniently as the apparatus made for the purpose.

Where emulsions are concerned, it is much easier to choose the best film or plate for the job Again the materials listed are the ideal ones.

Different aspects of a subject may call for different ranges of properties and the choice of emulsions is intended to cover these, rather than to indicate substitute requirements.

SUBJECTS AND SUITABLE EQUIPMENT

Subject	*Ideal camera*	*Accessories and Special Features*	*Remarks*
Action	Miniature or press	Rangefinder	High shutter speeds desirable
Aerial photography	Special aerial camera	Haze cutting filters	
Animals	Twin-lens reflex or miniature	Close-up lenses for small animals	Other types suitable, subject to limitations
Architecture	Technical or field	Filters, tele lenses, wide angle lenses	Camera movements desirable
Astronomy	Plate camera, special type		Invariably used with telescope
Candid shots	Miniature or twin-lens reflex	Short focus lens useful for depth of field	
Close-ups	Technical, single lens reflex or miniatures	Extension tubes, special gear for miniatures	Fixed lens cameras usable with close-up lenses
Commercial	Technical or field	Filters, various lenses	Camera movements desirable
Copying	Special copying cameras, also single-lens reflex	Extension tubes or close-up lenses, filters	Many simple cameras and miniatures suitable for limited work
Feature	Twin-lens reflex, miniature or press	Filters, interchangeable lenses, flash gear	Camera should be versatile to cover variety of subjects
Flash	Almost any, provided shutter is synchronized	Flash gun and equipment	XM-synchronized shutter permits high speed shots
Groups (large, formal)	Field or technical, or special types	Wide angle lens for confined locations	Large negative and ground glass screen desirable
Holiday	Any roll or miniature	Yellow filter	Simple operation useful
Industrial	Technical or reflex, interchangeable lenses necessary	Flash and other portable lighting equipment	Camera movements desirable
Landscapes	Field or reflex, but very simple cameras suitable	Filters, interchangeable lenses (if available)	Ground glass screen helps composition
Mountaineering	Small folding or miniature	Filters	Light weight deciding factor
News and Press	Press (taking sheet film and plates) with fast lens and shutter	Rangefinder, flash equipment, large frame finder	Miniature and 2¼ in. sq. also used. Rapid action important
Night	Any suitable for time exposures	Tripod, cable release with time lock	Lens speed not important with static subjects
Photomicrography	Single-lens reflex or miniature	Microscope and adaptor	Miniatures need special equipment
Portraits and studio groups	Studio or reflex	Long focus lens for head and shoulder portraits	Ground glass screen preferable
Snapshots	Any roll or miniature	Yellow filter	Simple operation useful
Sports	Press or miniature with fast shutter	Long focus lens, frame finder	Instant readiness for action important
Theatres and shows: from auditorium	Miniature with fast lens	Long focus lens	Preview of performance before shooting session desirable
photo-calls	Press or reflex	Flash, tripod	Subject carefully posed

SUBJECTS AND SUITABLE NEGATIVE MATERIALS

Subject	Speed ASA	Colour Sensitivity	Gradation	Grain	Other Properties
Aerial photography and photogrammetry	50 or faster	R, IR	h.	mf. or f.	Glass or low-shrink support, thin emulsion, high resolving power
Architecture	Medium or slow	O P	m.	mf. or f.	Glass or low-shrink support for accurate surveying work
Artificial light	160 or faster	R, P	m.	As fine as available	
Astronomy	As fast as available	O. R, IR	h.	As fine as available	Special colour sensitization may be needed
Colour separation	50–100	P	m. or s.	As fine as available	Equal contrast of all three separation negatives for the same development time. Plates preferable.
Commercial and technical	50 or faster	O, P, R	m. or h.	As fine as available	Colour sensitivity depends on colours of subject. Plates and sheet film preferred, as they allow single development
Copying (line)	Slow	B, O, P	eh. or uh.	f. or ef.	Colour sensitivity required depends on colours of subject
Daylight and outdoors (incl. amateur)	50 or faster	O, P	m.	As fine as available	
Copying (half tone)	Medium or slow	B, O, P	m. or h.	f. or ef.	Colour sensitivity required depends on colours of subject
Copying (micro)	Medium or slow	B, O, P	h. or eh.	ef.	Colour sensitivity required depends on colours of subject. Usually carried out on 35 mm. or even 16 mm. cine film.
Flash photography	80 or faster	R, P, O	m. or s.	As fine as available	Low reciprocity failure materials of higher contrast advisable for electronic speed flash
Fluorography	40 or faster	O, B	h.	As fine as available	
Forensic photography	25 or faster	R, P, IR, B	m. or h.	f.	Infra-red materials needed for special purposes, blue-sensitive emulsions for ultra-violet photography
Graticules	Very slow	B	uh.	uf.	Extreme fine grain and highest resolving power essential
Instrument recording	16 or faster	B, O	h. or eh.	f.	Material often supplied and used in continuous rolls
Industrial	Medium or fast	O, P	m. or h.	As fine as available	Artificial light work may need red pan materials. Plates and sheet film preferred, as they allow single development and individual control
Photogrammetry	As fast as available	R, IR	m. or h.	f. or mf.	Low-shrink support desirable. Infra-red materials often used in aerial photogrammetry
Photomechanical work	Very slow	B, O, P	h. or eh.	f.	Panchromatic materials needed for coloured originals and for colour separation work. Line copying needs the greatest contrast
Photomicrography	25 or slower	O, P	h. or eh.	f.or ef.	Blue-sensitive materials suitable for colourless specimens, panchromatic for stained specimens requiring filters
Portraiture	Medium	P, O	m. or s.	mf.	Different types of materials may call for different make-up
Spectrography	Varied	As relevant	eh.	mf. or f.	Colour sensitivity required depends on spectrum range to be recorded. Special U.V. sensitization may be necessary. Sensitivity should be uniform over the spectral range used

Abbreviations. Colour sensitivity: B—blue; O—orthochromatic; P—panchromatic; R—red panchromatic; IR—infra-red. Gradation: s—soft; m—medium; h—hard; eh—extra hard; uh—ultra hard. Grain: mf—medium fine; f—fine; —ef extra fine; uf—ultra fine.

TALBOT, WILLIAM HENRY FOX, 1800–77. English archaeologist, chemist, linguist, mathematician. Inventor of the negative-positive process of photography. Educated at Harrow and Trinity College, Cambridge. Used the camera obscura on a trip to Italy in 1823 and the camera lucida in 1833; this led him to experiment on the fixing of the images by chemical means. Investigated the action of light on paper treated at first with nitrate of silver and later with chloride of silver. He experimented to make his paper more sensitive, and in 1835 produced a picture of his home. Lacock Abbey, near Chippenham, Wiltshire. He used silver chloride paper to copy botanical specimens, lace, engravings and manuscripts. The announcement of Daguerre's invention in January 1839, led Talbot to describe his "Photographic Drawing" to the Royal Society in London on the 31st January, 1839. The manipulation was made known to the Royal Society three weeks later.

Soon afterwards he also discovered the great light-sensitivity of silver bromide paper. He next investigated the sensitivity of silver iodide and discovered that a latent image was produced which could be developed with gallic acid. The exposure needed for this calotype process, patented 1841, was much shorter than that for the old ("Photogenic Drawing") process. The paper negatives were made transparent by waxing, and positive prints were obtained by contact copying on to silver chloride papers. In 1844 to 1846 published *The Pencil of Nature*, the first book illustrated with photographs (showing many applications of photography, e.g., document copying). In 1852 patented Photoglyphy, having independently discovered the light-sensitivity of bichromated gelatin; this was a method of heliographic etching on steel as well as on copper. In 1858 he patented an improved process giving fairly good half-tone rendering.

Talbot patented most of his inventions, and demanded licence fees from those using them. In 1852 he publicly permitted the non-commercial use of his patented inventions.

TANKS

Many different types of tank have been produced for processing films and plates. Some are intended for use entirely in the darkroom, others must be loaded in the darkroom but may be used in daylight. A third type is intended for full daylight loading and operation without the need for any darkroom.

ROLL AND 35 MM. FILM TANKS

Tanks used for roll and 35 mm. film differ in design according to various requirements—e.g., daylight loading, wet loading. Some may not even allow processing in daylight at all.

Darkroom Tanks. The simplest, intended for use entirely in the darkroom, are straight, flat trays, sometimes provided with a lid, in which the film is held stretched out flat along the bottom. These are just slightly modified forms of a developing dish.

For processing roll film by the see-saw method, special dishes are available which have a roller or a pair of "dimples" under which the film passes to keep the loop of film under the processing solutions.

Even more elementary is a trough-like dish in which the film is developed by rolling and unrolling the strip of film upon itself.

The earliest type of tank for 35 mm. film was simply a long tubular container holding a straight length of film. Then came the developing drum consisting of a glass cylinder supported on a pair of "spiders" and turned by a handle. The film was wrapped around the drum and the ends secured to it with clips. The drum was supported over a developing dish and rotated so that the lower part of the drum dipped into the processing solution. This equipment is still used for developing cine film and long lengths of positive film for filmstrips.

Daylight Processing Tanks. Daylight processing tanks are of two types: apron and spiral loading. Probably the earliest of the apron-type tanks was that made by Kodak. It consisted of two main parts: a loading box, and a developing tank. In the loading box, the film and its backing paper were transferred from the camera spool to a special developing spool.

The film was eventually wound on to this

APRON REEL. The film is wound up on the tank reel together with a celluloid or plastic band (the apron) carrying embossed projections in both directions along the edges. These keep the turns of film apart and permit access of solutions.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

developing spool along with an apron which had corrugated edges. The apron itself was opaque to light but was permeable to processing solutions; so, when the film and apron had been wound on to the developing spool, the whole thing could be removed from the loading box and placed in the developing tank for processing in daylight.

Since the back of the film was in contact with the apron during the whole time of processing, it was only possible to develop films which had no coloured backing. Such tanks are useless for present-day films.

The Correx type tank is much used for processing 35 mm. film. The Correx system, originally used for processing 35 mm. professional motion picture negatives in lengths of several hundred feet, uses a celluloid band with dimples along its edges.

The film and celluloid band are together wrapped around a spool and loaded into a light-trapped tank into which processing solutions can be poured without danger of light leaks. The dimples along the edge of the apron keep it away from the film and allow the solutions to circulate freely between the layers.

Two lengths of 35 mm. film can be loaded on to a spool, back to back, thus doubling the effective developing capacity of the tank.

A more recent tank uses a special apron with very shallow dimples to save space. This will take a full 36-exposure length of film yet its capacity is little more than 4 ounces.

Correx type tanks are also made in sizes suitable for developing films of V.P. size and $2\frac{1}{4} \times 3\frac{1}{4}$ ins. size. The capacity of these tanks is about 25 ounces.

The spiral loading tank has a spool with continuous spiral grooves moulded on the inside faces of the cheeks. The spool is loaded by first removing the film from its backing paper (or cassette) and then threading it into the spiral track, the leading end passing round the spiral until it comes to the end of the track near the core of the spool. The loaded spool is then placed in the tank and covered with the light-tight lid, after which processing can be carried out in daylight.

In some models of the spiral loading tank the width between the two cheeks may be adjusted to suit any of the standard sizes of film between 16 mm. and $4\frac{1}{4}$ ins. wide.

Since the length of a 36-exposure 35 mm. film is appreciably greater than that of a size 127 or 120 roll film, adjustable tanks may incorporate a spacer to surround the centre core when using the shorter roll film lengths. This reduces the solution capacity of the tank, providing some saving in processing solutions.

The contents of both apron-type and spiral loading tanks are agitated by a separate spindle which is inserted through a light-trapped hole in the lid of the tank and engages with the core of the spool. This makes for even development. A thermometer may be inserted in place of the turning spindle to check the temperature of the tank contents.

The more modern way of agitating the solution inside the tank is by inverting the whole tank periodically. Many tanks therefore have a more or less leak-proof lid with a sealing cap which fits over the central opening. This arrangement allows little or no liquid to escape while the tank is inverted for a few seconds. The tank body is in this case rather larger than usual, to allow most of the liquid to drain away from the film reel during inversion.

One spiral loading tank is constructed entirely of stainless steel. The spool is made up from a spider which supports a spiral made of heavy gauge wire. In the centre of the spool there is a wire clip which anchors the end of the film. A special guide which curves the film laterally feeds the film into the spiral from the centre outwards. The final result is the same as with the other spiral tanks except that loading proceeds from the centre outwards instead of from the outside to the centre.

Multiple and Bulk-length Tanks. For processing several films at the same time some tank reels have an additional cheek in the middle between the two outside ones. That gives in effect two reels in one, permitting the two films to be loaded in the upper and lower spiral. Usually this is intended for 35 mm. film, and the same

FILM DEVELOPING TANK. DAYLIGHT LOADING 35 mm. TANK. The film cassette is loaded into a special chamber, and the film transferred to the reel while inside the light-tight tank.

reel can be used without the centre cheek for wider roll film sizes.

Some developing tanks take two or three (or even more) normal reels, again for simultaneous processing of several films. Here the tank body is of the appropriate extra height. When fewer reels than the full capacity are used, a spacer unit keeps the reels in position, avoiding excessive movement if the tank is inverted for agitation.

Spiral-loading tanks working on the same principle are used for processing 16, 35 or 70 mm. film of lengths up to 100 feet. The extra large spiral reel is loaded on a special stand. The film is led from its container through a long spout which reaches right into the centre of the spool. By rotating this spool—which may be done by a motor—the full length of 100 feet of film automatically winds into position between the spiral grooves from the centre outwards.

The loading spout squeezes the edges of the film inwards, making the film narrow enough to slip between the cheeks of the spool until it reaches the inner end of the groove where it is released and allowed to spring into place. Processing is carried out in circular darkroom-type dishes or scaled-up tank bodies of suitable size and, when washing is complete, the film still on its spool is rapidly dried in a current of warm air, on a rotary dryer.

Daylight Loading Tanks. A number of roll film tanks have been designed for daylight loading and processing. In one type the film is separated from its backing paper inside the tank. The paper is pulled out through a light-tight slot and the film is led into a separate vertical compartment in which it is stretched taut and developed. A similar type of tank of much more simple construction had a horizontal developing compartment.

One popular tank has a spiral spool into which the film is fed from the centre by a special built-in guide. Loading and developing of the film are conducted completely in daylight. The tank needs less than the usual quantity of developer because the spool rotates about a horizontal axis and is only half-immersed in the processing solution. In this type of tank the spool must be kept rotating continuously throughout processing.

Several manufacturers have produced 35 mm. daylight-loading developing tanks. In these the film is placed in the tank in its cassette and the loading end of the film is connected to the centre of the spool. The film is drawn into the spiral and then cut off at the mouth of the cassette. The cassette is removed and processing is completed as in a darkroom-loading type of tank.

The difficulty of persuading a length of film to traverse the spiral groove of the ordinary reel has been overcome in a number of tanks by a self-feeding device. This is produced by allowing one cheek of the reel to turn slightly on the centre spindle. The grooves of the spiral are moulded to give the effect of a ratchet, so that when the end of the film is started in the spiral and the cheeks of the reel are rotated backwards and forwards in opposite directions, the film is automatically drawn into the grooves.

This type of loading is particularly useful for developing colour film which must be removed during processing and fed back on to the wet reel.

Colour Film Tanks. For processing colour film there are elaborate stainless steel tanks. These may consist of five or six individual tanks built into a thermostatically controlled water-bath, which keeps the processing solutions at the recommended temperature. Stainless steel is not recommended for colour-processing solutions like certain bleach baths, for which a lead-lined tank is safer. Glazed porcelain or hard rubber tanks are very much cheaper than stainless steel and are suitable for all colour processing solutions.

Nearly all current spiral reel tanks have transparent perspex cheeks. These are essential for reversal processing of colour films and

SMALL PROFESSIONAL TANK SET FOR COLOUR DEVELOPMENT. The films are loaded into deep tanks in hangers and transferred from tank to tank. The tanks themselves stand in a water bath kept at a constant temperature. A, water for rinsing tanks (shown shaded) fed from temperature-controlled supply. B, processing tanks (shown solid). C, water bath. D, mixing valve. E, spiral reel sets for loading roll and miniature films.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

permit the necessary exposure to white light to be made without removing the film from the reel.

Agitation in commercial colour film tanks usually takes place by nitrogen burst equipment which passes bursts of nitrogen gas from cylinders through the solution at regular intervals. This stirs up the bath to bring fresh solution into contact with the film surface. The timing and length of the bursts is usually controlled by an automatic programming unit.

Aero Film Tank. Aero film is developed in daylight in a tank having two spools with winding handles. The film is wound backwards and forwards, from spool to spool, through the developer. Development proceeds reasonably evenly and, if the film has been thoroughly wetted, adjacent turns of film do not stick to one another when wound on the spools. Some models of this tank were provided with an automatic electrical drive since to wind 200 feet of film backwards and forwards for half an hour is tedious work.

Commercial Tanks. Wholesale photo finishing (D. and P.) establishments use large earthenware or plastic tanks of 12, 24, or 48 gallon capacity, deep enough to hold complete lengths of roll film.

Films are unrolled, weighted at the bottom, and supported at the top on a special double clip, which carries an identifying tag. These top clips are suspended from rods which rest across the top of the tank.

The tanks have two bung-holes at the bottom. One for a tap for draining the tank and the other to provide a lead-in for the immersion heater cable.

These establishments have to handle films in large numbers and they usually employ six tanks.

(1) Developing (10 minutes).
(2) Rinsing.
(3) First fix (10 minutes).
(4) Second fix (10 minutes).
(5) First wash (10 minutes).
(6) Final wash (10 minutes).

Since fixing and washing are the slowest parts of the process, taking twice the time of development, twice the number of tanks is used and the films spend the same time in each. Washing the films is usually carried out by leading water into the tank through the lower bung-hole and allowing it to flow to waste over the top of the tank. All tanks stand on a duck-board over a drain.

The conveyor-band principle is used for even higher production. After films have been loaded, together with their control tickets, on to double clips, they are unrolled, stripped of their backing paper, weighted and hung on a travelling band, which conveys them, in batches of ten, through the developer. They remain there for a predetermined time, and then they pass through a spray rinse and into the fixing bath. When fixed, they pass through the washing tanks, get a rinse in wetting agent to make them dry evenly, then go through a current of warm air in a drying tunnel.

PHOTO-FINISHER'S TANK. Developing tanks for large-scale processing at D. & P. establishments are usually tall containers taking the films suspended by clips from hangers or rods. A tank may have a capacity of anything up to 150 films suspended in rows on their hangers. Separate containers are used for developer, stop bath, fixer, etc., the films being moved from one tank to the next in batches on their hangers.

An alternative conveyor band method passes the films through the various tanks on hangers or racks. In more mechanized establishments the movement of the racks from one tank to the next (and the time they spend in each solution) is controlled by an automatic programming unit. This can be set to different programme sequences for various types of film.

If sufficient tanks are used, a programme can also be set up for colour film processing.

Large-scale processing machines, especially for 35 mm. colour and document copying film, may use a continuous film transport system. There the films are spliced together in a long band and passed through the processing solutions in the individual tanks in big loops. The size of the loop in each tank and the speed with which the film moves continuously determines the immersion time at each stage. The processing stages include the final wash and often even the drying process. After that the film is wound up on large reels, from which it is later unwound, separated in the individual strips, and where necessary cut up into single frames of transparencies and mounted in cardboard mounts.

PLATE AND SHEET FILM TANKS

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Plates and sheet films, in sizes commonly used by amateurs, can be developed in specially designed plate or sheet film tanks. These tanks are all of the same general pattern, holding up to a dozen plates in a grooved rack. The inside of the tank lid usually has a rubber gasket to make it solution-tight when clamped down.

Processing liquids are poured into the tank through a light-trapped spout. When loaded and charged with solution, the tank can be safely tilted or completely inverted to agitate the contents. Films or plates are loaded into the grooved rack in the darkroom. Usually the plates stand on edge, but in one pattern of tank they lie horizontally.

Sheet films are held by the edges in special carriers or frames which slip into the grooves in the same way as a plate. After the tank has been loaded in the darkroom, all the normal processing operations can be carried out in daylight.

Metal Tanks. These plate tanks are, nowadays, usually made of stainless steel; formerly they were of nickel. Both these materials are vastly superior to plated brass which is sometimes employed in the cheaper types of tank. The plating soon wears or chips off the surface, leaving the brass exposed. Copper in the brass is readily dissolved by the developer and leads to chemical fog during development. Only a few parts per million of copper in the developer will cause severe fogging of any photographic material during development. Hence brass or other copper-containing materials are never used in photographic processing equipment. Porcelain and glass are probably the best materials, though they are readily broken.

Stainless steel has the advantage of being unbreakable and if correctly treated during the manufacture of the equipment, can give excellent service. It cannot be used in conjunction with certain solutions (e.g., bleaching baths) used in colour processing. All stainless steel equipment must be thoroughly washed after use to prevent chemicals (particularly hypo) from crystallizing out on the surface, otherwise it soon corrodes. Stainless steel also corrodes if it comes into contact with steel wool.

Ebonite Tanks. Hard rubber (ebonite) is often used in the construction of processing equipment for professional use and gives very satisfactory service in temperate climates. But prolonged exposure to heat softens it and may distort its shape. Hard rubber tanks cannot be manufactured with the same precision or finish as the moulded plastic types.

Plastic Tanks. One type of moulded plastic tank holds four plates in closely-spaced grooves formed in the walls of the tank. Tanks of this sort have a remarkably small solution capacity but the spacing between plates is so narrow that efficient agitation is difficult.

PLATE TANK. The plates are carried in a stainless steel rack which in turn fits inside the tank. The latter has provision for filling and emptying. It closes hermetically, and is turned upside down for agitation. Sheet film may be accommodated in special stiff frames of plate size. The racks also serve for washing, and even drying. Alternative plate tanks may have grooves in the tank body to take the plates.

Film Pack Tanks. Film packs are usually developed in special tanks because the film base on which they are coated is thinner and less rigid than that of sheet film.

One of the earliest film pack tanks made use of a partitioned cage into which the individual films were loaded in the darkroom. The cage was divided into twelve sectors by radial partitions and the individual film pack sheets were folded lengthways, emulsion inwards, to fit into the compartments. The loaded cage was placed in the tank, which had a water-tight lid, and processing took place in the darkroom. Darkness was only necessary when pouring solution into or out of the tank.

A more recent tank for film packs contains a spool with rectangular ends which have curved grooves moulded on their inner faces. Film pack sheets are loaded into the spool by sliding them along the grooves from the open end so that they lie on edge and slightly curved, facing the core of the spool. Up to twelve films can be loaded and developed at one time. The tank is fully light-trapped and a darkroom is needed only for the actual loading.

Commercial Plate Tanks. Tanks for development of plates and sheet film of sizes used in commercial photography are a good deal larger than those commonly used by amateurs.

They are intended entirely for darkroom use and are not adapted for daylight loading or manipulation. They are mostly made of hard rubber, although stainless steel is becoming steadily more popular, in spite of its higher cost.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

These tanks are usually employed in sets of two or three; one each for developer, fixer and, possibly water rinse or acid stop-bath. They are provided with close-fitting covers and a floating lid to preserve the developer from oxidation whilst the tank is not in use.

Since these tanks are used to develop films or plates up to 8 × 10 ins. or larger—and several plates may have to be developed simultaneously—they are usually of several gallons capacity.

Special stainless steel hangers support the plates or films in the solutions in the tanks. Films are usually held taut in a frame provided with spring-loaded clips which grip the film firmly at each corner. Plates slide into a frame of channel-section.

For colour processing commercial tank sets incorporate some temperature control system, usually in the form of a thermostatically controlled water bath. Such tank sets for the professional darkroom are designed to handle not only sheet films in hangers or racks, but also roll films and colour papers.

Modern commercial tank sets are used in conjunction with semi-automatic or even automatic programming systems that ensure absolutely standardized processing conditions. The solutions in colour processing tanks are usually agitated by nitrogen burst equipment.

X-ray Film Tanks. Still larger tanks are used for X-ray film. These tanks must be able to take films up to 14 × 17 ins. They are sold in sets of four tanks, one for developer, one rinse tank, one fixing tank, and one washing tank. All four tanks are supported on a strong wooden stand, and the developing tank has a lid to protect the film from the darkroom illumination during development.

For processing X-ray films in quantity (up to 60 per hour in the largest sizes), as in the radiographic department of a hospital, special processing units are available. These have a stout tank, divided into two compartments; the larger holds the solution tanks and the smaller serves as a washing chamber. The processing tanks stand in water which is maintained at a constant temperature.

Three processing tanks are provided, one for developing and two for fixing; between the developing and first fixing tanks there is a spray-rinse compartment where a water spray removes surplus developer from the film and prevents it being carried over into the fixer. Two fixing tanks are provided because fixing takes about twice as long as developing and to prevent congestion in the fixing tank each film spends the same length of time in each tank.

Washing takes place in a strong current of water in the washing compartment, and a small tank in the washing compartment holds wetting agent into which the washed films are briefly dipped to assist even drying. G.B.M.

Book: *Developing*, by C. I. Jacobson (London).

TANNIC ACID. Tannin. Hardening agent in scratch-proofing solutions.

Characteristics: Brown powder.

Solubility: Very slightly soluble in water at room temperature. It is best dissolved in boiling water, cooling the solution afterwards.

TANNING DEVELOPER. Type of developer which tans or hardens the gelatin in a sensitized emulsion. This tanning action is proportional to the silver forming the image in the emulsion.

Tanning developers are necessary for certain processes in which a relief image is required—e.g., dye transfer. The effect can also be employed to prevent excessive highlight densities in a negative.

See also: *Developers; Dye transfer colour prints.*

TANNIN PROCESS. One of the many methods of preserving wet collodion plates in a "dry" (or rather tacky) condition. Introduced in 1861 by Major C. Russell. The plates could be kept for several weeks after having a tannin solution poured over them, but were only suitable for inanimate subjects since the exposure was six to eight times longer than for wet collodion.

TAPE RECORDER

Apparatus for recording and reproducing sound on magnetic tape. Tape recorders have two main uses in photography: they provide background music or sound effects while cine films or still transparencies are being projected and they provide a synchronized sound track for a cine film.

The recording medium is a magnetic tape ¼ in. wide, consisting of a thin cellulose acetate or plastic base coated with magnetic iron oxide.

The Tape Deck. The tape deck is a flat platform carrying two spool holders, one each side of a slot through which the tape passes from one spool to the other. Magnetic heads mounted in the slot (sound channel) either record a signal on the tape or play it back. On some machines one head does both jobs; on others there are separate heads. In addition there is an erase head which clears any existing magnetic record from the tape before it passes over the

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

THE BASIC TAPE RECORDER FEATURES. A, feed spool of tape. B, operation control switch (record, playback, fast wind forward and reverse). C, sound channel. D, recording level indicator. E, recording level volume control. F, output socket panel. G, speed selector. H, footage counter (tape position indicator). J, take-up spool. K, on/off switch of amplifier. L, input socket panel. The actual controls on commercial tape recorders may of course be differently shaped and differently positioned.

recording head. The erase head is put out of action automatically during playback.

As the tape passes through the sound channel it is gripped between two rollers, one of which, the capstan roller, is power-driven at a constant speed. This may be varied to give more than one of the standard tape recording speeds: 15/16, $1\frac{7}{8}$, $3\frac{3}{4}$, $7\frac{1}{2}$ or 15 ins. per second. The take-up spool which stores the tape coming out of the sound channel is driven through a slipping clutch which maintains just enough tension on the tape to wind it neatly on to the spool. While recording and playing back, a light brake prevents the supply spool from over-running and tangling the tape.

The tape transport mechanism also includes provision for winding the tape rapidly in either direction, a digital tape position indicator to facilitate finding any item on the tape, and a "pause" control which allows the tape to be stopped and re-started instantly.

The Amplifying Unit. This serves for either recording or playing back or both.

In recording, a section of the amplifying unit varies the strength of the incoming signal to the correct recording level actually at the head and indicates it on a magic eye or a meter dial. Most recorders have separate inputs for high and low level sources—e.g. one for a microphone which may deliver only a few microvolts and another for a radio or gramophone pickup which may deliver anything up to 200 or 300 millivolts.

The playback section of the amplifier boosts the feeble signal from the tape to make it powerful enough to drive the loudspeaker. This section includes circuits for tone control.

In addition to the built-in speaker there are usually outlet sockets which enable the tape to be played back through an external speaker or an external amplifier and speaker.

Recording. To make the record, the tape is drawn at a constant speed over the polished face of the recording head. This face carries a narrow gap where the magnetic signal is concentrated. The width of this gap and its position in relation to the tape determine the number of tracks that can be recorded on the tape.

For the highest possible quality the head is designed to make one record over the whole width of the tape. This system, known as whole track recording, being uneconomical, is used mostly by broadcasting and commercial recording companies. Normally, tape recorders use half-track recording in which a single head records two tracks on the tape. In this method, the gap in the head is slightly less than half the width of the tape and is placed so that it records along the top half of the tape with the tape running from the supply spool on the left to the take-up spool on the right. When all the tape has passed over the head, the full take-up spool and the empty supply spool are transposed. The tape then runs through the sound channel a second time, when a record is made on the blank half of the tape.

MAIN COMPONENTS OF TAPE DECK. A, feed spool. B, recording and playback head. C, erasing head. D, monitoring or play-back loudspeaker (earphones may also be used; in either case the connection goes through the amplifier). E, footage counter, driven from take-up spool. F, take-up spool. G, pressure roller. H, capstan. J, motor driving the capstan and the take-up spool.

CC-0. Jangamwadi Math Collection. Digitized by eGangotri

The quarter track method uses two heads, one above the other, each covering rather less than one quarter of the width of the tape. The upper head records along the top quarter of the tape and the lower head along the next-but-one track down, leaving a space equal to one quarter of the width of the tape between the two heads. A track selector switch enables either head to be switched in or out of circuit.

The four tracks are recorded this way: with the upper head switched on, the tape is run through from left to right, making a record on the upper track. The tape is then wound back on to the left hand spool and run through a second time with the lower head switched on, making a second record on the next-but-one track below. The spools are now changed over and the above process is repeated, filling in the two remaining blank tracks.

To play back the record the tape is run over the head at exactly the same speed and in the same direction as for recording but with the erase head switched off and the record/play head connected for playback.

Normally only one track can be played at a time, but some multi-track recorders have facilities for playing back two tracks at once.

Mixing. It is often an advantage to be able to mix sounds from two independent sources—e.g. a continuous musical background and a spoken commentary. Most tape recorders have separate inputs for connecting to signal sources according to type—e.g. microphone, radio and gramophone pickup. These inputs are usually all connected to a common input control so it is not possible to mix them or record two at a time. However some machines have separate controls for two or more inputs and these allow two separate signals to be mixed—i.e. adjusted independently.

A similar result can be achieved on a multi-track tape recorder by recording the signals to be mixed on separate tracks and then playing them back together. It is usually possible with these machines to listen to the first recording on headphones while making the second recording in synchronism with the other head on the associated track. The second recording can be faded in and out and varied in volume as required.

Stereo Tape Recorders. A stereo tape recorder has two sets of heads and two recording amplifiers. The heads are one above the other and record the right and left channel signals simultaneously on the tape. There may be two separate playback amplifiers and speakers, or there may be simply two output sockets for connecting to an external stereo amplifier and its speakers.

On half-track recorders, the single stereo record takes up the whole width of the tape, the left hand stereo channel being recorded on the upper half of the tape and the right hand on the lower half. On quarter-track recorders the heads are arranged as on a 4-track monaural recorder, so that each complete stereo record occupies only two of the quarter tracks.

A 4-track recorder can be used for playing back pre-recorded stereo tapes if it has facilities for playing back one track through its built-in speaker and the other through an external amplifier and speaker (or both tracks through an external stereo reproducer).

Types. From the photographer's viewpoint there are two principal types of tape recorder; mains operated and battery operated. In these two categories prices cover a very wide range. Broadly speaking, mains machines are heavier and bigger than battery machines and have more volume and better quality. Some machines can use either battery or mains.

Most mains operated recorders are designed to run off the normal alternating current supply, the usually incorporate an amplifier capable of delivering anything from 3 to 10 watts and will take tape spools up to 7 ins. diameter. While there is always a built-in speaker, the amplifier is generally powerful enough to give even better volume and quality when connected to a larger external speaker. Mains operated recorders are primarily for recording, dubbing (transferring a record or parts of one from a tape on a second machine) and playing back indoors. As they are powered by current alternating at a fixed frequency, the speed of the motor is constant within extremely narrow limits and does not vary either with time or the length of tape on the spool. They are mostly too heavy (20 to 60 lb.), and bulky to be carried far.

Battery operated recorders are designed for recording in the field so they are usually small, light and easy to carry.

The reproduction quality is never as high as from mains machines but it is good enough for recording sounds to go with projected films and transparencies. The exceptions are the cheapest models with a performance little better than a pocket radio and the expensive machines costing ten times as much which are used by roving reporters working for broadcasting and commercial studios.

On the better types of battery operated tape recorder, the capstan is driven by a governed motor and the tape runs at one of the standard speeds. On the cheaper machines there is no capstan and the motor drives the take-up spool. This means that the tape speed varies with the diameter of the tape wound on the spool, starting slowly and increasing as the tape builds up. Tapes recorded in this way must be played back on the same machine.

Some cine camera manufacturers produce miniature recorders of this type for recording a sound track as the film is shot. The recorder is carried on a shoulder strap and is connected to the camera by a plug-in lead which couples the pause control on the tape recorder to the stop-start button on the camera.

Tape and Transparencies. A tape recorder can provide a background of sound to a trans-

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

parency projection session without any special equipment. The machine may be simply set up in the normal way to reproduce suitable music while the transparencies are being shown. However it is better for the tape recorder to be placed alongside the transparency projector and connected to an extension speaker either behind or just to one side of the screen. The built-in speaker of the tape recorder is switched off so that all the sound comes from the screen end of the room. This arrangement allows the slide projector operator to control the tape recorder as well and results in a more finished presentation.

Synchronizing devices used in conjunction with the tape recorder can operate the slide changing mechanism of an automatic projector. Here a signal recorded on the tape (e.g. on the second track) actuates a relay when the tape runs past a special playback head (often on a separate tape coupler) to change the slide in the projector. The first track carries the recorded sound commentary.

Tapes and Cine Films. A tape recorder can be used for playing background music and sound effects to accompany a cine film. If the sound and action are to be synchronized, special coupling systems are necessary to keep the speed of the tape recorder in step with that of the cine projector.

Most such systems control the speed of the projector motor from the tape and do so mechanically or electrically.

The sound may be recorded as the film is being shot, or it can be recorded afterwards while the finished film is being projected. When the tape and film are to be run through together, the tape recorder is started, run through to the cue sound and held stationary on the pause button.

The film is then started; as soon as the marked cue frame on the leader flashes on the screen, the tape is released and from then on the sound and picture run in synchronism. Even when the sound track is recorded on a magnetic stripe on the actual film it is generally preferable to record and edit the sound on tape separately and then dub it from the tape on to the stripe with the aid of a synchronizing attachment. F.P.

Books: *Tape Recording*, by A. A. McWilliams; *The All-in-One Tape Recorder Book*, by J. M. Lloyd.

TAUPENOT, J. M., 1824–56. French professor of chemistry and physics. Invented in 1855 the Taupenot Dry Plates. These were glass plates coated first with silver iodide collodion and then with albumen; they were prepared in advance and required only supplementary sensitization in a silver bath before use. They produced good images and were convenient for outdoor work, but required longer exposures than wet collodion plates.

TAYLOR, HAROLD DENNIS, 1862–1943. English lens designer and manufacturer of optical instruments. In 1893 designed and patented the Cooke triplet lens which, owing to its simple construction and outstanding performance, became very popular. The Cooke design provided a foundation on which many subsequent advances in photographic lens design have been based. In 1896 suggested the use of thin coatings on lens components to diminish reflections. Patented in 1885 an exposure meter, the first of many patents for which he was responsible. Also wrote on optics; his book *A System of Applied Optics* (1906) was the first important English book on applied optics to have been published for nearly 100 years. Another of his books, *The Adjustment and Testing of Telescope Objectives*, is still a current reference work. H. D. Taylor was not related to the firm of Taylor, Taylor and Hobson Ltd., although they manufactured his triplet lens. Received the Progress Medal of the Royal Photographic Society in 1935.

TAYLOR, JOHN TRAILL, 1827–98. English writer on photography. Editor (from 1864 to 1898) of the *British Journal of Photography* and the *British Journal Photographic Almanac*. The Royal Photographic Society instituted in 1898 the Traill Taylor Memorial Lectures in his memory.

TECHNICAL CAMERA

The modern technical camera is a photographic instrument designed for maximum control of image scale and perspective. It therefore provides a high degree of versatility by camera movements, adjustable extension, interchangeable lenses and—in some cases—different negative formats and negative materials.

The earliest technical cameras closely resemble the large size studio camera from which they were derived. A movable plate holder and lens panel provide independent front and back adjustments, comprising movement along and at right angles to the optical axis, as well as swings and tilts about a vertical and a horizontal axes. Extra long bellows produce double and triple extension systems. The lens standard moves along a flat bed- or baseboard which pulls up to close the camera. Cameras of this type are also known as field, stand or view

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

MONORAIL TECHNICAL CAMERA. Derived from the older view camera type, the present-day technical camera is built on the lines of an optical bench based on the monorail. All units are individually adjustable in every direction to give the maximum operational flexibility. Lenses and shutters are interchangeable and sheet films or plates are invariably used. Negative sizes range from 2½ to 3¼ ins. to 8 × 10 ins. Top left: *General view.* Top right: *Fitting of behind-the-lens shutter between the front standard and the bellows.* Bottom: *Side view.*

ALTERNATIVE TECHNICAL CAMERA DESIGNS: Top: Old type field camera. The hinged-on baseboard permits a swing of the wooden camera back about a horizontal axis only. The lens panel has rising front and tilt movements. Centre: Modern technical hand camera. This is usually of all-metal construction. The hinged-on baseboard in conjunction with a ball-jointed extension of the film holder permits a limited back swing in all directions. The lens panel has a limited swing-and-tilt movement as well as rising and cross front. Bottom: Flat bed camera. The back, baseboard and lens panel are of wood. The baseboard provides up to triple extension. Both the back and front carry swing-and-tilt movements; the front also has a reasonable degree of vertical rise. This camera type is nearly as versatile as a monorail design.

cameras, reflecting their applications and methods of use.

Today the technical camera is used for the majority of static subjects requiring extensive image control in commercial and technical photography. It has wide applications in close-up work of all kinds, architectural, industrial, medical, etc. photography—in fact virtually all fields where the versatility and control possibilities of a technical camera system are more important than a light-weight and quick working instrument.

Negative Material. Technical cameras take sheet film or plates in single or double film or plate holders. They are made in various sizes from $2\frac{1}{2} \times 3\frac{1}{2}$ ins. (6.5 × 9 cm.) to 11 × 14 ins. (28 × 36 cm.). The commonest sizes are 4 × 5 ins. (10 × 12.5 cm.), the continental 9 × 12 cm. ($3\frac{1}{2} \times 4\frac{3}{4}$ ins.) format, 5 × 7 ins. (Continental equivalent 13 × 18 cm.), and 8 × 10 ins. (20 × 25 cm.). Half-plate and whole-plate ($4\frac{3}{4} \times 6\frac{1}{2}$ ins. or 12 × 16 cm. and $6\frac{1}{2} \times 8\frac{1}{2}$ ins. or 16 × 21 cm.) formats are also still in use especially among older camera types.

A number of advanced technical cameras take several negative sizes by using interchangeable rear units. Smaller negative sizes can be used with virtually all technical cameras by inserting reducing adaptors in the camera back.

Special materials, accommodated by suitable adaptors, include backs for diffusion-transfer prints (instant photography) and for roll film and perforated 70 mm. film. These are used mainly with the smaller sizes of technical camera, and then only for special applications requiring large film loads, or for occasions when the technical camera is used as a press camera.

There exists also a special technical camera taking 35 mm. film.

TYPES

The Monorail Camera. The contemporary technical camera design has no camera body as such, but is constructed on the principle of an optical bench. The basis is a single (sometimes double) rail unit with independent frames carrying the plate holder and the lens panel along the rails.

The rail itself may be square, triangular or round in section.

As in an optical bench, every part can be aligned individually. Apart from the camera movements themselves, the carriers run to and fro along the rail, usually by separate rack and pinion movements. On better camera types these can also be locked. This provides front and rear focusing and permits very precise control of sharpness as well as image scale.

The whole rail unit is usually mounted on a tripod or stand by means of a tilting head, providing a full range of inclinations and tilts in all directions.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Flat-bed cameras. A number of technical cameras still are based on the older design of a baseboard hinged to the camera back. The baseboard contains sets of extending runners which in turn carry the lens standard. Movement along one set of runners provides a normal focusing range; the extension of the runners gives extra long lens-to-film distances for close-ups or with long-focus lenses. Usually the runners extend to a total of twice or three times the lens-to-film distance with the normal lens set to infinity (double and triple extension cameras), permitting magnifications up to twice natural size. Macrophotographs on still larger scales of reproduction are possible with short-focus lenses.

The movement of the bottom unit of runners is generally linked to a rack and pinion drive or a pivoted lever movement for fine focusing. The additional extension is adjustable by hand. This controls the overall extension and coarse focusing.

Normally the baseboard, when open, is fixed at right angles to the camera back, being held rigid by means of struts. The baseboard can also drop down at a greater angle so as to be out of the way when using wide angle lenses; otherwise the front end of the baseboard might intrude in the field of view of the lens.

Flat-bed technical cameras usually have a more limited range of camera movements, especially for the rear frame, and back focusing is rarer. Sometimes the back is a shallow box hinged to the baseboard, and accommodates the bellows and lens standard when the camera is closed. Cameras of this design are sometimes also used as press cameras in the smaller sizes (up to 4 × 5 ins.) and are then fitted with a rangefinder coupled to the focusing movement, as well as an independent finder (since in press photography there is rarely time to focus an image on the ground glass screen at the back).

Technical Camera Systems. A number of modern technical cameras are designed on a construction set principle, with interchangeable components which can be put together in a variety of ways. The components are the rail, the front standard for the lens, the bellows, the

UNIVERSAL MONORAIL CAMERA SYSTEM. On some modern monorail cameras all components are interchangeable, providing amongst others a series of different camera backs for various film or plate formats. A, lens panel. B, interchangeable lens (usually with shutter). C, bellows-type lens hood. D, first bellows. E, front frame and carrier. F, central rail support. G, rail (may be extendable). H, second bellows for smaller format. J, ground glass screen frame and film holder for smaller size. K, rear frame and support for smaller size. L, second bellows for larger format. M, ground glass screen frame for larger format. N, rear frame and support for larger format.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

rear standard for the ground glass screen and film holders, etc. The rail will carry not only the front and rear units, but can if necessary take a centre frame as well, to provide support for extra long bellows extension with additional bellows units. The latter clip into the frames and are available in different forms and lengths. Frequently base rails of different length are also provided (or the standard rail can be extended by additional sections). The focusing range is thus very great, permitting close-ups down to a few inches and macro-photographs with a continuously adjustable magnification up to several times natural size. Alternatively, such an arrangement can accommodate a wide variety of focal lengths of lens from extreme wide-angle to very long telephoto. Special bellows are often provided for wide-angle photography to enable the lens and screen frames to be brought really close together.

Usually the rear unit is also interchangeable, providing ground glass screen frames of different sizes for various negative formats. One outfit of this kind might thus be built up into a 4 × 5 ins., 5 × 7 ins. or 8 × 10 ins. camera.

Some cameras provide a reflex housing as an alternative back unit. The latter is in effect a single-lens reflex camera, joined to the normal optical system of the technical camera on the rail. Sometimes the reflex housing incorporates some of the camera movements (swings and tilts). Other alternative back units may take adaptors for 35 mm. camera bodies; in this case the technical camera serves essentially as a close-up focusing bellows.

CAMERA MOVEMENTS

The technical camera carries more extensive adjustments than any other photographic equipment, to permit a high degree of control over proportions and perspective of the image. It is the ideal camera for the various techniques of corrective photography, including compensation and deliberate introduction of distortion in various directions.

The main adjustments are vertical and sideways movements of the back and the lens standard, and horizontal and vertical swings for both units.

For specially accurate and reproducible work the camera movements may be fitted with scales to indicate the exact angle of swing in any direction. On some cameras a positive stop or catch permits quick aligning and centering of all components in their basic position.

The Front Standard. Usually this is a U-shaped frame carrying the lens panel. This in turn takes interchangeable lenses (usually complete with shutter) on lens boards. The latter clip into position on the lens panel.

The lens panel moves up and down in its guides (rising front) and this movement may be controlled by a rack and pinion gear. Sometimes the panel will drop down below its normal (centre) position. In less expensive cameras the rising front movement is combined with a tilt about the horizontal axis, enabling the lens to point upwards or downwards as well. On better cameras the tilt is separate from the rising front movement, and may be either a centre tilt (about a horizontal axis running through the centre of the lens) or a base tilt (about the horizontal axis at the bottom of the U shaped carrier). The two types have various advantages; for example the centre tilt is quicker to adjust since it requires no refocusing of the image, while the base tilt permits a greater movement range.

The whole U-carrier frequently also slides sideways on its mounting (cross-front movement) and swings about a vertical axis.

The Rear Frame. On the modern monorail camera the rear unit usually has identical adjustments to the front one. This unit takes the ground glass screen frame and the film or plate holders. On older cameras the ground glass screen has to be removed before the film or plate holder can be inserted; on modern designs the screen frame is spring-loaded and the film holder slides in underneath after focusing.

On many cameras the screen frame can be fitted vertically or horizontally (or the film holders inserted from the top or from the side); alternatively the ground glass screen frame may rotate within a panel fixed to the rear standard.

With flat-bed technical camera designs the rear movements are usually more restricted. Unless the rear unit is mounted independently on the runners of the camera bed, there is rarely any swinging possibility about a vertical axis. The tilt about a horizontal axis is also more limited, and on flat bed cameras—especially the older field camera type—the rear unit has no vertical or horizontal sliding movements.

This is a limitation arising from the fact that the rear frame is usually hinged to the baseboard (though there are some technical cameras where the rear unit is as movable on the baseboard as the front). Certain cameras overcome this by using an extending back connected to the main rear unit by sliding brackets and a second set of bellows. This can be extended at the top, bottom or one side only to provide some degree of swing movement about either axis. One design has the extending back connected by ball joints to four sliding rails which move in and out of the main rear unit. These rails can be extended unequally when required.

In practical use adjustments of both the front and rear units are frequently required simultaneously. That is where the monorail type of technical camera scores over the older designs. Thus by tilting the rail upwards and tilting both the rear and the front units forward parallel to each other, a degree of front

rise results which is far in excess of that provided by the direct rising front movement. The same applies to the swings about the vertical axis (which can be used as a substitute for a cross-front movement), while opposite tilts of the front and rear standard provide a greater degree of depth of field control and simultaneous focus and perspective control.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

EQUIPMENT

Lenses. The choice of lenses for a technical camera is governed by much the same considerations as with any other interchangeable lens camera. Thus wide-angle lenses are required to cover large subject areas at short range, and long-focus lenses provide large-scale images at greater object distances. (This applies to distant as well as close-up views.)

Some early view cameras had convertible lenses consisting of two main components which could be used either together or separately, providing three different focal lengths. Modern demands on image quality are better met by having completely interchangeable separate lens systems.

Lenses for use in technical cameras require a greater covering power to permit utilization of the various camera movements. While the normal lens on a rigid camera rarely has to cover an image angle beyond 55°, a technical camera may require a "standard" lens covering up to 70°. Otherwise part of the image becomes vignetted or cut off as soon as the rising and cross front movements or the swing or tilt of the lens panel are brought into action. Similarly, wide-angle lenses need a useful image angle of 90° or over to retain the possibility of using the camera adjustments.

One way of obtaining extra versatility is to use as the standard lens a wide-angle lens system intended for a larger format (for example a wide-angle lens for a 5 × 7 ins. camera as the standard lens—the focal length should be the same—for a 4 × 5 ins. format).

Shutters. The subjects taken with a technical camera rarely call for fast shutter speeds, and comparatively long exposure times used to be quite common. Accordingly many earlier technical cameras have a simple shutter or none at all (some photographers still make their exposures by removing and replacing the lens cap).

The shutter on modern technical cameras may either be built into the lens or separate. In the former case every lens has its own shutter and is changed together with it on the lens panel.

Separate shutters may fit in front of the lens or may attach to the lens standard behind the lens board. One shutter, provided it has a large enough clear opening, can in this case serve a number of lenses.

Technical camera shutters usually have a separate opening and closing control, in addition to the normal shutter speed settings, to permit focusing on the ground glass screen. A few shutter designs incorporate an automatic diaphragm control that also closes down the lens aperture (from full opening for focusing and viewing) to a pre-set stop just before the exposure.

Tripods. The camera is always used on a tripod or other support. Sometimes the tripod uses the baseboard of a flat bed technical camera as a head on which the legs are assembled. Since technical cameras are comparatively heavy, tripods are nearly always bulky; they also have to be really rigid. An adjustable tripod head to permit tilting or inclining the camera in any direction is nearly always part of the camera support.

As the picture is arranged and focused on the ground glass screen, operation is slow; but the subjects photographed with a technical camera are nearly always static. L.A.M.

See also: *Camera movements.*

TECHNICOLOR. Colour process in which positive prints in colour of cine films are made by dye transfer or imbibition.

The basic principle of the process lies in the use of separate matrices which superimpose yellow, cyan, and magenta dye images in register on the final support.

The matrices may be produced in a number of ways. For many years there was a special Technicolor three-strip camera which exposed three separate films at once to provide three colour separation negatives. Coloured cartoons were photographed on a single strip of film, the three separations for each frame being initially photographed on to three frames, each through the appropriate tri-colour filter. Both these processes of photography are obsolete and it is now the general practice for photography to be undertaken on integral tri-pack materials which can be used directly, or indirectly, to produce the separate matrices.

The outstanding feature of the system is its flexibility; several negative-making methods may be used in shooting one picture and all are subsequently printed in Technicolor.

A great advantage of Technicolor is that large numbers of identical prints can be made at a relatively low cost because the raw stock used in the final prints is very similar to ordinary black-and-white stock, whereas most processes call for highly specialized materials.

See also: *Dye transfer colour prints.*

TELECINE. Systems and equipment for transmitting motion picture films by television. Telecine transmission involves projecting the film with a projector into a television camera and requires a number of provisions to adapt the

characteristic manner and the time in which the images change in a cine-projector and the properties of a television transmission system.

See also: *Television recording.*

CC-0. Jangamwadi Math Collection. Digitized by eGangotri Digital Preservation Foundation, Chandigarh

TELECINEMA. Live or recorded television transmissions projected on a large screen in a motion picture theatre. The television programme itself is produced in the normal way (it may be recorded on tape) and transmitted to a special television receiver in the cinema. This receiver is used for projecting the image on the usual large cinema screen.

To obtain enough light for projection, ultra-intense cathode ray tubes operating at up to 50,000 volts are used. The image displayed on a tube can then be projected by a conventional projection lens system.

An alternative method is to use a secondary projection system which does not derive its light from the power of the television tube. For instance the electron beam can scan an automatically and perpetually renewing oil film while a powerful light beam is focused on this film. The electric charge of the electron beam causes distortions in the oil film which the illuminating beam can project on a screen in the form of a visible image. Such secondary telecinema systems have the advantage of permitting projected images of much greater brightness.

TELEPHOTO ATTACHMENT. Afocal lens system to fit in front of the normal camera lens, converting the latter into a telephoto lens. The optical system is usually similar to that of a terrestrial telescope, often in the form of a prism monocular.

See also: *Afocal lens; Supplementary lens; Telephotography; Telephoto lens.*

TELEPHOTOGRAPHY. Long-distance photography depends on having the right apparatus and on knowing how to exploit it.

We can employ a long focus lens to produce a larger image on the negative than a normal lens would, or we can enlarge a small portion of a negative when printing, or we can combine both methods. Enlargement from a small portion of a negative may be accompanied by an unacceptably large grain size in the finished print. Also, sharpness decreases the greater the enlargement. For these reasons a good long focus lens on the camera is the better method. The effect of perspective must also be considered because it will appear correct only when viewed from the right distance and this is not always possible.

Rigidity. When using long focus or telephoto lenses on any camera, absolute rigidity is essential. When highly magnified images are recorded, the slightest camera movement will also be magnified and blur the image.

A reflex camera is particularly suitable for use with long focus lenses, firstly because most reflex cameras have provision for considerable camera extension, and secondly because the magnified image can be examined on the top focusing screen up to the actual moment of making the exposure. However, heavy lenses used with a long camera extension upset the point of balance when the camera is attached to a tripod. For this reason it is often helpful to mount the camera on a long baseboard which offers a direct support for the lens and can be mounted on the tripod at the point of balance. Some very long focus lenses have a tripod bush on the mount, and the camera (as the smallest part of the assembly) is attached at the end of the lens barrel.

With miniature cameras, telephoto lenses are often set in very light alloy mounts to reduce the tendency to overbalance.

Prism monoculars (one half of a prism binocular) can also be mounted in front of the camera lens for telephotography. They can increase the focal length of the camera lens 8 or more times, depending on the magnifying power of the monocular; certain models are marketed specially for this purpose with provision for rigid mounting.

The whole question of rigidity becomes very acute when long-distance photographs are taken from high viewpoints and exposed positions subject to strong winds.

TELEPHOTOGRAPHY. Left: *Camera with standard lens comparatively near to subject yields image with normal perspective rendering.* Right: *Camera with telephoto lens will yield normal size image at much greater subject distances. Perspective is, however, flattened, and the subject appears to have little depth in the picture.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Lens Hood. When a very long focus lens is adapted to a small camera, only a comparatively small centre portion of the image is recorded on the negative. The lens hood will have to be exceptionally long and narrow-angled to be really effective.

In expensive miniature outfits, stray light is not so serious because the lenses are so designed as to give no internal reflections.

With such lenses good negatives can usually be obtained with no lens hood at all.

Filters. Light coming from distant objects is apt to be "scattered" on the way. The maximum scatter is at the blue end of the spectrum and, in particular, in the ultra-violet. The human eye is especially sensitive to green and it is not nearly as sensitive to ultra-violet light as a photographic film. The scattered blue and ultra-violet light, unless filtered out, records as a haze on the negative. This is why distant objects seen clearly by the eye so often appear unsatisfactory when recorded in a photograph. To add to this effect, the intense brilliance of many distant views in comparison with the dullness of the immediate foreground may lead to over-exposure.

With panchromatic film, a pale pink or yellow filter designed to eliminate the ultra-violet band of the spectrum may be helpful without affecting the general colour balance of the subject. A green filter—i.e., a so-called full correction filter—will do the same thing to a greater degree and also improve the general colour balance. Much greater distant detail can be recorded by the use of a red filter, but only at the expense of the natural colour rendering. The maximum haze-penetrating effect (and greatest falsification of tones) is obtained on infra-red film used in conjunction with infra-red filters. By this method it is often possible to record distant detail not detectable by the human eye.

At the same time, light scatter in the shorter wave bands is produced by the presence of haze in the atmosphere. This can be penetrated by infra-red rays. But where dirt or carbon particles (smoke and dirty fog) are present it is impossible to obtain a clear result even by the use of infra-red technique. Therefore long-distance views in manufacturing areas are often disappointing. As a rule the best effects are obtained after the air has been washed by heavy rain, when clear visibility follows for a short period.

Perspective. Because of the abnormal focal length used in a telephoto picture, the natural perspective appears falsified if the picture is viewed from the usual distance of 10 ins. The nearest object in the picture may be a building about a quarter of a mile away, whilst the most distant object is some ten or fifteen miles beyond. In the resulting picture the two objects will appear comparatively close. This effect is further emphasized where deep filters or infra-red technique has removed even the natural haziness of the distance. Falsified tone values are then added to the flattened perspective to exaggerate the unfamiliar effect.

The great variation in the techniques, available when photographing long-distance views makes it possible to exercise considerable personal taste. Unless the photographer is deliberately sacrificing everything else to record the maximum detail, the various alternatives at his disposal can be adapted to produce creative effects far beyond the scope of mere topographical records. Many distant views are enhanced by the pictorial subject matter either in the foreground or middle distance. To narrow the view by means of a long focus lens may be to eliminate much of the charm. But if some nearer objects are included, the problem is usually how to compress the tone scale to obtain sufficient exposure in the foreground whilst not over-exposing the distance. The solution is usually to be found in using suitable colour filters and taking care not to over-expose the negative. B.A.

Book: *Photographic Optics*, by A. Cox (London).

TELEPHOTO LENS. Type of lens introduced in 1891, giving a bigger image than a normal focus lens without moving the camera closer to the subject and without using more than the usual normal camera extension.

This is especially useful with miniature and cine cameras taking interchangeable lenses, where long focus constructions are apt to be disproportionately heavy and bulky compared with the size of the camera. A telephoto lens under those circumstances yields images of equal magnification for only a fraction of the size of the unit.

The optical construction of a telephoto lens comprises two groups of lenses. The front group acts as a converging lens system, while the rear group—often separated by an appreciable distance from the front one—acts as a diverging lens unit.

Each group may be quite complex, comprising up to three elements per group to correct aberrations.

The front unit converges the rays from the subject, while the rear unit partly cancels this convergence. As a result the cone of light reaching the film appears to converge from a point some distance in front of the front unit. In other words the rear nodal point of the complete lens system is not inside the lens at all, but in front of it.

The distance from the rear glass of the lens to the film or plate is the back focus and is important when mounting the lens in the camera. In this instance the back focus is much shorter than the equivalent focal length (i.e., the distance from the rear nodal point to the focal plane)—a characteristic feature of all telephoto lenses.

Power of Telephoto Lens. The equivalent focal length divided by the real distance of the back

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

TELEPHOTO LENS. Top: *The lens consists of a front converging, and a rear diverging element. Both nodal points are in effect in front of the lens system.* Bottom: *The back focus of a telephoto lens is shorter than its focal length.* A, *front element.* B, *rear element.* N_1 *and* N_2, *nodal points.* F, *equivalent focal length of whole system.* BF, *back focus.*

of the lens from the film (the "back focus") gives the power of the telephoto combination. If the equivalent focal length is say, 12 ins. and the back of the lens is 4 ins. away from the film when focused on an object at infinity, the power of the lens is 12/4 = 3, usually written 3×. The power is approximately equal to the magnification produced by the lens.

Early telephoto lenses were made to give magnifications up to 10×, and the power of some types could be varied by adjusting the distance between the back and front components. A few lens makers supplied an accessory that turned the normal camera lens into a telephoto. This was simply a diverging lens group mounted at the back of a tube. The tube was fitted in place of the normal lens, and the normal lens was then mounted at the front of the tube, giving a conventional telephoto combination.

Modern telephoto lenses for still cameras have a fixed magnifying power, generally of around 4× to 8× and are made in apertures up to *f* 3·5 and greater.

Telephoto lenses of greater magnification and aperture than this are made for motion-picture photography and press work. Variable focus lenses are used to-day on movie cameras to give distance-to-close-up transition effects without moving the camera.

Increased focal lengths of telephoto lenses are obtained with mirror lens designs. Here the saving in overall length as compared with the nominal focal length is greater still, for the light path is folded back on itself two or three times inside the lens system. Mirror telephoto lenses are mostly in focal lengths of 500 and 1,000 mm. but extreme tele units exist with a focus of several metres. They are used with miniature or larger reflex cameras.

Inverted Telephoto Lenses. The telephoto principle is used in reverse to give longer instead of shorter back focus distances. This extra distance between lens and film is necessary in cameras like those used for Technicolor work where prisms and other mechanism have to be accommodated between the lens and the film. A diverging component in front of the normal converging camera lens in this case gives a short-focus combination with a long back focus.

Variable Focus Types. Variable focus telephoto lenses have some means of altering the distance between the front converging and rear diverging elements.

Lenses of this type can be made to give magnification from 2× to 10× and over, but they are not easy to correct for aberrations over the whole range.

Increasing the focus of the lens by moving the back component automatically lowers the relative aperture: if the magnification is doubled, the light falling on the film has only a quarter of its original intensity and the relative aperture of the lens falls two stop values.

This type of lens was popular in the days when all cameras had to be focused on a focusing screen, and they are still sought by owners of old type single lens reflex cameras. But they are generally unsuitable for use with scale focusing cameras. This and the need for correcting for change of *f*-number at every change of magnification, has resulted in their becoming almost obsolete.

Film studios use a special type of variable focus lens to give a quick transition from a distant to a close-up shot. In this lens the change of relative aperture and the effect of aberrations is automatically compensated for as the handle is turned to alter the focus. F.P.

TELEVISION

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Continuous transmission of a visible picture by means of electrical signals. The picture is converted into the signal in a special camera, and reconstituted as our image in a receiver. The link between the two may be a cable connection (closed circuit television) or wireless waves (broadcast television).

Scanning. For sound radio communication it is necessary to transmit an electrical signal corresponding to only one variable, the instantaneous amplitude of the sound wave impinging upon the microphone. In television the equivalent variable is scene brightness, but information is required simultaneously from all parts of the area of the scene. It would theoretically be possible to use a large number of parallel communication channels each one carrying information on the brightness of one picture point, but in practice a single channel must be used. An image of the scene is therefore scanned in the television camera in exactly the same way as a reader's eyes scan the words and lines of a page of print, and information on the brightness of successive picture points is transmitted in time sequence.

The picture is reconstituted at the receiver by a scanning process syncronized with that occurring in the camera, and persistence of vision is relied upon to give the effect of simultaneous presentation of all picture points.

In European systems the picture is scanned with either 405 or 625 lines, the entire picture scanning being repeated 25 times a second. The corresponding figures for American and some other systems are 525 lines and 30 times a second.

In practice interlaced scanning is used; each frame is scanned twice, first covering all odd-numbered lines, and then all even-numbered lines.

Television Camera. The camera used for taking the television picture is similar in principle to an ordinary photographic camera—i.e., it consists of a light-tight box with a lens in a focusing mount at one end, and a light sensitive surface at the other. The light reflected from the scene to be televised is collected by the lens and focused on to the light sensitive surface. Here the similarity between the two types of camera ends.

In the photographic camera, the optical image is transformed into a negative consisting after it has been processed of metallic silver. The density of the silver at any point is roughly proportional to the brilliance of the optical image; the brighter the image, the denser the deposit.

In the television camera, the optical image is transformed into an electrical signal. It is the electrical potential of the signal in this case that is proportional to the brilliance of the optical image.

A lens system, often a turret or zoom, forms an optical image on an electro-photo-sensitive surface inside the evacuated glass envelope of the camera tube. Two types of tubes are in common use, the image orthicon and the vidicon.

In the image orthicon, the photo-sensitive surface (the photo-cathode) emits electrons proportionally to scene brightness and an electron image is formed. This electron image is focussed by a magnetic lens on to a second surface where the impinging electrons form an electric potential image, i.e. the voltage to which a given point of the surface is charged is proportional to the scene brightness.

In the vidicon, the optical image is formed on a photo-conductive layer, the electrical conductivity of which increases with incident illumination. The increased conductivity of those parts of the layer which are brightly illuminated allows an electric charge to be conducted through to the back of the layer, where an electric potential image is thus formed.

In both types of tube, the electric potential image is scanned by an electron beam from an electron gun which discharges the potentials. The discharge currents form the output signal from the tube.

The Electronic Chain. In a television signal, the amplitude (voltage) corresponds to brightness, and non-linear electrical circuits are used to

TELEVISION CAMERA. Any one of the three lenses in the lens turret can be brought to focus the image on the photo-sensitive cathode of the image tube. Alternatively a zoom lens is used. The viewfinder is mounted on top. The whole unit is on a sturdy tripod or camera crane.

IMAGE ORTHICON CAMERA TUBE. The lens projects its image on a photo-cathode—usually about 5 ins. in diameter. The photo-cathode emits electrons in proportion to the amount of light falling on it. This electron stream is focused by magnetic coils on to the target connected to the output circuit. A scanning beam from an electron gun scans this image and produces the output signal. A, object. B, lens system. C, photo-cathode. D, magnetic lens coil. E, output signal. F, scanning beam. G, beam focusing and scanning coils. H, glass envelope. J, electron gun. correct or modify the grey-scale (gamma) characteristics of the picture.

The resolution of a television system is, in general, different in the vertical and horizontal directions. Assuming that the camera optical system is of adequate resolution and that the camera and receiver scanning beams are of adequately small diameter, the vertical resolution depends only on the number of scanning lines employed. Thus a 625 line system is superior in vertical resolution to a 405 line system by some 50 per cent.

Again assuming adequate optical and scanning arrangements, horizontal resolution depends only on the bandwidth (number of megacycles/second) of the electronic chain. The greater the bandwidth, the greater the resolution. But large bandwidths necessitate more expensive design and greater transmitter power; allow fewer channels in a given communication band; and introduce more "noise", the random electrical fluctuations which give an appearance similar to film granularity. The chosen bandwidth must therefore be a compromise: that selected for 625 lines is 5.5 Mc/second. The transmitted channel bandwidth must be greater than this in order to accommodate the accompanying sound signal.

Synchronizing. A certain level, often 30 per cent, of the electrical picture signal is arbitrarily defined as black level. Any signal greater than 30 per cent will give increasingly lighter greys. Any signal less than 30 per cent will be black and therefore invisible on a correctly adjusted receiver.

The zero-to-30-per cent range ("blacker than black") is used to transmit synchronizing pulses, which serve to lock the receiver scanning circuits so that camera and receiver scanning proceed exactly in synchronism. Two types of pulses are transmitted, one to synchronize the horizontal or line scan, the other to synchronize the vertical or field scan.

Television Receivers. In the receiver, the picture is finally displayed on the electro-luminescent screen of a cathode-ray tube. In this evacuated glass tube, a beam of electrons is ejected from an electron gun and impinges on the phosphor, which emits light at the point of impact. The brightness of the emitted light is a function of the electron density of the beam.

The television signal is applied to the electron gun so as to modulate the beam density: as the signal voltage increases, so the beam becomes denser and more light is emitted from the screen. Electrical circuits scan the beam over the screen area in synchronism with the television camera scanning, so that the bright and dark picture points appear on the screen in the correct relative positions.

Colour Television. By the use of optical filters (usually dichroic mirrors) the red, green and blue portions of the light reflected from the scene may be directed on to three separate camera tubes mounted in a single camera body. The camera then yields three electrical signals

VIDICON CAMERA TUBE. This is considerably smaller than the image orthicon and hence more suited to compact television cameras. The image is projected on to a photo-conductive layer which is scanned by a scanning beam from the electron gun. The gun discharges the charge formed by the optical image, and thus produces the output signal. A, object. B, lens system. C, image formed on photo-conductive layer. D, output signal. E, beam focusing and scanning coils. F, scanning beam. G, glass envelope. H, electron gun.

RECEIVER CATHODE RAY TUBE. The electron beam modulated by the transmitted picture signal scans over a luminescent phosphor layer inside the tube to build up an image. The receiver tube may have a front face diameter of up to two feet or so. A, electron gun. B, signal input. C, focusing magnet. D, scanning coil. E, scanning beam. F, glass envelope. G, phosphor layer.

SHADOWMASK COLOUR RECEIVER TUBE. Three electron beams pass through a masking plate to a phosphor mosaic of dots emitting blue, green and red light respectively to build up an additive colour image by simultaneous scanning. A, electron guns. C, focusing and scanning coils. D, electron beam. E, masking plate. F, phosphor mosaic. R, G, B, red, green and blue electron guns or phosphor dots.

corresponding to the three colour components of the scene.

These three signals could be simultaneously transmitted on three separate communication channels and the final colour picture formed by optical superimposition of the three separate primary colour pictures. This would, however, be wasteful of channel space and would require a cumbersome receiver.

To conserve channel space, use is made of the fact that normal black-and-white television makes very inefficient use of the bandwidth occupied. By a system of special electrical coding, signals carrying colour information are fitted into parts of the band left unoccupied by the black-and-white signals. At the receiver, decoding restores the original primary colour signals. Some interference occurs between the chrominance and luminance signals when coded as described, and this gives rise to a pattern of small dots on the final picture. One well-known coding system is that of the N.T.S.C. (National Television Systems Committee) and was originated in the United States.

To avoid the use in the receiver of three separate tubes with coloured screens, the shadowmask tube was developed. The screen of this tube consists of a large number of triplets of phosphor dots. A dot of red emitting phosphor, a dot of green and a dot of blue are laid down close together, these triplets being repeated over the whole screen area. Three separate electrons guns are employed, and the electron beams pass through a plate containing many small holes. The guns are so arranged that any one gun on "looking" through the perforated plate can "see" phosphor dots of only one colour: thus one gun activates only red dots, one only green and the third only blue. The three primary colour electrical signals can thus each be applied to modulate an electron beam activating only the required colour. The phosphor dots are sufficiently closely spaced to give the effect, at a normal viewing distance, of a continuous colour picture. D.P.L.

Book: *The Technique of Television Production*, by G. Millerson (London).

TELEVISION RECORDING. Recording of electrical television signals, both picture and sound, in such form that subsequent replaying will reproduce the original electrical signals as faithfully as possible. Two recording media are in general use, photographic film and magnetic tape.

Recording finds many uses in television operations. Delayed transmission, repeats, export, archive and editing are the most important.

Film Recording. Basically this is achieved by displaying the television picture on a cathode ray tube screen and photographing the display with a motion picture camera. The end product is a film which is almost identical to one produced by normal motion picture techniques. The line structure of the original television picture is as far as possible eliminated in the recording process, so that a film recording made on one television standard (e.g. 405 lines) may be replayed on a different standard (e.g. 625 lines): this greatly eases the problem of exchanging programmes between countries using different standards.

A fundamental design problem in film recording concerns pull-down time, since the time interval between successive television pictures is very short, of the order of 1½ thousands of a second. It is found just possible to pull down 16 mm. film in this short interval, but larger dimensions and greater mass rule

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

this out on 35 mm. A number of solutions to this problem have been devised, amongst which are continuous motion systems; suppressed field systems in which every other television scan is blanked off, the time thus gained being used for pull-down; and stored field systems in which the television picture information displayed during pull down is stored in the form of screen phosphor afterglow and presented to the film only after pull down is completed. All these systems have their drawbacks in terms of loss of resolution or blurring of rapidly moving objects, but the best are capable of very acceptable results.

On the American continent, means have to be found in terms of non-regular pull-down cycles to convert the television picture repetition rate of 30 per second to the film rate of 24 per second. On European standards the television repetition rate is 25 per second, and film is accordingly run at this rate since this differs from the normal 24 per second by only 4 per cent.

Telecine. Telecine equipment converts a film image into an electrical television signal, and is used to replay both film recordings and non-intermittent films.

SYNCHRONIZING WITH 60 CYCLE SYSTEM. When recording television pictures at the picture frequence of 30 per second from film at 24 frames per second, one television field in every five must be lost. The American method (left) uses a half field pull down time of 1/120 second (i.e. the film is advanced from one frame to the next in the cine camera while the television receiver displays half a field). Thus the first film frame records two fields, the second frame one full and two split half fields, the third frame again two fields and so on. This requires careful adjustment. The British system (right) uses a fast inter-field pull down at a non-regular pull down frequency. A shutter eliminates every fifth field. The television fields A, B, C, etc., are displayed at 60 per second, corresponding to 30 complete pictures per second.

The simplest, and most widely used, method of achieving this is to run the film in a standard film projector directed into a vidicon television camera.

Superior results are obtained, though with greater complexity and cost, by use of the continuous motion flying spot principle. Here, unlike the electron beam scanning of a television camera, the picture analysis is effected by optical scanning with a scanning light beam. The light source is a cathode-ray tube phosphor on which a moving spot of light is produced by means similar to that used in a television receiver. The scanning light beam, after passing through the film, is directed on to a photoelectric cell which produces the required electrical signal. The film is moving continuously at 25 frames per second, no intermittent mechanism being required. This system is suitable only for European standards where the picture repetition rate is 25 per second.

Video Tape Recording. The recording medium here is unperforated magnetic oxide tape very similar to that used for sound recording, although video tape is 2 ins. wide.

The electrical television signal is recorded on the tape in the form of magnetic variations and there is no visible image. A basic problem is to compress the television signal information into a frequency band which the tape can accommodate, and this is solved by causing the television signal to modulate a higher frequency carrier (between 5 and 10M c/s). Although this results in higher frequencies, the number of octaves occupied by the signal is reduced. Frequency modulation is employed to minimize the effect of variations of tape sensitivity, etc.

To enable such high frequencies to be recorded and reproduced, a very high head-to-tape velocity is required. The tape is moved longitudinally at only 15 ins. per second, but rotating heads are used which sweep laterally across the tape at 1600 ins. per second., laying down a series of closely spaced lateral tracks. To provide for longitudinal positioning of the tape during replay, a control track is recorded in addition to the signal recording: this is the video tape counterpart to film sprocket holes. Elaborate electro-mechanical servo systems are required for correct tape positioning. Lower tape tracking speeds can be used, but lead to lower image quality. This may be acceptable for certain purposes—e.g. industrial closed circuit systems.

A video tape recording can be replayed only on the television standards on which it was recorded: this renders video tape particularly inconvenient for programme exchange between countries using different field rates, since the unsatisfactory process of optical standards conversion must then be employed.

Sound is recorded longitudinally along one edge of the tape.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Film versus Video Tape. At its best, 35 mm. film recording can rival video tape in picture quality and, with separate magnetic sound film, surpass it in sound quality. On 16 mm. the picture is less satisfactory, and even on 35 mm. first class results are difficult to obtain consistently. However, the end-product of film recording is in essence a standard motion-picture film and can be handled, edited, viewed and copied by standard methods, equipment and personnel. It is the medium to use if much editing is required, if many copies are needed, or if copies are to be sent to an organization using different television standards.

Video tape offers the advantage of first-class quality, immediate play-back without processing and comparatively low running costs since tape can be erased and re-used. It is subject to the disadvantages of combined sound and difficult editing, restriction to one television standard, and the difficulty of making further copies. Video tape recording should be used for time delay purposes of any sort but is inconvenient when much modification of the original programme is contemplated.

It is also possible to record still pictures magnetically. In this case a magnetic disc may be used, rotating at high speed. Each revolution of the disc corresponds to a frame scan. The scans are presented to the receiver in continuous repetition. D.P.L.

Book: *Video Tape Recording*, by J. L. Bernstein (London)

TELEVISION SCREEN PHOTOGRAPHY.

It is a fairly easy matter to take reasonably well defined photographs of pictures on the screen of a television set. Within limits any camera can be used, providing that it is possible to give the suitable exposure time.

The Screen Picture. The image on the television screen is produced by a very narrow beam of electrons generated in the cathode ray tube. The screen consists of a coating of fluorescent material on the end of the tube.

When the electron stream (the cathode ray) strikes the screen, the fluorescent material glows visibly producing a bright spot on the end of the tube. This spot glows more or less brightly according to the strength of the cathode ray which in turn is controlled by the signal received by the set. When the set is working, the spot is made to "scan" the whole area of the screen—i.e., it is made to travel very rapidly in a pattern of horizontal parallel lines. As the spot traverses the picture space it is "modulated" by the incoming signal and generates an image.

Minimum Shutter Speed. In the television system in general use in Europe, the receiver picture is the sum of two sets of lines, one set occupying the spaces between the other. Each scans the picture space in 1/50 second, so it takes 1/25 second to produce a complete picture. It follows that an exposure of less than

TELEVISION SCREEN IMAGE: The picture is built up by a scanning beam which in one cycle covers the screen with a set of scanning lines, followed by a second interlaced set (starting top right). The camera exposure must cover at least one, or a whole number of, complete image cycles.

1/25 second will show only part of the screen image. This limits the shutter speed to not less than 1/25 second. American systems with a scanning time of 1/60 second call for a shutter speed of 1/30 second.

Definition. There are on European systems 625 or 405 lines across the width of the picture, and this number is the same no matter what the size of the screen. This figure governs the definition of the picture.

If the screen is 10 ins. high, then the image will have—on a 625-line system—62·5 lines per in. A photograph of the image 5 ins. high would therefore have 125 lines per in. So the lines are always more obvious than the grain of the fastest film or the shortcomings of the cheapest lenses. The figure of 62·5 lines per in. limits the rendering of detail. On American screens the number of lines is 525.

Taking the Photograph. The camera should be set up on a steady tripod with the lens opposite the centre of the screen and the back parallel to its surface. For a 12 ins. screen, the camera should be about 3 feet away—if it is closer than this, the depth of field of the lens will not be sufficient to allow for the curvature of the end of the tube. When measuring the distance it is necessary to add an inch or so for the space between the end of the tube and its protective glass window.

As the screen image tends to be over-contrasty, the receiver controls should be set to give a soft picture. Tube characteristics vary so the best exposure must be found by trial and error (an exposure meter is useless). With the lens stopped to *f*4, test exposures of 1/5, 1/10, 1/25 second should give one satisfactory negative. A shutter speed less than 1/25 second will not give a complete picture.

Shutter speeds longer than 1/25 second may lead to image movement, caused by the registering on the negative of more than one scan of the T.V. screen, and these longer exposure times can only be used when there is little or no movement on the screen. So it is advisable to choose a programme that is going to be repeated and to use the first transmission for

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

this out on 35 mm. A number of solutions to this problem have been devised, amongst which are continuous motion systems; suppressed field systems in which every other television scan is blanked off, the time thus gained being used for pull-down; and stored field systems in which the television picture information displayed during pull down is stored in the form of screen phosphor afterglow and presented to the film only after pull down is completed. All these systems have their drawbacks in terms of loss of resolution or blurring of rapidly moving objects, but the best are capable of very acceptable results.

On the American continent, means have to be found in terms of non-regular pull-down cycles to convert the television picture repetition rate of 30 per second to the film rate of 24 per second. On European standards the television repetition rate is 25 per second, and film is accordingly run at this rate since this differs from the normal 24 per second by only 4 per cent.

Telecine. Telecine equipment converts a film image into an electrical television signal, and is used to replay both film recordings and normal cine film.

SYNCHRONIZING WITH 60 CYCLE SYSTEM. When recording television pictures at the picture frequence of 30 per second from film at 24 frames per second, one television field in every five must be lost. The American method (left) uses a half field pull down time of 1/120 second (i.e. the film is advanced from one frame to the next in the cine camera while the television receiver displays half a field). Thus the first film frame records two fields, the second frame one full and two split half fields, the third frame again two fields and so on. This requires careful adjustment. The British system (right) uses a fast inter-field pull down at a non-regular pull down frequency. A shutter eliminates every fifth field. The television fields A, B, C, etc., are displayed at 60 per second, corresponding to 30 complete pictures per second.

The simplest, and most widely used, method of achieving this is to run the film in a standard film projector directed into a vidicon television camera.

Superior results are obtained, though with greater complexity and cost, by use of the continuous motion flying spot principle. Here, unlike the electron beam scanning of a television camera, the picture analysis is effected by optical scanning with a scanning light beam. The light source is a cathode-ray tube phosphor on which a moving spot of light is produced by means similar to that used in a television receiver. The scanning light beam, after passing through the film, is directed on to a photoelectric cell which produces the required electrical signal. The film is moving continuously at 25 frames per second, no intermittent mechanism being required. This system is suitable only for European standards where the picture repetition rate is 25 per second.

Video Tape Recording. The recording medium here is unperforated magnetic oxide tape very similar to that used for sound recording, although video tape is 2 ins. wide.

The electrical television signal is recorded on the tape in the form of magnetic variations and there is no visible image. A basic problem is to compress the television signal information into a frequency band which the tape can accommodate, and this is solved by causing the television signal to modulate a higher frequency carrier (between 5 and 10M c/s). Although this results in higher frequencies, the number of octaves occupied by the signal is reduced. Frequency modulation is employed to minimize the effect of variations of tape sensitivity, etc.

To enable such high frequencies to be recorded and reproduced, a very high head-to-tape velocity is required. The tape is moved longitudinally at only 15 ins. per second, but rotating heads are used which sweep laterally across the tape at 1600 ins. per second., laying down a series of closely spaced lateral tracks. To provide for longitudinal positioning of the tape during replay, a control track is recorded in addition to the signal recording: this is the video tape counterpart to film sprocket holes. Elaborate electro-mechanical servo systems are required for correct tape positioning. Lower tape tracking speeds can be used, but lead to lower image quality. This may be acceptable for certain purposes—e.g. industrial closed circuit systems.

A video tape recording can be replayed only on the television standards on which it was recorded: this renders video tape particularly inconvenient for programme exchange between countries using different field rates, since the unsatisfactory process of optical standards conversion must then be employed.

Sound is recorded longitudinally along one edge of the tape.

Film versus Video Tape. At its best, 35 mm. film recording can rival video tape in picture quality and, with separate magnetic sound film, surpass it in sound quality. On 16 mm. the picture is less satisfactory, and even on 35 mm. first class results are difficult to obtain consistently. However, the end-product of film recording is in essence a standard motion-picture film and can be handled, edited, viewed and copied by standard methods, equipment and personnel. It is the medium to use if much editing is required, if many copies are needed, or if copies are to be sent to an organization using different television standards.

Video tape offers the advantage of first-class quality, immediate play-back without processing and comparatively low running costs since tape can be erased and re-used. It is subject to the disadvantages of combined sound and difficult editing, restriction to one television standard, and the difficulty of making further copies. Video tape recording should be used for time delay purposes of any sort but is inconvenient when much modification of the original programme is contemplated.

It is also possible to record still pictures magnetically. In this case a magnetic disc may be used, rotating at high speed. Each revolution of the disc corresponds to a frame scan. The scans are presented to the receiver in continuous repetition. D.P.L.

TELEVISION SCREEN PHOTOGRAPHY. It is a fairly easy matter to take reasonably well defined photographs of pictures on the screen of a television set. Within limits any camera can be used, providing that it is possible to give the suitable exposure time.

The Screen Picture. The image on the television screen is produced by a very narrow beam of electrons generated in the cathode ray tube. The screen consists of a coating of fluorescent material on the end of the tube.

When the electron stream (the cathode ray) strikes the screen, the fluorescent material glows visibly producing a bright spot on the end of the tube. This spot glows more or less brightly according to the strength of the cathode ray which in turn is controlled by the signal received by the set. When the set is working, the spot is made to "scan" the whole area of the screen—i.e., it is made to travel very rapidly in a pattern of horizontal parallel lines. As the spot traverses the picture space it is "modulated" by the incoming signal and generates an image.

Minimum Shutter Speed. In the television system in general use in Europe, the receiver picture is the sum of two sets of lines, one set occupying the spaces between the other. Each scans the picture space in 1/50 second, so it takes 1/25 second to produce a complete picture. It follows that an exposure of less than

TELEVISION SCREEN IMAGE: The picture is built up by a scanning beam which in one cycle covers the screen with a set of scanning lines, followed by a second interlaced set (starting top right). The camera exposure must cover at least one, or a whole number of, complete image cycles.

1/25 second will show only part of the screen image. This limits the shutter speed to not less than 1/25 second. American systems with a scanning time of 1/60 second call for a shutter speed of 1/30 second.

Definition. There are on European systems 625 or 405 lines across the width of the picture, and this number is the same no matter what the size of the screen. This figure governs the definition of the picture.

If the screen is 10 ins. high, then the image will have—on a 625-line system—62·5 lines per in. A photograph of the image 5 ins. high would therefore have 125 lines per in. So the lines are always more obvious than the grain of the fastest film or the shortcomings of the cheapest lenses. The figure of 62·5 lines per in. limits the rendering of detail. On American screens the number of lines is 525.

Taking the Photograph. The camera should be set up on a steady tripod with the lens opposite the centre of the screen and the back parallel to its surface. For a 12 ins. screen, the camera should be about 3 feet away—if it is closer than this, the depth of field of the lens will not be sufficient to allow for the curvature of the end of the tube. When measuring the distance it is necessary to add an inch or so for the space between the end of the tube and its protective glass window.

As the screen image tends to be over-contrasty, the receiver controls should be set to give a soft picture. Tube characteristics vary so the best exposure must be found by trial and error (an exposure meter is useless). With the lens stopped to *f*4, test exposures of 1/5, 1/10, 1/25 second should give one satisfactory negative. A shutter speed less than 1/25 second will not give a complete picture.

Shutter speeds longer than 1/25 second may lead to image movement, caused by the registering on the negative of more than one scan of the T.V. screen, and these longer exposure times can only be used when there is little or no movement on the screen. So it is advisable to choose a programme that is going to be repeated and to use the first transmission for

CC-0. Vasantha Raghavan Digital Preservation Foundation, Chandigarh

this out on 35 mm. A number of solutions to this problem have been devised, amongst which are continuous motion systems; suppressed field systems in which every other television scan is blanked off, the time thus gained being used for pull-down; and stored field systems in which the television picture information displayed during pull down is stored in the form of screen phosphor afterglow and presented to the film only after pull down is completed. All these systems have their drawbacks in terms of loss of resolution or blurring of rapidly moving objects, but the best are capable of very acceptable results.

On the American continent, means have to be found in terms of non-regular pull-down cycles to convert the television picture repetition rate of 30 per second to the film rate of 24 per second. On European standards the television repetition rate is 25 per second, and film is accordingly run at this rate since this differs from the normal 24 per second by only 4 per cent.

Telecine. Telecine equipment converts a film image into an electrical television signal, and

SYNCHRONIZING WITH 60 CYCLE SYSTEM. When recording television pictures at the picture frequence of 30 per second from film at 24 frames per second, one television field in every five must be lost. The American method (left) uses a half field pull down time of 1/120 second (i.e. the film is advanced from one frame to the next in the cine camera while the television receiver displays half a field). Thus the first film frame records two fields, the second frame one full and two split half fields, the third frame again two fields and so on. This requires careful adjustment. The British system (right) uses a fast inter-field pull down at a non-regular pull down frequency. A shutter eliminates every fifth field. The television fields A, B, C, etc., are displayed at 60 per second, corresponding to 30 complete pictures per second.

to replay both film recordings and normal cine-films.

The simplest, and most widely used, method of achieving this is to run the film in a standard film projector directed into a vidicon television camera.

Superior results are obtained, though with greater complexity and cost, by use of the continuous motion flying spot principle. Here, unlike the electron beam scanning of a television camera, the picture analysis is effected by optical scanning with a scanning light beam. The light source is a cathode-ray tube phosphor on which a moving spot of light is produced by means similar to that used in a television receiver. The scanning light beam, after passing through the film, is directed on to a photoelectric cell which produces the required electrical signal. The film is moving continuously at 25 frames per second, no intermittent mechanism being required. This system is suitable only for European standards where the picture repetition rate is 25 per second.

Video Tape Recording. The recording medium here is unperforated magnetic oxide tape very similar to that used for sound recording, although video tape is 2 ins. wide.

The electrical television signal is recorded on the tape in the form of magnetic variations and there is no visible image. making notes of the moment when the action is suitably restrained.

As grain is unimportant it is as well to use a high speed panchromatic film.

Care should be exercised in the use made of pictures taken from the television screen. While generally the television companies would have no objection to photographs being taken for personal use, it should be remembered that copyright may exist in their productions and no commercial use should be made of the photographs without consent.

Television Monitor for Press Recording. A television unit is made by at least one firm specially for photography of the televised picture. It is intended principally for use in the news departments of the daily press.

The unit has a camera with electrically operated shutter release. Operation of the release automatically blacks out the picture tube, opens the camera shutter, brightens the picture tube for one or two complete frames, blacks out the picture tube, closes the shutter and then restores the television picture. This operation takes approximately $\frac{1}{5}$ second.

The advantage of this system is that there is no possibility of recording a fraction of a complete frame on the screen—as might occur with slight shutter speed variation. In other words the television screen and not the camera shutter controls the exposure. F.W.G.

TEMPERATURE COEFFICIENT (DEVELOPER). Factor by which the development time of a developer must be multiplied to compensate for a fall in temperature of 10° C. (18° F.). The figure varies according to the developer—usually from 1·25 to 2·8.

See also: *Developing negatives.*

TEMPERATURE OF SOLUTIONS. The temperature at which a processing solution is used is important because it affects the rate of action of the chemicals involved and the gelatin of the emulsion.

Effect on Rate of Action. The warmer a solution, the quicker it works, but it always works at the same rate at any given temperature.

Development times are therefore always quoted at a standard temperature (usually about 65–68° F., or 18–20° C.). So long as the temperature of the developer is kept constant its rate of action will remain constant (other things being equal). For temperatures above and below the normal, the rate of action can be found by multiplying the standard time of development by the temperature coefficient.

At low temperatures special rapid acting developers must be used, as otherwise processing times are inconveniently long. At very low temperatures anti-freeze agents may be necessary.

Certain developing agents are almost inactive below 55° F. (13° C.).

Fixing baths, intensifiers, reducers, etc., all work faster at high temperatures than at low.

Effect on Gelatin Layer. The higher the temperature of a processing solution, the more water the gelatin layer absorbs, and the more it swells. At the same time it becomes increasingly soft and sensitive to scratches and other injury.

In its swollen state the emulsion must therefore be handled very carefully. The surface should never be touched with the fingers, or they may leave permanent marks. The extra warmth of the fingers on the swollen emulsion may even cause it to melt.

At temperatures above 75° F. (24° C.) special hardeners must be used to counteract this softening and all solutions should contain neutral chemicals to prevent excessive swelling.

Sudden changes in temperature from one solution to the next—specifically going from cold to warm—cause the gelatin layer to ex-expand irregularly. It then forms tiny wrinkles all over the surface, which look—and print—like very coarse grain. This effect is known as reticulation. The emulsion may also frill or form blisters by locally leaving the support as a whole.

So all processing solutions must be at the same temperature, particularly in hot weather. There should be no more than one degree difference between developer and rinse or between rinse and hardening fixer, and no more than two degrees between the hardening fixer and the washing water.

Temperature control systems. Methods for ensuring the correct processing temperature can vary from primitive water bath set-ups for occasional amateur purposes to complex thermostatically-controlled installations for professional and trade processing.

The various solutions can be kept at a uniform temperature throughout by standing all bottles, tanks, and dishes in a large dish of water. This should be a few degrees warmer (or, in hot weather, colder) than the processing temperature. The solutions should be left there for about half an hour before processing. Hot or cold water may be added from time to time to keep the temperature of this water bath constant.

The film is therefore inserted in the developing solution in the tank, rather than the developer poured into the tank. This is the only reliable way of accurate temperature control in processing (see below). Even there the reel holding the film should also be at approximately the correct temperature to avoid appreciable cooling or warming of the developer. Having a large solution volume helps, since the cooling effect of a film on a reel immersed in the bath is comparatively smaller.

Water baths—with an appropriately large volume of water—are also the most reliable method for controlling the temperature in large-scale installations. There a pump keeps the water circulating, and a thermostatically-

controlled heater keeps the temperature at a preset level.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

If the consumption of water is no economic problem, a temperature control system can use a water bath fed by continuously-running water from a thermostatically-controlled mixing tap. This adjusts the proportion of hot and cold water to the required temperature level. Mixing taps of this kind are frequently used in any case for the rinsing and washing stages in commercial processing.

For specially accurate temperature control the developing tank can have its own smaller water bath with an extra-sensitive thermostat and heater unit.

Where absolute accuracy of temperature levels is less important, direct heating of the solutions is also a suitable method. In large tank installations it provides the same accuracy as a water-bath; but direct heating of small volumes of solution may lead to unpredictable temporary temperature variations within the solution. Available methods include the use of heating (and also refrigerating) coils immersed in the liquid in the tank. The heating or cooling unit is then brought into action by a thermostat system.

Temperature control by thermo-elements has also been proposed. There the cold end of a set of thermo-couples cools down the processing solution (or a water bath surrounding a processing tank) while a heating coil warms it up. The two are controlled thermostatically.

In amateur darkroom practice a simple dish heater, consisting essentially of a light-tight metal box containing one or more 60 watt light bulbs, keeps developing dishes warm in cold weather. Such a unit can easily be made home-made, but requires appropriate precautions regarding efficient earthing and wiring. The degree of control is only approximate, and temperatures have to be checked with a thermometer in the bath.

Optimum Processing Temperatures. The best temperature for developing, fixing, and after-treatment is the highest at which the material can be handled without risk of damage to the emulsion.

The normally useful range of processing temperatures for films and plates is about 60–75° F. (15–24° C.), with 65–68° F. (18–20° C.) as the optimum. Above this range there is a real danger of excessive softening of the gelatin, below it the development and other times become very long.

In regions where extreme climatic conditions make it impossible to observe these temperatures (e.g., tropics, arctic, etc.) special processing solutions and procedure may be required.

For papers, the safe range of temperatures extends up to about 85° F. (30° C.), and even higher. It is quite usual to process printing papers at 70–75° F. (21–24° C.).

Emulsions coated on paper are less sensitive to temperature changes than films or plates, as the gelatin layer is much more intimately bonded to the paper grain.

Colour processing. Accurate control of solution temperatures is specially important when processing reversal colour materials. For the first development and colour development stages the manufacturer's recommended temperatures should be adhered to within ½°F. or ¼°C. This is because the rate of formation of the different colour images may be affected in slightly different ways by changes of temperature; a higher or lower processing temperature may thus lead—even with corresponding decrease or increase of the development time—to a shift in colour balance.

With negative colour films the developing temperature is specified with similar precision, though here some colour correction is possible in making the print. The other solutions (stop baths, hardeners, bleaches, etc.) offer somewhat more latitude, and the temperature should be exact within about 2°F. or 1°C. either way.

Special Processes. Certain processes, especially colour development and print toning, have very sharply defined optimum temperatures.

Processes which are based on dissolving away part of the emulsion layer, such as carbon, carbro, bromoil, gum-bichromate, etc., need temperatures round about 110–120° F. (45–50° C.). Most of the printing methods involving the reduction of chromates or bichromates in contact with gelatin or other organic materials fall into this category.

A few special toning methods such as hypo-alum are worked at about 140° F. (60° C.). At such temperatures even paper emulsions must be hardened. L.A.M.

Book: *Developing*, by C. I. Jacobson (London).

TEMPLATE. Exact, full-scale pattern used as guide in cutting out or machining some part of a manufactured article or mechanical structure in quantity.

Templates (which have been in use for over 150 years) are usually flat, made of metal, wood or plastic, and carry constructional details to aid quick assembly. Although photographic production of such templates was suggested as early as 1910, this method was not applied on any scale until 1940, when it was adopted for use in the aircraft industry. A modern aircraft contains thousands of parts cut from templates, and if templates laid out manually from data derived from blueprints are replaced by templates marked out photographically thousands of pounds per prototype aircraft can be saved and the time between design and test flight shortened by months.

In a typical photographic system, the working drawings are laid out on white painted metal in the drawing office (in the case

CC-0. Agamnigam Digital Preservation Foundation

of small parts), or on lofting tables in the case of the larger sheets (up to 5 × 18 feet) used in aircraft, boat and automobile drafting. The drawings are made on a dimensionally stable material, so it is practical to transfer the finished layout photographically to the metal from which the part is to be made.

For small parts the original drawing may be made on ground glass or copied by reflex printing from metal on to polyester direct-positive matt film—the reflex negative being then used for printing on to metal sheets coated with photographic emulsion. These polyester materials give good line positives directly, and have remarkably good dimensional stability. For larger parts the original drawing is photographed on to glass plates and the negatives are subsequently projected at the required magnification on to metal sensitized by spraying with a photographic emulsion.

The metal prints are then cut out and become the templates or patterns. This projection process not only facilitates the production of scale models, but permits the correct allowances to be made for the shrinkage of castings when dies in other metals are required.

Dye-line sensitizing solutions (diazo compounds) can also be applied to suitably treated metal sheets. Drawings made on low-shrink translucent materials can be contact-printed, using UV-rich light sources. D.A.S.

TESSAR LENS. Anastigmat lens designed by Paul Rudolph and introduced by Zeiss in 1902. It was one of the early forms to break away from the symmetrical type of lens which suffered from zonal aberrations and which was therefore limited to medium relative apertures of *f*5 or *f*6.

The Tessar utilizes collective and dispersive lens elements separated by air spaces to correct curvature of field and achieves wider relative apertures and useful angular fields. The change from a single rear collective element in the triplet to the cemented doublet at the rear of the Tessar was a logical step forward which provided further improvements of zonal aberrations.

The presence of a cemented contact surface in the rear component provides a useful control over higher order aberrations and, since the expiry of the original Zeiss patents of 1902 and later, this form has been modified for various purposes by nearly every lens manufacturer. In the shorter focal lengths covering medium angular fields the relative aperture has been extended up to about *f*2·8. The Tessar form has been used extensively in medium price and expensive cameras for all focal lengths at apertures of *f*3·5 and *f*4·5 covering angular fields between 50° and 60°.

The Tessar form has been found particularly useful for front-cell focusing since it can be designed so that variation of the front separation between lens elements provides the requisite change of focal length whilst the correction of aberration suffers only small departures from the ideal balance. Inevitably there is a certain loss of definition and, generally, the lens is adjusted on the camera in such a way that the separation yielding best definition will focus objects at a medium distance. This ensures that focusing for infinity or short distances does not demand considerable variations from the ideal separation.

With the introduction of new types of optical glass in recent years the Tessar type of lens has undergone further development and, whilst its general shape and construction remains unchanged, the modern lens attains a standard of performance superior to that of the earlier forms. G.H.C.

TEST PAPERS. Strips of absorbent paper impregnated with indicators for testing the acidity, silver content, etc., of solutions.

See also: *Indicator chemical.*

TEST STRIP. Narrow strip of sensitized material which is used to find by trial the most suitable exposure—generally for a contact print or enlargement, but also occasionally for a negative.

The strip is exposed to light section by section in such a way that each section receives a constant multiple of the exposure given to the one preceding. The right exposure is determined by examining the developed image.

It is quicker and cheaper to find the correct exposure with test strips than by trial and error. The disadvantage of the method is that each section of the strip shows a different part of the picture—and not always a characteristic part.

There are special test-strip holders designed to overcome this disadvantage. The holder usually takes a strip of paper about 1 in. wide and 6 ins. long in a flat metal sheath. Only a small rectangle of the paper—about 1 in. by ¾ in.—is exposed, the remainder being

TEST STRIP HOLDER. Movement of the test strip by fixed distances indicated by notches brings successive portions of paper under same aperture. It thus records identical subject portions side by side on one strip of the paper.

CC-0. Agamnigar Kashmir Digital Preservation Foundation, Chandigarh

covered by the metal mask that forms the top of the holder. The edge of the holder is marked to indicate how much the paper must be moved after each exposure step to give a continuously exposed strip.

The holder is laid on the enlarging easel so that the open section lies under a typical part of the negative. It is then pinned or weighted in position, and the paper strip is given the desired series of exposure. In this way the same part of the negative image is used for each step along the test strip.

See also: *Enlarging.*

TEXTURE. Strictly, the arrangement of the constituent parts of a material—e.g., the weave of a fabric, the fibrous composition of wood, or the granularity of sandstone.

In art—and by extension, photography—the term refers to the structure of the material in so far as it is apparent on the surface. The characteristic surface texture—e.g., of cloth, skin, brickwork—can be made more obvious by the use of hard lighting from the side.

See also: *Lighting the subject.*

TEXTURE SCREEN. A special pictorial purpose is sometimes served in breaking up the image by printing the enlargement through a texture screen.

Such screens usually consist of a transparent film or plate, printed or engraved with a fine background pattern. This pattern is projected with the negative or printed by contact on the picture.

The texture relieves the monotony of large areas of tone in much the same way as rough or textured paper surfaces. The effect is mainly suitable for subjects consisting of broad tone masses rather than a lot of intricate and distributed detail.

The range of patterns obtainable in texture screens is very much wider than that provided by paper surfaces.

Screened Print Method. One way of giving a texture to the image is to lay a suitable screen on the printing paper. Screens for use in this way may consist of an open fabric like silk, muslin, etc. There are also special screens sold which imitate the effect of etchings, etc.

The screen is laid on the enlarging paper and pressed down with a glass plate to keep it in good contact. The print is then exposed in the normal way with possibly some adjustment in exposure.

The screen is not often left in position during the whole of the exposure. With large patterns in particular, only a partial exposure is given, so that the real image can be seen even in the texture pattern.

Screened Negative Method. The other way is to place the screen in contact with the negative in the negative carrier of the enlarger.

The screen used may again be thin fabric like silk or muslin, or it may be a special texture negative made by photographing any desired pattern (e.g., textures of wood, stone, cloth, leather, etc.) as background to the picture.

Where the screen is in contact with the negative, the texture effect may be diffused by the normal soft-focus methods. When very fine texture patterns are diffused in this way, they disappear in the shadow areas being overlaid by the spreading of light on the paper, and show through only in the highlights. L.A.M.

THEATRE

There are two main approaches to theatre photography—the professional and the amateur.

The professional is chiefly concerned with taking commissioned pictures of the production on the stage or in the studio. Such pictures may be used for display in the theatre foyer and for various publicity purposes. In practice the field is restricted to a handful of specialists who possess an intimate acquaintance with the needs of both the theatre managements and the artists, and who are experienced in working within the peculiar limitations of the stage itself.

The amateur is mostly interested in taking photographs of the actual performance from the auditorium. This branch of photography has been made possible by the 35 mm. camera with its wide aperture lens equipment and the extremely fast panchromatic films which are available today.

ON STAGE

Stage photography involves taking photographs on or around the stage itself, usually of a complete production. The management of the show, or their press representative, commissions the photographer, who is usually given the fullest co-operation by the actors and technicians. A period of one to four hours is set aside for this photo-call, usually on a day just before or shortly after the show opens. The prints are used for display in frames outside the theatre, and for issue to the newspapers and magazines from whom editorial publicity is sought. (Editorial use of pictures means their reproduction in the parts of a publication under the direct control of the editor and his contributors. This type of space cannot be purchased and, whilst it is given free of charge, there is always the possibility that the comments of the critic will be unfavourable. Photographs supplied by a theatre for editorial

use are usually expected to be made available free of reproduction fee.)

To be of value the whole procedure must be rapid from submitting proofs to completing the press and display prints. In addition, as the photographer does not know which press copies may be sent to newspapers with coarse-screen blocks and which to weeklies with the highest standards of reproduction, every print must be very carefully finished. In close-ups, the stage make-up and wig or false hair lines require a lot of discreet retouching if they are to be acceptable. For this reason much of the best stage photography has been done on quarter-plate or larger negative sizes.

Cameras. Theatre time is expensive, and some forty different pictures may have to be made in about three hours. So some stage photographers prefer a quarter-plate single-lens reflex because it allows them to see the image right up to the moment of exposure, which makes for rapid working. Others however, work almost as fast with the half-plate technical camera. Their familiarity with their instrument enables them to judge visually the effect of minor variations which may occur—or have to be made—between closing the shutter and drawing the dark slide ready for the actual exposure. In either case, at least two interchangeable lenses are carried: one of about 45°–50° angle of view, for groups and full-stage shots; and one of about 30° angle of view for close-ups and small group shots from a box or the circle of the auditorium.

A plentiful supply of film holders is also necessary, as there is no time to spare for reloading.

Oddly enough, the ruthless time limits, far from being a handicap, actually benefit the photographer who does not let himself get flustered by the pace and difficulties of theatre life. These conditions tend to produce interesting and lively pictures, because the actors can build up and retain the character and tempo of the piece much more effectively when they are not kept waiting about with little to do.

This is especially so in very light farces or revues, and for such shows a 6 × 6 cm. twin- or single-lens reflex may well be used, as occasonal minor defects in make-up and décor are of secondary importance to the capturing of some of the sparkle and animation of the show. It is also possible to use this type of camera for character plays or unglamorized dramas in small theatres, as such pictures also require little or no retouching.

Emulsions. High-speed (but not super-speed) panchromatic films or plates are the usual negative material.

Lighting. Most experienced stage photographers carry lighting equipment of their own. This simplifies exposure estimation and reduces loss of time in handling unfamiliar and often heavy stage lamps. The portable equipment usually consists of two or more 500 watt spotlights on telescopic stands with rubber wheels, and at least one 1,500–2,000 watt floodlamp, similarly mounted. One or two hand-floods and ample cables and distributors feeding from, and interchangeable with the standard theatre plugboards, complete the outfit. Every advantage is taken of the apparatus of the theatre itself, and, in general, basic lighting is arranged to retain the atmosphere of the production. It is usual, however, to employ the footlights or a portable floodlamp to give more fill-in illumination than would be desirable at a public performance.

For ballet and acrobatic performances, but seldom for other work, two or more flash-heads, mounted on stands and used as if they were spotlights, are synchronized with the shutter. In view of the modest fees current in stage work, flash bulbs are less frequently used than electronic flash.

Exposure. The stage photographer must see earlier rehearsals of the play so that he can prepare notes of the points in its progress which will make good pictures or which are essential to his collection of record shots (not always the same thing). Where possible, he notes down the actual spoken words to identify particular moments in the action. From these notes he prepares a photo-plot giving, scene by scene, the moments selected, with a note of the characters involved and other essentials. This is given at the photo-call to the stage director, whose job it is to call and check costumes of the actors and to supervise the changing of settings and props as the photographer works through the play.

Each picture is roughly grouped and lit, the actors do a brief rehearsal of that particular passage of the play, then the photographer decides at which precise point the movement is to be arrested for the exposure. Then the grouping is improved by rearrangement of the characters, the lighting finally adjusted and the camera positioned exactly and made ready. Now, the actors go through the scene—acting as if in a public performance—until the determined moment arrives. At this point the photographer tells them to "hold it", and while they "freeze" the action for an instant, he makes his exposure. Then he goes right on to the next picture; there is no time for retakes, unless the need is recognized immediately.

Properly handled, more feeling of movement can be compressed into such a picture in this way than in any taken during a performance. Exposures vary widely; but average conditions will permit ¼ second at *f* 11 on medium-speed panchromatic material. With high-speed panchromatic material and development for maximum speed, the 2¼ × 2¼ ins. roll film camera may use 1/50 second at *f* 11 under equivalent conditions.

Processing. The larger cameras produce negatives of suitable quality for enlargement if they are developed in a soft working formula.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Development by time and temperature at tank strength is standard practice because of the large number of negatives made at each session. 2¼ × 2¼ ins. roll film users will need a fine grain formula giving full speed rating.

Printing. The whole-plate or 8 × 10 ins. glossy prints for issue to the press must be made rapidly and in quantities, but the quality must be good enough to permit any of them to be reproduced full-size in good quality magazines. It is impossible to know in advance which may be selected for this purpose from the dozens made. The display publicity prints, 12 × 15 ins. in size and frequently larger, must be equal to any salon prints in quality, yet some thirty or forty of these must be produced within two or three days of taking. These prints will hang outside the theatre if the play is a success for a year or more, in all weathers, flooded with sunshine for hours each summer day, becoming humid in wet weather. Prints exposed to such conditions rapidly deteriorate unless they are given really thorough fixing and washing. For the same reason, only artists' quality water-colour may be used for print finishing. Dye is apt to fade or diffuse into the surrounding image areas.

Portraiture. Although at first sight a stage portrait is not essentially different from any other portrait, it is, in fact, a highly specialized type with its own very strict set of requirements. Portraits of stage personalities are needed for three main purposes: publicity and fan-mail, theatre display frames and job-getting. One portrait can seldom fulfil the requirements of all three purposes.

Deceptive retouching or "rejuvenation" has now more or less passed out as a fashion in the theatre. The average actor has found that interviews based on such pictures waste the time of casting directors and his own time. Nevertheless, no one wishes to draw attention to facial defects which make-up can successfully disguise. Rather large features look well on the stage, at audience distance. They may not look so well, or so co-ordinated, in a close-up, unless the photographer is very clever in his choice of viewpoint and lighting.

The aim in a job-getting portrait is to obtain a true likeness with some hint of the range of character types and "style" which are the special talent of the actor. For publicity, there must be some pictures which do this and which are also suitable for reproduction on a small scale in coarse-screen newspaper columns. Fan-mail pictures in postcard size usually show the star in more casual and informal poses and surroundings than would be employed for normal display and publicity. For theatre display, in the actor's private frames, pictures may be somewhat more imaginative, and are certainly more successful if they have some artistic merit. For display exciting photographs can be used, even if unsuitable for newspaper reproduction or casting purposes.

The retouching of all theatre portraits must be impeccable and the quality and permanence of the prints themselves must conform to the same standard. Many actors and actresses work exclusively for the theatre and radio without appearing before film or television cameras in their customary stage rôles. It is legitimate in such cases to use retouching to make the close-up portraits of such artists appear as they would do to a theatre audience, but to go further is undesirable, and discretion is more important than skill in applying artificial glamour.

COLOUR IN THE THEATRE

Theatre managements cannot usually afford to photograph an entire show in colour and purchase large colour prints for display. Nevertheless, they are frequently asked for colour shots by editors of illustrated magazines and the best way of doing this economically is to use reversal transparency film. Transparencies should not be less than 2¼ ins. square, preferably larger, owing to difficulties of cropping and photo-engraving from very small images.

The time-factor may well necessitate the use of film which can be processed by the photographer himself or by a professional laboratory which offers a rapid service. Very slight under-exposure of reversal film is far preferable to over-exposure, even though such transparencies may seem a little heavy in viewing.

For colour prints, negative type colourfilm should be used as colour prints from transparencies can be disappointing unless using highly expensive masking-methods. From colour negatives paper prints may be made and also enlarged transparencies for rear-illumination. In either case, it should be remembered that the dyes of the positives are not completely permanent. Display within the building, where the sun does not penetrate, will give a reasonably long life to the pictures, but exposed to daylight they will fade in a few weeks, even if protected by a final bath in an ultra-violet conversion substance before drying, and later coating them with a UV-absorbing lacquer. The client should be advised of these facts and encouraged to order duplicates when the first set of display copies are made. Their price is thereby lower than if reprinted at a later date. Greater permanence is obtainable in carbro and dye-transfer colour processes, but the high cost makes their use rare.

Historically important productions will justify the taking of negative colour pictures because the photographer may preserve the negative safely over many years and yet provide from them colour-slides and prints without parting with his original. J.V.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

FROM THE AUDITORIUM

Modern high-speed emulsions in conjunction with lenses with an aperture of *f*3·5 or wider make it possible to take fully exposed pictures with a hand camera from the auditorium by normal stage lighting.

Lens. The minimum speed for a hand-held exposure is 1/25 second, and under favourable stage lighting and with the fastest panchromatic films this speed calls for an aperture of about *f*4. So this is the smallest aperture that can be considered for this branch of photography. But a lens of this class leaves no margin for action or for shooting scenes with a low level of illumination, and anyone who wishes to take stage photography seriously should be prepared to work at *f*2.

The focal length of the lens is as important as the aperture, because it decides how much of the stage will be included from a given position in the auditorium. It is obviously wise to arrange for the width of the scene to fill the negative so as to keep the amount of enlargement down to a minimum.

There are three ways of tackling the problem: to choose a seat from which the camera with a particular lens will just include the width of the stage and cover the depth of the stage sharply at its maximum aperture; to accept whatever seat is available (as one must in a heavily booked show) and use a lens of a suitable focal length to give the necessary cover; or to choose the position that gives the best view of the stage and let it dictate the focal length of the lens.

The answer, in any case, will depend on the dimensions of the auditorium and stage. In a typical theatre with a stage 30 feet wide, 20 feet deep and 50 feet away from the front of the dress circle, the approach in each case would be along these lines:

(1) A camera equipped with a normal angle lens would cover the stage from a distance of 30–35 feet—i.e., from about the 6th–8th row of the orchestra stalls (allowing for the depth of the orchestra pit and a sparing of about 3 feet per row). A camera with no provision for interchanging lenses will get the biggest picture from this position. From a photographic point of view, however, this may be a poor choice—i.e., the feet of the performers may not be visible and the camera may have to be tilted unduly.

Under these conditions most hand cameras with the lens at *f*3·5 will cover the whole depth of the stage sharply with the focusing scale set at 50 feet.

(2) If the only seat obtainable is closer than about the 6th row of the orchestra stalls, there would be no point in using a wide angle lens to get the whole of the stage into the picture because the perspective would be unpleasant and the viewing angle too steep. But if the seat is very much farther away, then a long focus lens can be used to put matters right—e.g., from the back of the stalls or the front of the dress circle, a lens of about double the normal focal length will be satisfactory. And even at *f*3·5 the lens will cover the depth of the stage comfortably.

(3) In most theatres the best view of the stage is to be had from the front of the dress circle. From this position a normal angle lens will use only about one half of the width of the negative. To keep the scale of enlargement down, the camera should have a lens of one and a half to two times the normal focal length.

A long focus lens is also useful at closer range for taking individual pictures or small groups. If the photographer is at liberty to move about—e.g., during an amateur performance or at a photo call—a long focus lens will be most useful. But when working from a seat in the stalls, the camera should also have a normal angle lens for shots of the whole stage.

Lighting and Exposure. The stage lighting—and therefore the exposure—varies with the scene, the size of the stage, and the nature of the scenery. It is impossible to guess the combined effect of these things in advance. Once the curtain has gone up, the experienced photographer can make a reasonable estimation of the light value. An exposure meter is difficult to read in the darkness of the auditorium and even then it will probably give either an unreliable reading or none at all.

While the lighting may range from dim to dazzling and from white through all the colours of the spectrum—all in the course of a single performance—extreme lighting effects are generally reserved for special scenes. The average set is lighted to give reasonable visibility all over the stage with extra lighting on the principals from spots high up at the sides and front of the house—e.g., from the sides of the gallery, and the front of the circle or upper circle.

Tests have shown that in a London theatre with a very small stage, the exposure under full stage lighting might be 1/50 second at *f*2 for a fast film developed in a non-solvent developer. Under the same conditions, the exposure for another theatre with a very large stage is about 1/250 second at *f*2.

For average stages with full lighting the beginner should start with a trial exposure of 1/50 to 1/100 second at *f*2 on fast pan film.

Predominantly blue or pink lighting will call for 1/25 second; and green, yellow, mauve or red, 1/10 second.

Amateur companies cannot command the banks of high powered lights available on the professional stage, but on the other hand the stage is generally smaller and the lights have a proportionately greater effect. So for a well-lighted scene, there will not be a great deal of difference between the exposures for an amateur or a professional show.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The important thing is to expose for the highlights and let the less strongly lighted areas of the stage look after themselves. Any attempt to produce good shadow detail will leave the highlights as staring white areas, right in the most important part of the picture. This technique may give a picture of which two-thirds of the area are under-exposed, but this is infinitely better than one in which the principal feature is a patch of blank paper.

Viewpoint. The best position for the amateur is a seat on a level with the stage or slightly above it—i.e., in the dress circle or balcony—and about a quarter of the way across; not exactly in the centre. A viewpoint away from the centre conveys a better impression of the depth of the stage and avoids the formal appearance of a fully frontal picture. Photographs can be taken from a seat in the front row without interfering with the view of the people behind, whereas a photographer sitting in the body of the audience may be considered a nuisance. However, in most theatres the angle of view from the front row is too low.

Types of Show. The actual technique varies with the type of show; only the broad differences can be indicated here:

(1) Plays. The lighting is usually moderately good and not coloured. Normally an exposure of 1/25 second at *f*3·5 or *f*2 will give a reasonable print. It is as well to study the action of the play beforehand and choose a dramatic moment. Photographs taken during the ordinary course of the play are uninteresting. The normal angle lens will include the whole of the stage, so the exposure should be made when the action is spread out.

THEATRE PHOTOGRAPHY. Suitable camera positions for taking pictures during a performance are shown shaded. They are the centre stalls (about sixth row onwards), and the front row of the dress circle. Avoid seats dead centre of the stage. Seats in the boxes will give good angle shots, but may take in the wings at the far end of the stage.

(2) Musicals. The lighting here ranges from excellent to impossible and to make matters worse it is generally changing colour. The principals, however, are usually spotlighted and can be taken with a relatively short exposure. One good time to shoot is on the entrance of the star. There is usually plenty of warning and when she or he makes the traditional entrance and pauses for effect there is plenty of time to give the exposure required even with a modest lens. When taking sketches, the grouping should be watched and the exposure made when the players are mutually occupied—not when action is disintegrated.

(3) Pantomime. The conditions here are similar to the ordinary music hall but the changes of scene, performer and lighting are apt to be more abrupt. On the whole it is better to use the fastest lens and film and take pictures of everything that comes along in the hope that some at least will be worth printing. The fun is so fast and furious that planning in advance is impossible. Any really worthwhile pictures that fail to come up to expectations at the first attempt can always be made the subject of a second visit.

(4) Opera. On the whole this is an easier and more rewarding subject than the straight play. So far as the opera is a play set to music, the two techniques are the same, but the expression, gestures and grouping generally are more dramatic and sustained. Anyone with the most elementary musical sense can anticipate the instants of climax and crisis. But the singers should never be taken when they are singing open-mouthed right at the camera. The time to photograph a singer is when he is singing to another member of the cast.

Permission. Photography in the theatre is not as a rule permitted, and there is usually a notice printed on the programme to this effect.

And while provincial theatre managers will often allow a local photographer to take pictures, this permission can be overruled by the manager of a touring company.

Amateur and repertory companies, on the other hand, are generally very pleased to allow a certain amount of photography at their dress rehearsals provided they are supplied with some prints for the outside of the theatre.

At a Performance. When the photographer has permission to take photographs during a performance, he should take care not to let his actions inconvenience other members of the audience. He will be less likely to cause annoyance if he can arrange to have a seat at the end of a row. He must on no account stand up, in spite of the strong temptation to do so.

It is a mistake to try for pictures at the first visit to a show. Wherever possible two visits

should be made. The first should be given up entirely to taking notes of the shots to be made later.

There should be a note of the point in the action that is going to be taken together with an indication of any suitable cue that heralds its arrival. There should also be a note of the lighting of the scene, the proposed exposure and the type of lens, normal or long focus. This information must then be memorized since it will not be practical to try to refer to notes during the performance. When the photographer makes his second visit, this time with his camera and a plan of action, he is much more likely to get correctly exposed and well-timed pictures.

Amateur Theatricals. There is always more freedom for the photographer at an amateur show than in a professional theatre. Most producers are eager to co-operate with anyone who wants to take photographs and will usually afford special facilities at dress rehearsals for the purpose. Even during an actual performance, the photographer will be permitted to roam around and shoot from several viewpoints —even in the centre of the gangway, so long as he does not obstruct anyone's view of the stage.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Under these conditions he can place himself at the right distance to fill the field of view of his lens from whatever angle he is shooting. This means less enlarging and better picture quality.

At a rehearsal, things are easier still. The photographer can have the action of the play arrested or repeated and he can have the lighting modified to give the best photograph without reference to the dramatic aspect. (This means calling for plenty of general white lighting from above and cutting down side and footlights to a safe, fill-in light level.) This avoids the characteristic harsh contrasts of photographs made by stage lighting. L.V.

Book: *My Way With the Miniature*, by L. Vining (London).

THERMOFAX. Proprietary document copying process using a heat-sensitive paper. Exposure takes place to infra-red radiation by the reflex method. The black portions (lettering or lines) reflect the heat radiation strongly and darken the corresponding portions of the paper in contact with the original. The paper requires no further processing, but does remain heat sensitive. The process is only suitable for originals printed, written or drawn in opaque pigment inks, but not suitable for many dye images which do not reflect infra-red.

See also: *Document copying.*

THERMOGRAPHY. Processes of image formation by heat. These are not new—Niépce de St. Victor and Robert Hunt were experimenting along these lines over 100 years ago and Hunt coined the name thermography in 1840. But it was not until 1952 that the first commercial heat process was introduced.

All heat processes are based on the fundamental fact that when a document having an infra-red absorbing image is subjected to an intense source of heat for a brief period, the image will become hotter than the background: the temperature difference can be as high as 30°. This heat image is converted into a visible image in an adjacent copy material by utilizing a suitable physical or chemical change that takes place over a small temperature range. The most common change is melting, but boiling and decomposition are also used.

The melting or fusion processes can be further subdivided according to whether the change is restricted to a physical one, or initiates a chemical change, or the softened image is transferred to another support.

Physical Processes. Basically, the image is formed from a layer of dispersed solid that melts when heated image-wise and remains as a super-cooled liquid when cooled. The liquid provides a window in the translucent layer of dispersed solid and an underlying dark layer is rendered visible. The liquid can also be made visible by dusting the surface after exposure with dye particles that will dissolve in the liquid. The dye does not adhere to the non-melted areas.

In a variant, the dye particles can form part of the original coating. It is well known that a given weight of solid dye is a much less efficient absorber of light than when in solution. Hence in the image areas the dye dissolves to give an image of high density on a tinted background. A similar process uses a cellular layer of a thermoplastic polymer. In the heated areas the cellular structure collapses and the dispersed dye dissolves in the softened polymer.

Chemical Processes. This group comprises the majority of the thermographic processes described in the patent literature. In some processes the image is formed by a simple chemical decomposition that occurs with heat, e.g. the formation of black lead sulphide from lead dithioformate. But most of the patents describe image formation from chemical reactants that are brought together by fusion or softening to form a coloured reaction product. The reactants may be solids that are dispersed in the same layer, or they can be coated in adjacent layers. Examples of chemical reactions that have been described are those between iron stearate and gallic acid, a hydroquinone and a quinone, a leucotriphenylmethane dye and an oxidizing agent, and an aromatic triazene and an azo dye coupler.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Transfer Processes. These utilize two surfaces to provide the final copy. The heat image causes the layer in the copy material immediately adjacent to the original and the softened substance is transferred image-wise to a receptor support. The transferred image, which is laterally reversed, can be used for making many copies by spirit duplication or lithography. Alternatively if the receptor material is translucent, the image can be read in the correct sense by turning the sheet over and viewing from the back.

Distillation. In one distillation process a thin film of oil is applied to the original. The higher temperature of the image (i.e. printed text) when it absorbs infra-red radiation causes the oil to distil selectively from the image and it condenses image-wise on an adjacent sheet of plain paper. The oil image is rendered visible by dusting with dye particles, such as the toner powder used for electrophotographic development. These particles adhere only to the oil and can be fixed by heat treatment as in electrophotography.

The copy is laterally reversed but if the receptor sheet is translucent the copy can again be read from the reverse side.

Another process involving distillation uses reactants contained in layers on two separate supports. One reactant is volatile and distils from a heat image to condense on the adjacent material where it combines with the second reactant to form a visible image.

Thermography in Practice. Since the image in the original must absorb infra-red radiation, the thermographic process will not reproduce every printed document. Carbon black images (pencil, typescript, letterpress printing) and metallic images such as silver are all copied well. Aniline dyes, as are used in ball-point inks, do not normally absorb infra-red so they are not copied.

The resolution of the process is poor but good enough to give readable copies of quite small print. The best definition is obtained if the original and heat-sensitive layer are in direct contact, but adequate copies are still obtained if the copy material is exposed to heat with the uncoated side in contact with the original, since the heat image passes by conduction through the support. This ability to obtain copies by both methods is of advantage with transfer processes.

Exposure can be made either by reflex, when the copy material is between the original and the source of heat, or, for single sided originals, with the copy material on the side away from the infra-red source. The best-known heat-copying paper is exposed by reflex with the heat-sensitive layer in contact with the original. This layer is coated on to thin (40–50 grams per sq. metre) tracing paper and the reproduction is viewed through the support. In one type of machine, the original and copy sheet pass close to a 1200 watt infra-red tungsten filament lamp, so that the original is scanned by infra-red in a total time of about 4 seconds. Each section is heated for not more than half a second. In order to avoid overheating, controls are provided so that the lamp lights up only when the paper passes through. The non-image areas are still heat-sensitive and the paper will blacken uniformly if heated to about 100° C. In practice, the copies are sufficiently stable in a file but the background will darken on exposure to sunlight.

The thermographic process has enjoyed wide popularity for office convenience copying because it will reproduce both single- and double-sided originals quickly by a completely dry process.

Special products are available that, by a combination of light and heat exposures, will allow of the reproduction of both dye and carbon black images. D.J.F.

Infra-Red Scanning. Heat radiations emitted by objects at normal or increased temperatures can be accosted by optical and mechanical scanning techniques with an infra-red detector. The output of the latter modulates the intensity of a light beam which scans over a photosensitive material. The resulting image shows colder and warmer portions of a subject as darker and lighter areas. Very accurate evaluation of the temperature of any point of the object is possible in this way, and such techniques have been used for military surveys, industrial testing and medical and biological investigations.

See also: *Document copying; Heat recording; Infra-red photography; Pyrometry.*

THERMOMETER. Instrument for measuring temperature.

The commonest form consists of a liquid filling a bulb connected to a long and very narrow glass tube which is sealed off at the other end. As the temperature around the glass bulb rises or falls, the liquid expands or contracts, and fills more or less of the tube The position of the liquid level is therefore a measure of the temperature, and the tube may be calibrated in degrees of the scale used.

The liquid is most commonly alcohol (with a blue dye added to make it more easily visible) or, in more accurate thermometers, mercury. The latter, owing to its high boiling point, can also be used at much higher temperatures. Such mercury or spirit thermometers are available in various sizes for darkroom use.

Amateur developing tank thermometers have to be sufficiently thin to go down the central opening of the film reel. In addition the useful part of the scale, i.e., about 50–80° F. must protrude well outside the tank for easy legibility.

Some developing tanks have a hollow and partly transparent agitating rod which takes a thermometer. The latter is thus permanently immersed in the solution, yet protected.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

THERMOMETER SCALES. Left: *Fahrenheit.* Centre: *Centigrade (Celsius).* Right: *Réaumur. The boiling points of water are 212°, 100°, and 80° respectively, the freezing points 32°, 0°, and 0°. Usual processing temperature is 68° F., 20° C., or 16° R.*

Dish thermometers often incorporate a clip or similar fitting to hang or fix the thermometer on the edge of a developing dish out of the way, but easily seen. Certain types of dish thermometer may have a bent stem to ensure that the bulb is always fully immersed in the solution.

Large-scale professional processing tanks may have built-in thermometers. Alternatively a normal glass thermometer can be fitted in a floating holder, or suspended in a cage near the top of the tank.

Other forms of thermometer may consist of a strip consisting of two layers of metal with different coefficients of expansion; the strip therefore changes its shape at different temperatures, and is connected to a pointer moving over a scale. Many dial thermometers are of this type.

There are three common scales of thermometry, called after their inventors: Fahrenheit, Celsius and Réaumur. The Celsius scale is better known in Britain as the Centigrade. The freezing and boiling points of water on the various scales are given below.

COMPARISON OF SCALES

Scale	*Freezing point*	*Boiling point*
Fahrenheit	32	212
Centigrade	0	100
Réaumur	0	80

To convert Centigrade degrees to Fahrenheit degrees, multiply by 9/5, and add 32 to the result. Thus 20° C. = (20 × 9/5) + 32 = 68° F. Conversely, to convert Fahrenheit degrees to Centigrade, subtract 32 and then multiply the remainder by 5/9. For instance 50° F. = (50 − 32) × 5/9 = 18 × 5/9 = 10° C.

To convert to and from Réaumur degrees, proceed in the same way, but multiply by 9/4 or 4/9 instead of 9/5 or 5/9 (as for centigrade) respectively.

To convert Centigrade degrees to Réaumur degrees multiply by 4/5 (without adding or subtracting anything); to turn Réaumur degrees into Centigrade multiply by 5/4.

The Fahrenheit scale was invented in 1714 and has been used exclusively in Britain until the present century when Centigrade temperatures have been increasingly used.

The Centigrade scale was invented in 1740 and has been used on the Continent and in many other parts of the world since then.

The Réaumur scale, dating from 1731, has been popular only in Russia.

THERMOPLASTIC RECORDING. System of image formation relying on the physical stress induced in thin plastic layers under the influence of an electrostatic field. The field is produced by an electrostatic image, after which the application of heat followed by immediate cooling converts the stresses in the plastic layer into a physical pattern. The latter can be made visible under suitable conditions of illumination. The image is suitable for playback immediately after recording, and can also be erased by re-warming the plastic layer.

The recording material is a thin layer of heat-sensitive plastic on top of a transparent con-

THERMOPLASTIC RECORDING. Top: *An electron beam scans the moving tape and records a charge pattern on it. PROJECTING THE THERMOPLASTIC IMAGE. A series or slit light sources is so arranged, that a condenser system projects their light on to a grid of opaque bars between the thermoplastic film and the projection lens. Hence no light reaches the latter, except where the wrinkle pattern B in the film scatters light between the bars of the grid so that the lens records the wrinkle as a point of light at F on the projection screen. A, thermoplastic film with wrinkle images at various points such as B. C, slit light source. D, condenser lens. E, parallel grid of opaque bars. F, screen. G, projection lens.

ducting layer which may be coated on a plastic or film support. There are two possibilities of image formation. In the first an electron beam scans the surface of the plastic film and charges it in a pattern corresponding to the input signals. This produces an electrostatic image-wise distribution of charges. Alternatively, the plastic layer can be pre-charged by a coronary discharge and an image exposed on this afterwards by light.

Immediately after the exposure the plastic film passes over a heating unit which partially melts the thermoplastic layer (usually by induced currents in the transparent conducting coating). The conducting coating attracts the charges in the plastic layer and locally depresses the surface of the latter. This produces a ripple pattern which is immediately frozen into the film surface as the plastic cools again.

The image in the plastic film can be viewed directly if illuminated by light at the correct angle. For projection a system based on a Schlieren-optical set-up is used. This consists of a series of line light sources ranged in a plane behind a condenser lens, a grid some distance in front of the condenser lens, and a normal projection lens. The light is focused in such a way that the image of each line source falls on one of the bars of the grid. Hence no direct light reaches the screen at all. When the film with the thermoplastic image is introduced in front of the condenser lens, the surface ripples of the plastic layer deflects the light rays, so that they pass between the bars of the grid, forming an optical image on the screen.

Colour images can also be recorded on thermoplastic material by superimposing a diffraction grating on each picture element. In an electronic recording system this can be produced by an extra input signal to another electrode of the electron gun. The grating is an additional physical pattern on the processed thermoplastic layer and during projection produces a spectrum to each side of the central beam. The slots of the grid in front of the condenser permit only one colour to pass through the projection lens. The colour of a projected image portion is thus produced by the diffraction grating on the thermoplastic film; the colour depends on the spacing of this grating.

Applications. Originally thermoplastic recording was developed for direct recording of images produced in a manner analogous to a television screen image. In a recording unit the film can there run through at a standard speed (about 10 ins. per second) while the picture is scanned in a sequential frame fashion.

The thermoplastic film can also be used for information storage from a computer in the form of a binary digital system. The storage capacity of thermoplastic film is about 100 times as great as of magnetic tape. Thermoplastic film can record and store the contents of complete libraries in equipment the size of an office desk. Its potential applications also include optical and non-optical data recording in satellites and space ships, where the more favourable ratio of storage capacity to weight gives it advantages over straight-forward television and photographic systems. L.A.M.

THIOCARBAMIDE. Thiourea. Used in certain warm tone developers, stabilizers, clearing baths and toners.

Formula and molecular weight: $CS(NH_2)_2$; 76.

Characteristics: White crystalline powder.

Solubility: Fairly soluble in water at room temperature.

THIOUREA. Chemical used in some warm tone developers and toning baths. It may also be used in clearing baths.

See also: *Thiocarbamide.*

THIRTY-FIVE MM. CAMERA. Miniature camera using perforated cine film 35 mm. wide. Generally 35 mm. cameras are regarded as the true miniature cameras, and are associated with the special techniques developed for making normal photographs from very small negatives with an area of 24 × 36 mm. or less.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

THOMSON, JOHN, 1837–1921. Scottish explorer and photographer. After travelling for ten years in the Far East, settled in London *c.* 1870 and became instructor in photography to the Royal Geographical Society. In 1876, made the first social photo-documentation, *Street Life in London* (1877). 1880, pioneered another field—"At Home" portraiture of celebrities. Also had a portrait studio in Grosvenor Street, London.

THORIUM NITRATE FOREBATH. Forebath which produces a soft print from a harsh contrasty negative. It consists of a 10 per cent solution of thorium nitrate, with enough nitric acid added (if necessary) to clear the solution of any turbidity.

Prints to be treated in this forebath must be given two to three times the normal exposure. They are then immersed in the solution for two to three minutes, rinsed, and developed in the normal way.

The thorium nitrate forebath does not decrease the over-all contrast in the same way as the Sterry process, but mainly effects the shadows, extending their tone range. It does not change the image colour.

See also: *Contrast control; Sterry process.*

THREE-BATH DEVELOPMENT. In warm-tone development of chlorobromide papers, it is possible to make satisfactory pictures from very much over-exposed prints as long as the exact tone colour is not important. This type of paper has a wide exposure latitude when developed in diluted and restrained developer, but the tone varies with the exposure.

This latitude can be fully exploited by three-dish development.

Three dishes of developer are required:

Dish No. 1 contains full strength developer with no added potassium bromide.

Dish No. 2 contains quarter-strength developer with one part 10 per cent potassium bromide in every 50–100 parts of developer.

Dish No. 3 contains even more restrained developer: diluted eight times, with one part 10 per cent potassium bromide added to every 20–30 parts of working developer.

The approximately correct exposure is first found for an average negative to produce prints of the right density when developed in Dish No. 2. This development time is noted.

The exposures for other negatives are then guessed and the development of each exposed print is started off in Dish No. 2. If the image appears much sooner than it ought to for a correctly exposed print, the print is immediately transferred to Dish No. 3 and developed there to the right depth.

If the image appears much later than it would do with a correctly exposed print, the print is rinsed and transferred to Dish No. 1, which contains no restrainer and can produce images of the right density with shorter print exposures.

The total exposure latitude made available by this method may be as much as 4 : 1. Image tones will vary from warm black to brown, depending on the paper and the developer.

THREE-DIMENSIONAL PROJECTION. System of conveying an impression of depth when projecting slides or motion picture films. The depth may be conveyed by projecting on a specially wide screen to extend the angle of view of the audience, or by stereoscopic methods.

See also: *Projection practice.*

THRESHOLD EXPOSURE. Smallest exposure given to a sensitized material that will just produce a visible density above the fog level on development.

See also: *Characteristic curve; Speed of sensitized materials.*

TIME BASE. Time scale photographed along the edge of cinematograph films recording high-speed phenomena. The scale—generally a wave form or a succession of dots—is produced by impulses from an electrically excited tuning fork or an oscillatory circuit of known constant frequency (in electronics, also called a time base).

By referring the action in the film to the time base, the period taken up by any particular incident can be accurately measured, irrespective of any speed variations in the camera motor.

See also: *High speed cinematography; Timer.*

TIME EXPOSURE (T). Exposure made with a device fitted to some shutters whereby an initial pressure on the release opens the shutter and a second pressure closes it. This method of exposure is used when the shutter is to be left open for more than a second or two. The shutter setting is indicated by the letter T, or, on Continental shutters, Z (Zeit).

For short-time exposures—up to two or three seconds—the B (Brief or Bulb) setting is used in which the shutter stays open only as long as pressure is maintained on the release. Cameras with double exposure lock have only a B setting; there a long time exposure must be made with a locking cable release.

TIME GAMMA CURVE. Graph of change of gamma with time of development. The slope of the curve varies with the sensitized material and the nature of the developer. The usefulness of such curves lies in the guidance they give on the length of time a sensitized material should be developed in a given formula under certain conditions to produce a desired gamma value in the negative.

See also: *Developing negatives; Gamma.*

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

TIME LAG. With most photographic electric light sources there is a time lag between the initial switching on and the arrival at full working brilliance.

In filament lamps the lag may be as long as a second. This is not serious in normal photography, but in automatic recording camera systems—e.g., for time lapse work or for instrument dial recording—it must be taken into account. The mechanism that operates the shutter in such cases must be arranged to switch on the lamp in advance so that when the shutter opens the illumination is at its normal brilliance. (Under these conditions it is advisable to keep a small residual current flowing in the filament to protect it from the shock of repeated switching from cold.)

With flash bulbs, the time lag from closing the contacts to the peak brilliance of the flash is from three to twenty or more milli-seconds. Where the whole light output of the bulb is being used—i.e., in open flash working—the time lag is unimportant, but if the exposure is so short that it occupies only a fraction of the burning time of the bulb, it becomes important to know the exact length of the delay. The shutter synchronizing mechanism must be adjusted to allow for the time lag or it will open before the bulb has reached its peak brilliance.

Certain types of compact source lamps as used for projection and in film studios have an appreciable time lag on first switching on, and once they are switched off they must be given time to cool before the arc can be started again.

See also: *Flash synchronization.*

TIME LAPSE PHOTOGRAPHY

Technique of taking a series of photographs at set intervals, so that the changes in an object that slowly alters with time are recorded for future study.

For its simplest form, a still camera is used and exposures are made manually by an operator. The resultant photographs will form a series from which comparisons or measurements can subsequently be made.

More usually, however, a motion picture camera is employed so that the separate exposures form a motion picture film. On projection at a normal speed, this will synthesize the changes in the object which will show as movement at a greatly accelerated rate.

For work of this type, involving hundreds or perhaps thousands of exposures, manual operation is impossible and a mechanism must be provided to operate the camera automatically.

Time lapse photography is a technique that can be applied to an enormous variety of subjects, but some fundamental requirements are common to all, and the principles can be applied to any particular circumstances.

In its simpler applications, the technique presents no serious difficulty, particularly if the user has some degree of mechanical ability, though in the more specialized fields of work, highly complicated equipment is necessary.

Time lapse cinematography is usually carried out with botanical subjects such as germination of seeds, growth of plants and development of flowers and fruit. The beginner should start on an easy subject such as the opening of a well-developed flower bud, cut and kept in water. Work can be carried out in a darkened room and exposures made with artificial light. The flower will open in a reasonably short time, usually without any difficulty.

Precautions. As a general rule, slow growth is much more difficult to record than rapid changes, such as flowering, because the plant must be kept growing under favourable conditions and this may be difficult over long periods of time.

All plants require warmth, moisture, air and light for active growth, and if the arrangements for photography interfere with their proper requirements, either by reducing or increasing them, serious trouble may be encountered.

Incandescent lighting is usually not suitable for long periods owing to the large proportion of heat present and the complete absence of ultra-violet radiation. The plant will probably wilt sooner or later. Fluorescent lighting can, on the other hand, be used successfully over quite long periods but several fluorescent tubes will be needed in order to get sufficient illumination, particularly with colour film.

For the maintenance of good growing conditions over periods in excess of, say, one month, daylight is probably essential and this necessitates the provision of some arrangement of shutters to exclude light at the times of exposure. The shutters must be arranged to open and close automatically and with complete reliability, which introduces further mechanical complications.

It is not generally appreciated that many growing plants require better ventilation than human beings. For example, a box of germinating seeds may fail to grow in a closed room. The damp soil tends to go "sour" and moulds may develop. An open door and window will prove beneficial. Care, however, must be taken that the plant is not disturbed by draughts as even slight movements are distressingly apparent on the screen.

Watering must be sufficient and not overdone. Water may darken the colour of the soil, which may be undesirable. The watering of seeds in soil is difficult as the water must not disturb either the seeds or the soil. A very fine spray, frequently applied, is often the best method.

The most important point in this field is to

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

MERCURY SWITCH. Switch short-circuits resistance in series with continuously underrun Photofloods, and brings them up to full brilliance whenever required for exposing one frame.

provide suitable conditions for growth and development of the plant and to avoid any interference with these conditions. The balance is not always easy to maintain but this provides at least some of the interest in the work.

Still Camera: Manual Operation. Simple types of time lapse photography can be undertaken with almost any type of camera provided an operator can carry out the required sequence.

The basic operations will be as follows: load the camera or transport film, set the shutter, turn on lights (if used), make the exposure and turn off the lights.

Still Camera: Automatic Operation. If conditions make manual operation of the equipment impracticable, some mechanism has to replace the operator.

The automatic mechanism of any equipment for time lapse photography can be divided into two main parts: the timing unit and the operating unit.

The timing unit can be of any type, mechanical clock, electric clock, electronic timer or any other device whereby at the conclusion of any suitable interval of time, an event occurs that causes the next photograph to be taken. The operating unit replaces the human operator and must perform the sequence of operations for taking a photograph.

In some simple types of equipment both functions may be carried out by a single mechanical unit but, even so, this unit consists of these two essential parts, the timer and the operating unit.

Certain types of miniature still camera with built-in or accessory spring motor drive lend themselves to simple time lapse work. All they need is some elementary form of timing mechanism which will trigger the camera at ascertained intervals. Cameras of this type are quite often used to record the readings of a bank of instrument dials; they are known as dial recording cameras.

Cine Camera: Manual Operation. Many motion picture cameras make provision for taking single exposures either when spring driven or by means of the single turn handle. The scope of such simple equipment is limited mainly by the patience and endurance of the operator. The method has the advantages that the equipment is portable and that electric supplies are not necessary.

Many films have been made manually in circumstances when automatic operation would be impossible.

Cine Camera: Automatic Operation. For work over long periods, automatic operation is clearly essential. At least one camera for this type of work is available commercially. It is a 16 mm. motion-picture camera which is specially adapted and normally holds 50 feet of film in a daylight loading cassette, other magazines being available to hold up to 200 feet of film.

The camera is electrically driven (no spring to run down at the critical moment), and a variety of lenses is available. There are two models which can be run from either 12 or 24 volts D.C., and a mains unit is also obtainable. For normal operation, speeds of 8, 16 and 24 frames per second are possible, but for time-lapse work an interval timer, driven by a synchronous electric clock motor, is supplied which allows intervals up to 60 minutes. For situations where there is not much light, extended exposures are also possible.

For work with the microscope, a special form of observation eyepiece is required, whereby the operator can see the preparation and maintain focus whether or not the camera is running. Such eyepieces are available from a number of firms.

For use with the Bolex camera a complete outfit with an electronic interval-timer (maximum time interval three hours) can be obtained commercially. This apparatus also embodies

SIMPLE TIMING UNIT. A geared-down synchronous motor operates a cam which closes the mercury switch once during each revolution of the cam and starts the control unit. Intervals of closing the switch determined by motor gearing.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

COMPLETE OPERATING UNIT. A geared down motor drives five cams, each operating a mercury switch. Four switches in turn switch on lights, start camera drive motor, release shutter, and operate an electric counter. The fifth switch controls the motor driving the sequence switch, so that the camshaft makes one revolution only at a time.

an electro-magnetic shutter whereby the preparation on the microscope stage is protected from possible harmful effects of the illumination, except at the actual moment of exposure. It also has a special electric motor drive for the Bolex camera.

Construction of Equipment. The user can also design and construct his own equipment to suit his requirements.

Complete reliability of operation is of paramount importance. If the apparatus should fail to function during a run, not only is film stock wasted, but also time. On long runs, waste of time may be much more important than waste of film stock and, in any case, breakdowns are always annoying.

In designing any equipment for time lapse work, every unit should as far as possible be the most reliable of its kind. For example, mercury switches control electrical circuits more reliably over longer periods than ordinary switches and contacts. Springs should be avoided and gravity control used instead. Electric motors should be of generous proportions and rated for continuous operation.

SINGLE TURN CLUTCH. Motor drives single-picture shaft on camera through slipping clutch. Driven shaft held by pawl and notched disc. To make an exposure, the electromagnet raises the pawl to release the driven shaft for one revolution.

When considering reliability, the frequent switching of lamps will often lead to early failure. This can be largely overcome by using a considerable number of lamps and providing supervision. If one of a number of lamps should fail the result may not be very noticeable, whereas with only a few lamps the result will be spoilt.

The better solution, however, is to use a normal lighting arrangement and to arrange for the lamps to be on continuously but very much under-run, and only brought up to full brightness when an exposure is to be made. This is very easily arranged by means of a resistance (which itself may be a lamp of suitable rating) wired in series with the lamps so that the lamps are normally fairly dim. Closing a mercury switch across the resistance then applies full voltage and brings the lamps up to full brilliance for the exposure. Since the lamp filaments are never allowed to cool down and are only run at full brightness for a few seconds per exposure, their life is very much prolonged.

The Timing Unit. It is not a difficult matter to construct a simple and reliable timing unit using the movement of an electric clock. Such movements are available commercially and consist of a small synchronous motor and a train of gears, the final shaft of which makes one revolution in one minute. By means of suitable gears or pulleys a cam-shaped disc can be made to turn, say, once every 5 minutes and tilt a small mercury switch. Closing the switch initiates the automatic cycle of operations leading up to exposure.

The Operating Unit. This again can be constructed in simple form to do whatever is required by anyone with mechanical aptitude. A

CC-0. Alamirda Digital Preservation Foundation, Chandigarh

suitable arrangement may consist of a single shaft carrying, say, five cam-shaped discs each operating a mercury switch as in the timing unit.

A small electric motor with worm gear reduction drives the camshaft so that it makes one rotation in about five seconds (12 r.p.m.). Four of the switches can then be arranged to carry out the following: turn on lights or bring them up to full brilliance; start camera drive motor (if used); release camera shutter to make exposure; operate an electric counter, if required.

The fifth cam and mercury switch are used to control the motor driving the sequence switch so that the camshaft can make only one revolution each time.

This is accomplished by shaping the cam of the timing unit so that the mercury switch is only closed for a short time. The fifth cam of the sequence switch is shaped so that it closes the mercury switch immediately the motor starts and holds it closed for almost the whole revolution. Both mercury switches are wired in parallel and are in series with the supply to the motor of the sequence switch.

If the timer motor is running, both switches will be in the off position and the sequence switch will be stationary. Immediately the timer switch closes, the sequence switch motor will start. The timer switch opens quickly, but the other switch is still closed and the sequence switch motor continues to run. When the sequence switch has made, say, three-quarters of a turn, the switch opens and the sequence switch motor stops in a position to operate again as soon as the shaft starts to revolve.

The Camera Release. The motion picture camera must be arranged to take a single exposure when required. The details will depend upon the type of camera to be used.

If the camera is spring-driven it must have a single-frame release button and some form of electro-magnetic tripping mechanism will have to be constructed to operate the button. Ordinary spring-driven cameras without a single-frame button are not suitable as they would require considerable modification which would be difficult and expensive.

Nearly all motion picture cameras which are not spring-driven have a single frame shaft, one complete turn of which makes one exposure. This type of camera is ideally suited for time lapse operation.

Single Turn Clutches. To use a motion picture camera fitted with a single picture shaft, provision must be made to drive this shaft at a suitable speed for one revolution only. This usually involves the use of some form of clutch in the drive transmission.

The simplest method is to provide a slipping disc clutch. The driving shaft is driven at low speed, say 120 r.p.m. or one turn in half a second, and the driven shaft is held back by means of a pawl and a notched disc. To make the exposure, the pawl is raised by an electro-magnet to release the driven shaft.

This type of friction clutch is fairly satisfactory but remains reliable only if carefully supervised and maintained. The chief difficulties are that with insufficient friction between the two discs the clutch will slip when it should be operating the camera. On the other hand, when the friction between the two discs is high, considerable power will be required from the motor which may slow it down. On releasing the pawl, the motor speed will then increase and the time of exposure may be somewhat variable.

In addition, the faces of the discs become either polished or scored with use, which may lead to further unreliability in the operation of the clutch.

More involved designs exist for a clutch that runs quite freely but is capable of transmitting the full power of the motor to the camera. A

COMPLETE TIME LAPSE SET-UP. A, lamps. B, subject. C, frame counter. D, quick discharge circuit. E, single turn clutch. F, camera. G, camera motor. H, cams and switches operating the lamps, camera motor, single turn clutch through quick discharge circuit, counter, and sequence switch in turn. I, Motor. J, timing unit.

clutch of this type can be made without much difficulty but must be more of a precision job if it is to operate satisfactorily.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Quick Discharge Circuits. If the single turn clutch is driven by a motor so as to make one revolution in a quarter of a second or less, the electrical impulse to operate the clutch must be brief enough to avoid taking more than one picture.

An impulse of short duration cannot be expected from the tilting mercury switch of the sequence switch and a quick discharge circuit will be necessary.

This may consist of a simple resistance-capacitor circuit supplied with direct current so that the capacitor charges up and is then discharged through the magnet coil of the single turn clutch.

Selecting the Time-Interval. Selecting a suitable time interval should not present any difficulty when all the factors are known.

Supposing it is desired to photograph the opening of a flower and it is known that this takes ten hours. If this is to be shown on the screen in 20 seconds, the total number of exposures required will be 16 (for a silent film) or 24 (for a sound film) multiplied by 20, say 480 frames. Ten hours is 600 minutes, in which time 480 pictures have to be taken. The time interval is thus 600/480 minutes or $1\frac{1}{4}$ minutes.

R.McV.W.

QUICK DISCHARGE CIRCUIT. A, mercury switch. B, mains metal rectifier. C, high resistance. D, capacitor. E, magnet coil of single picture clutch. Mains voltage through rectifier charges capacitor. On closing switch, capacitor momentarily energizes coil, and camera takes one picture.

TIMER

Some form of timing device is always needed in the photographic darkroom to time the processing of negative materials and to measure exposure times in printing. While an ordinary clock with a seconds hand, or a wrist-watch with a sweep-second hand, will suffice, they are often inconvenient. A specially designed timer is more easily observed and places less strain on the photographer's attention.

The design of a timer will vary according to the precise requirements of the instrument—i.e., it may function solely as a clock or stop-watch, it may include an audible alarm, or it may automatically operate a printing light. The type of drive or timing mechanism involved—pendulum, clockwork, electric motor, or electronic circuit—will also, of course, affect the design.

According to their intended application, timers are designed to function primarily within a range of minutes or of seconds. A timer calibrated in minutes is usually intended for negative processing and one calibrated in seconds is designed for timing printing exposures.

The main features required in a timer are that it should give an audible alarm at the end of a variable pre-set period and should have a bold, easily observed dial. This latter feature is of particular importance in seconds timers which are normally operated in near darkness.

Automatic interval timers provide a convenient way of controlling enlarging exposures in particular. They consist of some form of timing device incorporating a switch. An indicator, which is usually a rotary pointer (or sometimes a telephone-type dial), is first set to the length of exposure required. Starting the timer running (generally by means of a push-button) switches on the exposing light and allows the pointer or dial to rotate back to its initial position. When the required time has elapsed, the switch is automatically opened and the light extinguished.

The chief characteristics of the various types of timers are listed below.

Pendulum. This type of timer is based on the fact that the time of swing of any given pendulum depends only upon its effective length and is always the same, no matter how great the swing. The commonest example of this principle is a musician's ordinary metronome. A simpler form comprising a hanging pendulum has been marketed for photographic use. This gives audible signals at 1 second intervals for 5 minutes or so after being set in motion by the touch of a finger. Both forms are especially useful in "dodging" since the audible ticks can be counted mentally leaving the photographer free to keep his eyes on the work while shading, or dodging intricate shapes. The main disadvantage is the inconvenience of counting long exposure times.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Clockwork. Spring-driven, gear-train mechanisms are used as a source of power for driving a wide variety of popular timers. There are two basic types, normal clock movements and short-time movements.

The first type is wound up once only, before commencing operations. It includes the continuously running darkroom clock, with a large seconds hand, and the stop-clock which can be stopped and started at will by the movement of a lever and is usually provided with a simple control for returning the indicating hand to zero. This type has the advantage of easy resetting for subsequent operation and often has a loud tick to serve as an audible timer in a manner similar to the pendulum type.

The absence of an audible alarm at the end of a desired period is, however, a disadvantage as the operator has to keep one eye on the dial.

The second type of clockwork timer is similar to that found in many kitchens, in which the action of setting the indicating pointer to the required time interval also winds the spring. On pressing a release button the pointer rotates steadily back to zero, whereupon a bell or similar alarm is sounded. This audible alarm is an advantage but resetting is a two-handed job which can become tiresome, particularly in repetition work.

Automatic clockwork timers are usually based on the second type of movement above, the alarm being replaced by a switch which closes when the release button is pressed and opens at the end of the set period.

To obtain a high degree of accuracy over timed periods from a second, or less, to several minutes, some automatic clockwork timers are made double range clocks. The whole of the setting dial is used for both ranges and two separate escapements are used.

Electric. These are basically clockwork timers in which the spring is replaced by a synchronous electric A.C. motor. The continuous running form is no more than a standard electric clock with an extra large seconds hand, while more powerful types operating an alarm or automatic switch are available. The advantage of the really accurate time-keeping provided by the synchronous motor is somewhat offset by the absence of a tick for audible timing.

Electronic. Electronic timers work on the principle that an electrical condenser takes a definite time to charge to a definite voltage (or, alternatively to discharge) through a fixed resistance. The actual time depends upon the capacity of the condenser, the value of the resistance, and the applied voltage. The time may be controlled by varying any of these factors but usually it is the resistance that is made variable in relation to a scale calibrated directly in seconds. The condenser capacity or the working voltage is sometimes also changed to alter the range covered by the variable resistance.

ELECTRONIC TIMING CIRCUIT. A, lamp. B, variable resistance. C, neon tube. D, condenser. E, switch. F, magnet holding switch closed during exposure, released on flashing of neon tube. G, mains supply (must be D.C.).

The most elementary form of electronic timer is simply a relaxation oscillator. This is arranged by connecting a neon lamp across a condenser which is being charged from a D.C. supply through a high resistance. The voltage across the condenser terminals builds up until it reaches the breakdown potential of the neon lamp. At this point, the lamp flashes and discharges the condenser. This sequence repeats automatically as long as the voltage is applied, causing the neon lamp to flash at regular intervals. By suitable adjustment of the condenser or resistance the neon may be made to flash at any desired intervals—e.g., 1 second. Since the light emitted by a neon lamp of this type does not fog printing paper, the flashes may be counted as a means of timing exposures in enlarging. The flashes are readily observed without the visual concentration required by a clock dial and the device has advantages similar to the pendulum timer.

Such a simple arrangement, however, is rather unreliable where great accuracy is essential. In practice, more complex circuits are employed, with a thermionic valve or a transistor system which trips a relay at a particular point on the charge or discharge of the condenser. This relay may be made to operate a signal lamp, an audible alarm, or a switch, so electronic timers are especially suited for automatic operation. These timers have the advantage that they operate by pressure of a button, and repeat the timing, without resetting, as often as the button is pressed.

Electronic timers may be designed for A.C. or D.C. supplies but most makes are available for A.C. operation only. The main disadvantages of electronic timers are their relatively high cost, large bulk and limited time range. Few models provide for intervals greater than 1½ minutes, although at least one expensive make will time up to 35 minutes.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

NEON FLASHER. A, resistance. B, neon tube. C, condenser. D, D.C. supply. The supply charges the condenser which discharges when the striking voltage of the neon tube is reached This cycle repeats itself, making the tube flash at regular intervals as long as the supply is connected.

Tape Recordings. For timing a complex sequence of operations, e.g., in colour, processing, a tape recording is useful. The instructions are recorded at the appropriate instant on a continuously running tape. On playing back, the operator receives these instructions without having to observe or separate times.

Special Timing Devices. Highly specialized timers are used in the various departments of scientific, industrial and commercial photography. These are usually complex equipment beyond the scope of this article, but the following brief comments cover a few of their uses.

In instrument recording by cinematography it is often essential to have a time record in addition to the readings of the various scientific meters; for this reason a clock is often included in the field of view. This takes up valuable picture space, however, and it is not always convenient to keep the clock in focus. To overcome both these disadvantages, edge-mark time impressions may be made on the film by a small neon lamp. This lamp shines on the edge of the film through a slit inside the camera and is flashed by an accurate pulse generator.

A time scale is also included in the photo-finish pictures of racing events. There are two systems in use. Both rely on the fact that the horizontal dimension of a photo-finish picture is a function of time and not distance along the race track. One system reproduces a series of short white vertical lines, looking something like a fence in the background of the picture. The white lines mark off fiftieths of a second and each represents a flash from a beacon on the finishing post opposite the camera. They enable the time difference between any two runners to be accurately estimated.

The other system prints small numbers along the base of the picture which indicate the time elapsed from the start of the race in minutes, seconds and hundredths of a second. The timer in this case is built into the photo-finish camera and has a separate optical system through which a revolving drum counter is photographed on to the moving film. The speed of rotation of the counter drums is electrically controlled by an extremely accurate quartz oscillator, and a synchronized shutter is used to produce a record every fiftieth of a second.

Electronic timers, in particular, lend themselves to adaptation for special purposes. Two timers may be linked to repeat a chosen exposure continuously and automatically, with any desired interval between operations. This is of use in some forms of D. & P. work. Another modification of electronic timer for printers provides automatic compensation for changes in developer temperature by using a resistance thermometer in the basic condenser charging circuit. An automatic timer for mass-produced enlargements has been designed in which the condenser charges through a photo-electric cell. The cell detects the brightness of the image on the enlarger baseboard, so the exposure time is automatically compensated for degree of enlargement, negative density, lens aperture and lamp brightness. This timer needs resetting only on change of paper speed, and this can be readily done by switching in different capacitors or changing the scanning aperture of the photo-electric cell.

For commercial contact printing one form of timer has been devised to speed up output by avoiding long exposure times. A synchronous electric motor rotates a make-and-break cam giving a fixed exposure time of only five-eighths of a second. To compensate for the short exposure, a relatively powerful lamp is used and its brightness is controlled by a variable resistance. Printers of this type can turn out 750 to 1,200 prints an hour.

For blue-sensitive materials, such as bromide paper, the effective intensity of a tungsten filament is proportional to the fifth power of the lamp voltage. In order to make printers that are independent of supply voltage fluctuations, electronic timing circuits have been developed which effect changes in exposure intervals which are inversely proportional to the fifth power of the changes in the supply voltage. The result is that the exposure (intensity × time) given will be substantially constant irrespective of any alterations in the mains voltage—provided that the timer and lamp are run off the same supply.

Time lapse photography is performed by a special timer which switches on the lamps to illuminate the subject, operates the camera shutter and switches off the lamps in the correct sequence at the required (pre-set) intervals.

This method reduces the power consumption of the lights and makes constant attention to the apparatus unnecessary. R.E.

TIME-TEMPERATURE DEVELOPMENT. Method of developing exposed sensitized materials. The material is immersed in a developer of a particular activity, maintained at a constant temperature and given a definite amount of agitation. Under these conditions the same material will always develop to the same gamma in the same length of time. The makers of the film or plate publish a table of recommended development times for different temperatures (and, sometimes, concentrations) of the developer for each type of material. In practice, the photographer soon learns to make any allowances necessary to produce the particular type of negative he prefers and to modify the times to suit special subject conditions—e.g., flat or contrasty lighting. Where the negative material is a length of film or a tank of plates covering a range of subjects, it is not possible to make allowances for individual subjects in development, but any discrepancies can always be put right at the printing stage—e.g., by choosing a paper of the correct grade to suit the contrast of any individual negative.

See also: *Developing negatives.*

TINTING. Term for colouring prints and lantern slides by applying suitably coloured dyes with a brush. Tinting cannot change the greys and blacks of the silver image and is mostly effective only over the highlights; nevertheless the results often succeed in being pleasing.

TINTYPE. Another name for a ferrotype—a photograph made on a wet collodion emulsion coated on a japanned metal plate and developed in an iron developer. Introduced in 1852, it was still popular in the earlier part of this century with beach and street photographers.

See also: *Ferrotype.*

TISSUE. Very thin and loosely textured soft paper. One type, known as Japanese tissue, is used as a texture screen to give enlargements a bromoil print appearance.

The term is also applied to:

(1) Dry-mounting tissue. This is a shellac impregnated tissue paper used for mounting prints. The shellac in the tissue, laid between print and mount, melts on application of heat, bonding the print to the mount.

(2) Carbon and carbro tissues. These are somewhat thicker paper with a pigmented gelatin coating which is rendered partly insoluble on sensitization with bichromate and exposure to light or chemical interaction with a silver image. Used for producing pigment images by the carbon or carbro process.

(3) Photogravure tissue. A carbon tissue which provides the etching resist on gravure cylinders.

TITLE. It is often necessary to print a title or signature upon a photograph—e.g., of a view—to record the place and sometimes the date of taking. The easiest way is to print the title on the negative so that the picture and the title are printed at the same time.

Titles on Negatives. Titles may be applied to negatives by hand or by photographic means. The first is quick, but it demands some skill. If the work is done neatly it can be quite satisfactory but anyone not accustomed to hand lettering is unlikely to make a good job. On the other hand the photographic title is easier and generally neater, although it takes more time. Whichever method is employed, titles should be used on negatives when only contact prints are required; subsequent enlargement will make all but the finest lettering appear ragged and imperfect. For enlarging it is generally better to apply titles directly on to the print—either by hand or photographic methods.

If the photographer is capable of producing good lettering, the easiest method of titling negatives will be by hand. Photographic methods, although suitable for the inexperienced artist, generally take much more time to prepare.

Hand Titles. If the negative is on film the title can be lettered on the celluloid side in block letters or script. The lettering is best done with a very fine mapping pen.

Ordinary writing ink is not suited to this purpose; the opaque medium used for blocking out negatives and indian ink used by draughtsmen are both satisfactory. If either medium is too thick, or it is thought the lettering will print too white, it can be thinned with water.

The dyes used for retouching—red, grey, or black—are also suitable. These also may be diluted and one of their advantages is that they can be removed at any time by soaking in cold water.

When the title is put on the celluloid side of the film there is some slight diffusion in printing owing to the thickness of the film, but this is not objectionable.

Those who are not skilled in the art of lettering can use printed typescript as a guide for tracing the title in this way:

First cut out a sufficient supply of letters or words from some suitable source—e.g., old magazines or Christmas cards. Then paste them on a sheet of thick paper or card, using the negative as a guide for spacing and size, and starting at the left hand side of the picture. The title is then fixed to the negative with transparent adhesive tape to keep it in the same place during tracing. It is now easy to copy the outline of each letter on the celluloid side of the film.

There must not be too much of the medium on the pen. It is best to work with a pen nearly dry, and to make two or three applications of the medium to build up the letters.

If the title is printed on the emulsion side of

the negative, the lettering must be reversed. This can be done by first tracing the letters on to a sheet of transparent material such as an old film negative bleached in Farmer's reducer. This is placed in position on the glass side of the plate and the title can then be traced on the film side. Alternatively the title may be traced on a strip of clear celluloid and attached to the negative with cellulose tape.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Black lettering is often preferred as being less glaring than white while being just as easy to read. The lettering is scratched on the film side of the negative with a sharp point—e.g., of a darning needle—mounted in a cork and pressed into a pen holder. The lettering in this case must be drawn reversed as for titles on plate negatives. The clear lines left on the negative come out as black lines on the print.

Another way of introducing black lettering is to write on the negative with a small brush dipped in Farmer's reducer. This is not an easy method as the solution is not easy to control, and there is some risk of spoiling the negative. It is not suited to small negatives.

Photographic Methods. Although these involve rather more work they give more pleasing results especially in the hands of beginners and they avoid risk of damage to the negative. Moreover if the title is no longer needed it can easily be removed.

For black lettering the title should be lettered in indian ink on stiff white paper or card. The characters should be 1½ to 2 times the final size as this makes the work easier and helps to minimize any small imperfections. It is possible to build up a title using typescript cut out and pasted on paper or card or to have it set up by a printer, and the "pull" used.

Another alternative is to build the title with the card or plastic letters used for titling cine films. The title is set up in front of the camera and photographed. The negative should be used as a guide to see that the title is in the correct position and of the correct size.

High contrast film of the process type and a contrast developer should be used. This combination will ensure that the lettering is sharp and clear against an opaque background. Any slight veil can be removed by treatment (for a few moments only) with Farmer's reducer.

The title is printed as follows: expose the picture negative under the enlarger or in the printing frame; remove it, and replace with the title negative, taking care that the title comes in the right place; expose through the title negative and develop the print.

If white letters are preferred it is only necessary to make a contact positive from the first negative and print it simultaneously with the picture negative. Title strip negatives may be made in this way and attached to the film or plate in the correct position with transparent adhesive tape.

Titles on Prints. If the print is on matt or rough paper, the title may be written on the surface in

PHOTOGRAPHIC PRINT TITLES. To print a black title on to an enlargement, proceed as follows. 1. Photograph a white card, bearing the title lettering in the correct position, on a high-contrast negative material. 2. Process in the usual way, making sure that everything except the lettering is as dense as possible. 3. After setting the enlarger for magnification and focus of the picture negative, place the title negative in the carrier, position the enlarging paper, and expose. 4. Without disturbing anything else, replace the title negative by the picture negative, and expose again to print the picture. 5. Final combination print with black title on light background.

CC-0. Adamjee Digital Preservation Foundation, Chandigarh

indian ink of a colour to match the tone of the print. Ordinary writing ink is not suitable and pencil should not be used as it gives a glossy surface that reflects the light and makes the lettering difficult to read.

The dyes used for print spotting and retouching can be used for tilting and are the only suitable medium for glossy surface prints. They should be diluted to match the tone of the print.

These dyes may also be used to tone down too obtrusive white lettering. Black, brown, grey, or even red dye is suitable.

To print a title on the photograph without interference with the negative, the necessary data may be written upon a separate sheet of celluloid and attached to the negative with transparent adhesive tape. An old film negative with the emulsion cleaned off with hot water can be used and the data written or printed upon this using one of the opaque liquids employed for blocking out. These will take easily upon celluloid by using a hard pen nib with a fair amount of pressure. A small trace of liquid gum added to the medium helps. Alternatively the celluloid may be given a matt surface by rubbing with valve grinding paste or fine emery paper. The data may then be written on the surface with ordinary pencil.

For black lettering, fog a sheet of film, place it in a developer until opaque, and fix, wash and dry. The title or reference can be scratched on the film side with a darning needle. The title is then mounted over a hole in a sheet of opaque paper and placed over the exposed print. A white light is then shone on the title for a second or two and, when the print is developed, the title appears in black lettering. R.M.F.

TITLING

Preparation and photography of written titles at the beginning and sometimes during the course of a cine film. The principle types of title are:

(1) The main title. This is the identifying label of the film—the name of the story in a feature film, or the subject of a film in a non-feature production. It adds the finishing touch even to a completely informal amateur film. A main title is the minimum a film should have.

(2) Credit titles. These tell the audience who made the film and who helped to make it. In professional feature films credit titles are usually a lengthy sequence, listing everybody from the star to the wardrobe mistress and from the producer to the continuity girl. In amateur films made by a small team or even a single movie maker one credit title is often sufficient. The credit line of a one-man film can sometimes even be added to the main title.

(3) Sub-titles. These tie together groups of sequences, establish the location and where necessary the time. In silent films they may also indicate the dialogue.

(4) The end title.

Some processing laboratories prepare titles for cinematographers according to texts supplied and following certain styles of lettering and presentation. Home-made titles give, however, a greater scope as well as individuality.

Titling involves preparing the title itself and filming it with the cine camera. The latter is pointed squarely at the title, illuminated by suitable lamps. The title is filmed either at the normal camera speed or—for special effects—by single-frame exposures. To be suitable for titling, the camera must also be able to focus on near subject distances. A variety of commercial titling units are available which accurately line up the camera opposite the title and may

HORIZONTAL TITLER. A, *title board (here with flap-over feature).* B, *title frame.* C, *titler base.* D, *adjustable lamp.* E, *close-up attachment.* F, *camera.* G, *twin rail base.*

incorporate the lighting units and provision for other titling accessories.

With fixed focus cameras a supplementary lens provide appropriate near focusing distances. If the title size is constant, a single supplementary lens is sufficient.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Titlers. Basically a titler consists of an easel or other arrangement to hold the title, a support for the camera, and the lighting unit or units to illuminate the title. The lay-out of the titler may be horizontal or vertical. A horizontal titler carries the camera on carriage or support moving along the single or double rail to keep it accurately centred opposite the easel. It also permits it to move nearer or farther away while remaining centred.

In a vertical titler the easel is horizontal, and the camera moves up and down on the vertical column.

Horizontal titlers with a vertical easel are usually more rigid, and adequate for printed or drawn titles or stick-on title letters. Vertical titlers permit more scope in arranging and animating title solid letters on the horizontal easel.

Ideally, titles should be made at least 8 or 10 ins. large; the easel dimensions will then be correspondingly larger. Smaller titles can be produced. But they need a closer camera-to-title distance for filming, and any roughness in the lettering shows up far more obviously on the screen.

The distance the camera has to be from the title depends also on the focal length of the lens. With an 8 mm. camera an 8 × 10 ins. title can be filmed at about 2½ feet from the camera fitted with a standard 12·5 mm. lens. For a 9·5 mm. camera the titling distance is just over 2 feet with a 20 mm. lens. A 16 mm. camera with a standard 25 mm. lens would cover an 8 × 10 ins. title area again from about 2½ feet.

In practice the exact title area covered by the camera at various lens-to-easel distances is best determined by test exposures, or by visual observation—if the camera has a through-the-lens reflex finder.

SIMPLE VERTICAL TITLER. A, camera. B, alignment control. C, supplementary lens. D, column. E, lamp. F, baseboard. G, title in guides.

EMERGENCY TITLING SET-UP. The camera is supported above two chairs pushed together. The title board lies between them and is illuminated by two lamps on each side. The seats of the chairs shield the camera lens from direct light.

Lettered Titles. Titles should in most cases be as short as possible, to aid readability and also to reduce the amount of lettering required.

At one time virtually all titles were white letters on a black background. This is now considered unnecessarily dull, and black or grey letters on a tinted or light background are preferable.

Very short titles can be drawn or painted free-hand, but should still be neatly set out. Stencils are a useful way of producing letters of various kinds. So are transparent plastic sheets of self-adhesive letters which only need cutting out and pressing into position on a suitable background.

Plastic, cork and felt letters are easy to handle on a horizontal titling board, and are obtainable in a wide range of sizes, styles and colours.

Backgrounds. The easel of the titler can be covered with drawn, painted or other background patterns. Textured backgrounds are also effective, especially in conjunction with solid title letters when illuminated by a low glancing light to emphasize the depth relief.

Titles can also be set up against a still photograph or a live scene. In professional motion picture work the latter type is produced by combination printing; the amateur method is to film the live scene and then wind that section of film back in the camera for re-exposure a second time to the title. The latter thus appears in super-imposition on the scene.

Alternatively, the title may be set up on a transparent sheet and arranged in front of the camera against a live background. In this case the title should be rather larger, and small lens apertures are needed to make the background at least recognizable.

Titles should always be carefully centred within the title frame. Deliberately non-

ACCESSORIES FOR EFFECT TITLES. Left: *Flap-over title board.* Centre left: *Drum for rotating title.* Centre right: *Shutters for title wipes.* Right: *Travelling title on continuous rollers.*

symmetrical arrangements still require careful layout for balance.

Informal Titles. Formal lettered titles are always obvious in a film, and when used to link scenes or sequences, may break up the smooth flow of the film. The information to be given in the title can however also be conveyed in a variety of other less obvious ways. Thus signposts establish locations in holiday films. A close-up of a calendar on the wall indicates the date. Linking shots of a map, posters advertising a sports event (being filmed), and even newspaper headlines are examples of informative shots of this nature which can obtrusively replace orthodox set titles. Even dialogue titles can be largely cut down in number by linking scenes which make it obvious to the audience what is being said.

Shooting. The exposure for a title depends of course—apart from the film speed—on the intensity of illumination provided by the lamps. These should be set up in such a way that they evenly illuminate the titling area, yet do not reflect any glare (especially from shiny-surfaced title cards) into the camera lens.

Where titles are shot at the normal camera speed of 16 or 24 frames per second, fairly intense lighting is necessary, comparable to that recommended for indoor shooting with the film employed. With colour film the appropriate artificial light type emulsion should be used, unless the titles are superimposed on an outdoor shot. With colour film, titles can, however, be lit by coloured lights for special effects.

A meter measuring the light reflected from the title give a reliable indication of the exposure. The meter should take in just the title area and the title should have a fairly balanced tone range. Alternatively, the light reflected from a white card in the position of the title area may be read and the camera lens set to two stops larger than the indicated value.

The footage devoted to a title depends largely on its length. Credit titles and sub-titles should be held long enough to be read comfortably by an average audience. Approximately two words per second is suitable for descriptive titles. Main titles need a longer time.

For trick titles (e.g. letters unscrambling themselves) the time to count is the period for which the fully readable title stays on the screen. Running titles should be held long enough for reading about two-thirds of the text before the title starts to move. Hold it again after it has come to rest.

Special Effects. Titles may incorporate the usual camera tricks and effects such as feeds, dissolves, wipes, etc. which are largely made in the same way as when shooting live scenes. In addition there are moving titles obtained in several ways.

A long descriptive title—or even a series of credit titles—can be made to move past the field of view by being mounted on a drum or on a long strip of paper wound from one roller to another.

Moving titles to be created in the titler also include the flap-over where a pivoted title board carries successive titles on its two sides and swings over for the change. Another classic way of changing from one title to the next is to have title sheets arranged in a book, and to turn over the pages one by one.

Letters that appear in jumbled fashion and then sort themselves out to the titles are usually filmed by reverse action. The title is set up with movable plastic or cork letters, filmed with the camera upside down, and the letters then scrambled up by suitable means. On splicing this sequence into the film upside down in the desired unscrambling effect. (In 8 mm. this effect requires a camera with reverse drive since splicing in a film length upside down brings the perforation to the wrong side of the film. Reversing the film left-to-right would also reverse the lettering.

Advancing titles are easy if the camera has a zoom lens; otherwise they involve moving the camera smoothly towards the titling easel during the shot. The title must be held and sharp in its final position.

Animated titles are made in much the same way as animated cartoons, by drawing or arranging lettering step by step while photographing them with the single frame release of the camera. Animated or inanimate titles can also be combined with a still or moving cartoon background.

TOMOGRAPHY. Special method used largely in medical radiography to reveal details of internal structure normally shielded by other parts. During exposure the X-ray tube is swung in an arc of a circle which is centred on the point of interest. Meanwhile the film cassette, which is connected to the tube by a lever, is slid in the opposite direction. In the resultant radiograph, all structures above and below the pivot plane will be blurred, leaving a relatively clear impression of the selected object.

See also: *Medical radiography.*

TONE. Area of uniform density in a positive or negative image which can be distinguished from darker or lighter parts. A picture may consist of two tones—e.g., a black and white woodcut; or a number of tones—e.g., a photograph.

TONE-LINE PROCESS. Photographic method of converting a continuous-tone image into a line drawing, while preserving full detail of all outlines and supressing all tone values. The resulting line image may be negative or positive. Such line images can also be reproduced photo-mechanically for printing by line blocks or plates.

Principle. The process uses a negative and an exactly matching positive transparency of the same contrast and density. The two are superimposed with a thin spacing layer between them (the film supports of the negative and positive material are enough for this purpose) and contact printed on to another film by an oblique moving light source. By going through the negative and positive images at an angle, the light can spill past outlines of the superimposed images, recording these outlines on the printing material. The greater the separation between the negative and positive, and the more oblique the angle of the light, the thicker the lines are reproduced. The resulting image shows black lines on a white background; this can be printed directly on a printing paper to yield white outlines on black, or indirectly via another transparency to yield a print with black outlines on white.

Method. The image on the original negative should be as sharp as possible and with a density range of about 1·5. If the original image is on miniature film it is usually preferable to make a large-size duplicate negative.

The negative is printed by contact on to a continuous tone film and developed in the normal way. Exposure and development of this positive transparency should yield an image that matches the negative as closely as possible in contrast and density.

The negative and positive images are then registered back to back and placed in contact with a high contrast line or process film. This combination is now printed with a lamp placed at an angle of 45° to the surface of the sandwich. During the exposure the printing frame

THE TONE-LINE PROCESS. 1. Loading the selected negative into a printing frame with a positive film. 2. Exposure. 3. Development. 4. Combining the negative and the positive in a printing frame with a further unexposed film. 5. Exposure and development. Exposure takes place with relative movement between the printing frame and the light source. 6. Resulting line image.

containing the films is made to rotate (for example by placing it on top of a gramophone turntable) so that the light can penetrate obliquely through the vertical space between the outlines from all sides.

Finally the film print is processed for maximum contrast and can be used for making negative or positive prints or line blocks as already indicated. L.A.M.

Book: *Design by Photography*, by O. R. Croy (London).

TONE RENDERING. The human eye is most sensitive to yellow-green light, least to blue and red, and completely insensitive to ultra-violet and infra-red rays. When considering the sensitivity of the eye to light of different colours, amounts of light energy are measured by their ability to heat up a heat measuring instrument.

The colour sensitivity of photographic materials does not in any way resemble that of the human eye. This means that a photograph does not reproduce the tone values of coloured objects in the same brightness as they appear to the eye.

The early photographic materials were sensitive to ultra-violet radiation and blue light only. To a material of this sort any blue objects appear very bright and any green, yellow, or red objects appear dark by comparison. White clouds and blue sky seem to have equal tone values with hardly any differentiation.

Late last century it was found that certain dyes would extend the sensitivity of photographic emulsions towards the green and red and in certain cases even infra-red parts of the spectrum. The resulting emulsions are known as orthochromatic, panchromatic, and infra-red sensitive emulsions.

Orthochromatism. Orthochromatic emulsions are sensitive to blue and green light and give a much better tone rendering than the earlier blue-sensitive emulsions. But they are insensitive to orange and red and tend to make them too dark in the print. Even so, orthochromatic emulsions are widely used for general photography and their performance is much improved if they are used with a yellow filter which cuts off some of the excessive sensitivity to blue.

Panchromatism. The colour sensitivity of panchromatic emulsions is nearest to that of the human eye. Nevertheless they are still excessively sensitive to blue and somewhat too sensitive to red light. So correction filters are used to give correct colour rendering.

Fairly accurate rendering of colour in terms of different tones of grey can be obtained with a panchromatic emulsion and a yellow filter which cuts out the excessive sensitivity to blue and ultra-violet light.

Even more exact colour rendering is obtained by using a greenish filter which corrects the excessive sensitivity to red light as well as cutting down the blue.

Contrast Filters. The photographer does not necessarily want to reproduce every colour according to its brightness to the eye. The human eye distinguishes between different objects in a scene not only by their different brightness, but by the contrast in colour.

Unfortunately, the colour contrast cannot be captured by the normal photographic material and it is quite possible for the effective contrast between two objects to be lost entirely in a black-and-white photograph. For instance red poppies in a green meadow may become quite inconspicuous. In such cases the photographer often resorts to contrast filters to suppress one colour and increase the contrast between it and another colour. Filters can be used in this way to give striking, though unnatural effects.

Orange and red filters, for instance, turn a blue sky almost black in suitable lighting conditions, and are often used to add drama to sky and cloud scenes.

Infra-Red Emulsion. Infra-red sensitive materials give completely unnatural tones but they have a number of specialized applications in which truthful tone rendering is not important. Thus to an infra-red sensitive material the green of meadows and trees appears a brilliant white since the chlorophyll responsible for their green colour reflects the infra-red light. So an aerial reconnaissance photograph, if taken on infra-red material, will clearly show up otherwise perfect camouflage.

Infra-red material is also used for photographs of distant objects. This is because atmospheric haze tends to allow infra-red rays to pass while it scatters blue light. Therefore if a photograph is taken with an infra-red sensitive material and a filter which cuts out blue light, haze is much less noticeable than it would be with ordinary photographic materials. W.F.B.

TONERS

Toners change the colour of the black silver image of a print. They are commonly used for giving a black-and-white print a colour more suited to the subject of the photograph—e.g., for making a sepia-coloured print of a portrait or a subject in sunshine, or for making a blue or green coloured print of a sea study. Most toners can be used equally well on lantern slides or other positive transparencies.

There are four general types of toner:

(1) Sulphide and selenium toners, which convert the silver image into silver sulphide and/or selenide. These usually give a range of reddish brown tones.

(2) Metal toners which convert the black silver image into a compound of the desired colour. This compound may be an insoluble coloured silver salt or a double salt with another metal.

(3) Dye toners, which act by depositing a dye image on top of the silver image. The silver image can, if necessary, be removed completely in a suitable reducer.

(4) Colour developers, which form a dye image as well as a silver image. The dye is formed during development by oxidation products.

SULPHIDE AND SELENIUM TONERS

In indirect sulphide toning, the image is bleached out in a halogenizing bleacher, washed, and then darkened in a sulphiding solution.

The Bleacher. The standard bleacher is a solution of 1–5 per cent each of potassium ferricyanide and potassium bromide. A permanganate or copper sulphate halogenizing bleacher containing sodium chloride will work equally well.

Variations in tone can be obtained by using an alkaline potassium ferricyanide and potassium iodide bleacher. There are several alternative bleachers which give slightly different tones from those obtained by the standard process. One of these is a solution of 0·5 per cent potassium bichromate containing 4 per cent hydrochloric acid.

The Darkener. In sulphide toning the standard darkener is a 1–5 per cent solution of sodium sulphide—usually made by diluting a 20 per cent stock solution, since dilute sodium sulphide solution does not keep well. Those who object to the smell of sulphide toning with sodium sulphide solutions may use a darkener containing 0·25 per cent each of thiocarbamide and caustic soda, with or without up to 2 per cent potassium bromide. It is possible to control the tone to some extent by varying the proportions of thiocarbamide and caustic soda.

For selenium toning the darkener may be a 1 per cent solution of sodium sulphide containing 0·05–0·1 per cent selenium—dissolved in the hot solution. Those who object to the smell of the sulphide may use the thiocarbamide darkener (above) containing 0·1 per cent of selenium.

With most bromide papers, sulphide toners give a warm sepia image colour. There are some papers, however, which cannot be made to yield anything better than an unpleasant yellow-brown. Such papers are unsuitable for sulphide toning.

Selenium toners give a colder purplish tone.

Controlled Sulphide Toner. The image tone obtained by sulphide toning can be varied to colder brown or even warm-black by adding up to equal parts of 2·5 per cent mercuric chloride solution to the standard ferricyanide and bromide bleacher. The higher the proportion of mercuric chloride, the colder the tone obtained. At the same time, the more mercuric chloride there is in the solution, the more the print will be intensified.

After any bleacher containing mercury, the prints should be rinsed in several baths of 1·5 per cent hydrochloric acid, before being washed and toned.

Warmer tones (to brownish-red) follow the use of the standard bleacher with a darkener containing a proportion of 1 per cent sodium thioantimonate (Schlippe's salt) solution. This adds orange-yellow antimony sulphide to the image. The warmest tones of all are given by the thioantimoniate solution only as a darkener.

Direct Toning. For direct sulphide toning the print or transparency is immersed in the toner without previous bleaching. The bath converts the image into silver sulphide or selenide.

The solutions take rather longer to act than in indirect toning—some 10–20 minutes instead of 3–5 minutes. The prints are taken out of the solution just before they reach the required tone, because the action continues slightly during washing.

Most direct sulphide toners are of the polysulphide type. A suitable direct toner can be made by adding powdered sulphur to boiling 50 per cent sodium sulphide solution until no more will dissolve. When cold, the solution is diluted ten times for use. A 1 per cent solution of liver of sulphur (potassium polysulphide) is equally satisfactory.

On the same principle, a direct selenium toner can be made by dissolving powdered selenium in hot 10 per cent sodium sulphide solution. This toning solution tends to stain the prints, but it can be improved by mixing 3 parts of it with 20 parts of a 15 per cent sodium thiosulphate (hypo) solution containing 5 per cent of potassium metabisulphite.

An odourless selenium toner can be prepared by dissolving 1–2 parts of selenium powder in 150–200 parts of 15–20 per cent sodium sulphite, and adding 30–40 parts solid ammonium chloride. This solution may be diluted with an equal volume of water.

Hypo-Alum Toners. Hypo-alum toning is an-

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

other method of direct sulphide toning. The prints are first hardened in a formalin or similar hardener and then immersed in a hot solution of 20 per cent sodium thiosulphate (hypo) containing 2·5–5 per cent potash alum. The tone obtained depends on the temperature of the bath: the hotter the solution, the colder the tone. About 120–130° F. (50–55° C.) is the optimum temperature. Toning usually takes 10–15 minutes.

A fresh hypo-alum toning bath has a slight reducing action on the image. This action can be exhausted by immersing a few waste prints in it or by adding a small amount of 10 per cent ammoniacal silver nitrate solution (about 1 part in 200).

Because of the high temperature of the solutions, hypo-alum toning is not suitable for lantern slides or other transparencies.

METAL TONERS

With most metal toners the silver image is first converted into an insoluble silver salt in a bleaching bath. The silver salt is then acted on by a darkener which converts it into a coloured compound consisting of a double salt of silver and the metal contained in the darkener. The salts most commonly used in this double salt formation are ferrocyanides.

Some toners contain both the bleaching and the darkening agent in one solution, so that the whole process takes place in one bath.

In other toners—e.g., iron toners—the silver itself may even be removed altogether, leaving only the coloured metal salt in its place.

A few metal toners deposit another metal directly on the silver image. The deposited metal has to be a metal nobler—i.e., of lower chemical activity—than silver, e.g., gold.

Uranium Toning, In uranium toning the silver image is converted into silver and uranium ferrocyanide which is reddish-brown in colour. The image is not, however, as permanent as the original and tends to be destroyed by alkaline solutions.

For this reason, all rinses and the final wash should take place in slightly acidified water—e.g., 0·1 per cent acetic acid.

For indirect uranium toning the image is bleached in a 3 per cent potassium ferricyanide solution containing a trace of ammonia. It is washed and then toned in a 2·5 per cent uranyl nitrate solution containing 1 per cent of acetic acid and 0·5 per cent of potassium bromide.

For direct uranium toning the print or transparency is treated in a toner containing uranyl nitrate and potassium ferricyanide in a suitably acid buffer solution—e.g., the Kodak T-9 formula:

Uranyl nitrate	44 grains	2·5 grams
Potassium quadroxalate	44 grains	2·5 grams
Ammonium alum	105 grains	6 grams
Potassium ferricyanide	18 grains	1 gram
Hydrochloric acid, conc.	10 minims	0·5 c.cm.
Water to make	40 ounces	1,000 c.cm.

The prints are toned to the desired colour, and washed in changes of 0·1 per cent acetic acid until all stain is removed.

Uranyl nitrate solutions are slightly sensitive to light, and should be stored in the dark.

Gold Toning. There are two methods:

(1) A plain black-and-white print or transparency can be made to turn a rich bluish-black by immersing it in the gold toner. In the resulting image, each individual silver particle is gold-plated. This type of image is more permanent than the original silver image. The process can also be used to improve greenish-black tones caused by exhausted or excessively restrained developers.

(2) A sulphide-toned print or slide can also be toned subsequently with gold. The effect of this is to turn the image chalk-red.

The usual gold toner contains 0·1 per cent of gold chloride and 1 per cent of potassium or ammonium thiocyanate. This can be made up by mixing the components as 1 per cent solutions in the appropriate proportion of 1 : 10.

The image is toned to the colour required, and the print or transparency is then washed and dried in the usual way.

Nickel Toners. In normal nickel toning the print is first immersed in the following bleaching bath, in which the toner converts the silver image into silver and nickel ferrocyanide.

Nickel nitrate	2 ounces	50 grams
Potassium citrate	12 ounces	300 grams
Citric acid	1 ounce	25 grams
Formalin, 40% solution	4 ounces	100 c.cm.
Water to make	40 ounces	1,000 c.cm.

Just before use, 5 parts of this solution are mixed with 1 part 15 per cent potassium ferricyanide.

After bleaching, the print is immersed in a 5 per cent sodium thiosulphate solution for 5–10 minutes.

For bright red tones the print is then toned with a dimethyl glyoxime toner:

Dimethyl glyoxime, saturated solution (7–8 per per cent) in alcohol	10 parts
Ammonia solution, 0·880	1 part
Sodium hydroxide, 5% solution	1 part
Water to make	100 parts

Final washing in changes of 0·1 per cent acetic acid solution completes the process.

For violet tones the nickel-toned print may be immersed in a 25 per cent solution of ferric alum containing 0·5 per cent of sulphuric acid and 10 per cent of potassium bromide.

For bluish-green tones the original black-and-white image is bleached in the nickel bleacher, washed, and immersed for five minutes in 5 per cent ferric chloride, followed by hydrochloric acid diluted 1 : 6. The print or transparency is then washed in several changes of 1 per cent citric acid, fixed in 5 per cent sodium thiosulphate solution, and washed again in eight to ten changes of 1 per cent citric acid.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Lead Toning. In lead toning the silver image is converted into yellow lead chromate.

The print or transparency is first bleached in a 2 per cent potassium bichromate solution containing 0·5 per cent of thiocarbamide. It is then washed and toned in 5 per cent lead acetate containing 0·5 per cent of acetic acid. After toning it is fixed in 5 per cent sodium thiosulphate and washed again.

Cobalt Toning. Cobalt toning gives green tones. The image is bleached in a 3 per cent potassium ferricyanide solution containing 0·5 per cent of potassium bichromate, cleared in 3 per cent potassium metabisulphite solution, and toned in a solution containing 2·5 per cent each of crystalline cobalt chloride and acetic acid, and 0·5 per cent of ferrous sulphate. Washing, fixing, and a final wash complete the process.

Vanadium Toning. Vanadium toners have also been used to obtain green image tones. They are, however, uncertain in their action, and can now be considered obsolete.

Iron Toning. Iron toners convert the silver image into a brilliant prussian blue ferro-ferricyanide compound. These blue toners also intensify the image, so prints or slides should be made slightly lighter if they are to be toned blue afterwards.

All iron toners consist essentially of a mixture of a ferric salt—usually a more stable double ferric ammonium salt like ferric alum or the double oxalate or citrate—and potassium ferricyanide, in acid solution. The silver is converted into silver ferrocyanide which immediately forms a ferro-ferricyanide. Various other substances may be added to stabilize the toner and improve its consistency and keeping qualities.

A suitable formula is:

Ammonium persulphate, 10% solution	1 part
Ferric alum, 10% solution	3 parts
Oxalic acid, 5% solution	12 parts
Potassium ferricyanide, 10% solution	2 parts
Ammonium alum, 10% solution	10 parts
Hydrochloric acid, diluted 1 : 9	2 parts
Water to make	200 parts

The solutions are mixed in the above order, and filtered if necessary.

The prints or transparencies are immersed in the toning solution until they are completely blue, and washed in changes of slightly acidified water.

For green tones the blue-toned image may be treated in a solution containing 0·5 per cent each of sodium sulphide and concentrated hydrochloric acid. It should afterwards be washed in slightly acidified water.

DYE TONERS

Mordant dye toning depends on the fact that certain dyes will not stain ordinary gelatin, but they will dye gelatin which has been impregnated with certain insoluble compounds, known as mordants, on which the dye can be adsorbed. Suitable mordants are the insoluble thiocyanates, ferrocyanides, and halides of some metals.

For mordant dye toning the silver image is converted into a mordanting compound of this type and then dyed in a dye bath.

The formula for copper thiocyanate mordanting bleacher is:

Stock solution A		
Copper sulphate (blue vitriol)	1 ounce	25 grams
Potassium citrate	4 ounces	100 grams
Glacial acetic acid	390 minims	20 c.cm.
Water to make	40 ounces	1,000 c.cm.
Stock solution B		
Ammonium (or potassium) thiocyanate	1 ounce	25 grams
Water to make	10 ounces	250 c.cm.

For use 1 part of B is slowly stirred into 4 parts of A. The solution must be clear, otherwise it is useless.

The image is bleached until it is a dirty grey, soaked in several changes of still water, and dyed in a dye bath.

The formula for a silver iodide mordanting bleacher is:

Potassium iodide	2 ounces	50 grams
Iodine	265 grains	15 grams
Glacial acetic acid	1 ounce	25 c.cm.
Water to make	40 ounces	1,000 c.cm.

The image is bleached in this solution, washed, and dyed. This mordant gives clearer colours than the copper thiocyanate because the silver iodide is practically colourless.

Other mordanting bleachers can be prepared with uranium nitrate and potassium ferricyanide, or with potassium iodide, thiocyanate, and thiocarbamide.

The following dyes are suitable for the dye bath:

TONING COLOURS

Colour	*Dye*
Violet	Methyl violet, benzyl violet
Blue	Methylene blue, thionine blue
Green	Victoria green, malachite green, methylene green
Yellow	Auramine, thioflavine T.
Orange	Chrysoidine 3R
Red	Rhodamine, basic fuchsine, safranine A, neophosphine
Brown	Chrysoidine brown

Most of these dyes can be mixed in any proportions to give intermediate shades.

A suitable dye bath consists of 1 part of the dye dissolved in 500 parts of 1 per cent acetic acid. Higher dye concentrations dye the image more rapidly, but produce less contrast; weaker dye baths act more slowly, but produce a contrastier image.

If the highlights tend to become stained, they can be cleared by adding more acetic acid to the dye bath.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

When the dye image has reached its required density, the print is washed. This operation must be carefully watched, because prolonged washing may remove some of the dye from the image.

COLOUR DEVELOPERS

For colour development, the image is bleached in a normal halogenizing bleacher and re-developed in a chromogenic (colour generating) colour developer. The oxidation products of the developing agent combine with the colour-formers in the solution to form a stain image at the same time as the developer develops the silver image. The silver image may be removed, leaving only the stain image.

Suitable developing agents usually consist of derivatives of paraphenylene diamine or para-aminophenol. Proprietary compounds of this type are commercially available under various trade names.

The colour obtained with each colour-former varies slightly according to the developing agent used.

A suitable colour-coupling developer formula is:

Diethyl para-phenylene diamine hydrochloride or bisulphite	44 grains	2·5	grams
Sodium sulphite, anhydrous	44 grains	2·5	grams
Sodium carbonate, anhydrous	265 grains	15	grams
Potassium thiocyanate, 10% solution	190 minims	10	c.cm.
Colour former solution	95 minims	5	c.cm.
Water to make	40 ounces	1,000	c.cm.

The developer should be made up immediately before use.

The colour formers can be stored as solutions in alcohol (colourless industrial methylated alcohol will do), acetone, or a mixture of equal parts of alcohol and acetone.

COLOUR FORMERS

Colour	*Colour Former*	*Solvent*	*Strength of Solution*
Blue	Alpha-naphthol	Alcohol	1–2%
Blue	5-nitro-alpha-naphthol	Alcohol	1–2%
Blue-green	2 - 4-dichloro-alpha-naphthol	Alcohol	1–2%
Green	Pentabromo-alpha-naphthol	Alcohol	3%
Pale-green	Dichloro-ortho-cresol	Alcohol	2–3%
Yellow	2 - 5-dichloro-aceto-acetanilide	Alcohol or acetone	5%
Yellow	Ortho-chloro-aceto-acetanilide	Alcohol	5%
Yellow-brown	Cyanacetanilide	Alcohol and acetone	1%
Orange	Benzoylacetanilide	Alcohol or acetone	5%
Red	1 : 3 : 5-phenyl-methyl pyrazolone	Acetone	3–5%
Magenta	Para-nitrophenyl aceto-nitrile	Alcohol or acetone	5–8%

The above colour formers may be mixed in any proportion to produce intermediate tints.

The silver image can be fully removed with Farmer's reducer, or, better still, it can be bleached in a ferricyanide and potassium bromide bleacher, followed by a plain 10 per cent sodium thiosulphate fixing bath.

If the bleaching process is arrested before it is complete, leaving the silver image only partially removed, the colour tones will be darkened by a certain amount of black, silver deposit. If the bleaching bath is followed by a sulphiding solution, the colours will be combined with brown. L.A.M.

TONE SEPARATION. Since a paper print hardly ever shows a tone range of over 30:1, it can rarely record the true tones of the negative. On a soft grade of paper the tone gradation from high lights to shadows may be compressed to as little as one-tenth of the range of the negative—i.e., if the negative has a long scale of tones ranging from deep shadows to bright highlights, or if the negative includes tones at both extremes of the density scale. While the darkest part of a negative may be 300 times as opaque as the thinnest section, the blackest shadow of the print cannot be more than about 30 times as dark as whitest paper tone. This means that the print will look flat, even if it includes a complete range of tones from black to white, simply because the separation between the individual tones is not great enough.

Selective Printing. One way out of the difficulty is to print only the medium tones and part of either the shadow or the highlight detail on a contrasty paper—i.e., some of the tones are deliberately sacrificed, so that the whole of the available tone scale of the paper can be exploited fully in reproducing a relatively narrow section of the negative tone scale. This method is satisfactory if the tones that are sacrificed are unimportant or even completely absent in any case.

Separation Printing. The other way out is to print the highlights and the shadows separately, and to allow the tone scale of each to overlap. This method is called tone separation; it is particularly useful for subjects consisting of extremes of light and shade, with nothing much in between them.

While tone separation falsifies the gradation of the subject, it is capable of giving a print that looks more natural than one made by normal printing procedure with its resulting compressed tone scale. The reason for this lies in the differing psychological reactions that are brought into play when we look at a real object

and a two-dimensioned representation of it in tones of grey.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

There are two steps in making tone separation prints; making the highlight and shadow negatives from the original film or plate; printing the two negatives, one after the other, in exact register on to the same sheet of printing paper.

The separation negatives can be made by direct printing and reversal processing, or via an intermediate transparency. In either case, they may be the same size as the original or enlarged to exactly the same degree.

The highlight negative should be thin and soft, with sufficient detail in the highlights, but none in the shadows. The shadow negative should be dense and contrasty with the highlights almost opaque, but full of detail in the shadows.

The correct type of negative in each case is arrived at by suitably adjusting the exposure, development, or both. If the original negative is dense and contrasty, it may be used as the shadow negative. In this case it is only necessary to make the highlight negative.

The original negative is marked with a couple of crosses on opposite margins. These crosses are reproduced on the separation negatives and are used to bring the images into exact register on the printing paper.

The shadow negative is printed first. When the negative has been focused, and just before it is exposed, the registration marks are marked on the paper with pin-pricks. The highlight negative is then printed on the same sheet of paper, after the registration marks have been made to coincide exactly with the position of the pin-pricks.

The relative exposures are best found by test strips. The exposure for the shadow negative should be long enough to render the shadows satisfactorily. The highlight negative will need about one-twentieth to one-tenth as long; the highlights should just print through.

The character of the result depends on the length of each exposure, as well as on the density and gradation of the separation negatives.

Certain methods of processing—e.g., water-bath development—or aftertreatment of the original negative may also be employed to adjust the highlight and shadow gradation independently to give a measure of tone separation on printing. The control possible in this way is, of course, much more limited.

Person Process. Another variation of the principle of tone separation was described in 1930 by A. Person. His method was to expose and process the negative so that it embraced a range of densities much greater than the softest paper could reproduce. From this negative he made a positive transparency in which the highlights were printed in full detail and the shadows were allowed to block up completely. He then made a contrasty negative of the high-

TONE SEPARATION. Reduces the contrast range of excessively hard negatives by separating and overlapping the highlight and shadow tone scales. 1. Prepare positive transparency and mark registration crosses on opposite margins. 2. Make shadow negative of great contrast and almost opaque highlights, but showing good shadow gradation. 3. From the same transparency make also a highlight negative with detail in highlights, but none in shadows. 4. Focus shadow negative in enlarger, and adjust paper position. Mark registration crosses on paper with pin pricks, then expose. 5. Replace shadow negative by highlight negative, register crosses on negative with pinpricks on paper, and expose.

light detail by printing the transparency with a very short exposure on contrasty material.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

The two negatives were then printed one after the other in register on the same sheet of bromide paper, and by varying the exposure given under each negative it was possible to produce a print in which the shadow and highlight tones were registered simultaneously. The fact that the middle tones are compressed by the process is not obvious, and the tone quality of the finished product can reach a very high level indeed.

Posterization. By carrying the tone separation process still further it is possible to eliminate all but two or three tones of the subject, producing a broad poster-like effect. This is known as posterization. L.A.M.

TRAFFIC PHOTOGRAPHY. Part of police photography largely connected with the recording of scenes of road accidents of all kinds so that a pictorial record of the incident is available at a later date.

These photographs may be used as evidence in a prosecution or at an inquest; to assist those responsible in planning improvements at accident "black-spots"; or for road safety propaganda.

Working conditions vary considerably as the operator has to be available at any time of day or night and in all weathers. Speed of operation is essential as in many instances traffic is held up by damaged vehicles, debris, etc., which may be blocking the road and need to be moved as quickly as possible.

A certain amount of survey work is done by photography and a limited amount of surveillance by means of cameras attached to patrol cars and in helicopters.

Road Accidents. The camera in general use for this type of work is the modern 4 × 5 in. technical camera. It enables the operator to deal satisfactorily with both types of work. The camera should be fitted with a coupled rangefinder for quick and accurate focusing and equipped with a good flashgun for night time operation. Stand cameras of $4\frac{3}{4} \times 6\frac{1}{2}$ ins. are still in limited use but are slower to use and not so convenient in busy streets or at night-time. Some operators also work with 35 mm. and other roll film cameras.

Advantages of the larger negative if it has to be produced in Court are that the image is big enough to be seen without difficulty and it is possible to make enlargements from small areas of the negative. A lens of standard focal length for the camera should always be used as there is a tendency for the wide-angle lens to produce an elongated view, i.e. with the planes separated. A long focus lens has the opposite effect—it tends to flatten the planes. Where it will assist the enquiry on the spot prints are produced by an instant-picture camera.

A fast panchromatic film is generally used to permit the use of a small aperture. Process film may be used on occasions when dealing with such things as scratch or fabric marks on vehicles.

Fairly large flash bulbs having a maker's flash factor of about 720 with the film in use are generally favoured, though electronic flash may be employed for close up work.

The number and nature of the photographs may vary with the type of accident being dealt with. It is better to take too many photographs than too few. Everything likely to assist in the investigation or to apportion the blame, if any, should be recorded. No attempt must be made to favour one side or the other, the photographs should be a true and accurate record of the scene. The operator should find out before starting if anything has been moved from its position immediately following the incident. No attempt should be made to put things back into position or to reconstruct the scene after things have been moved.

"General view" photographs looking in the direction of travel of the vehicles involved are necessary to begin with. Maximum depth of field is required here as everything on the photograph should be reasonably sharp. Therefore as slow a shutter speed as possible is chosen in order to allow the operator to stop down to a fairly small aperture. When taking these photographs the operator should stand roughly in the position that an approaching driver should have been in were he in his correct position on the road. This will show the view available to the driver as he approached the point of impact. Care is necessary when showing bends as a wrong viewpoint can give a false impression of the rate of curve, etc. Where possible, road warning signs should be included as should buildings or overhanging trees which may have obscured vision.

These photographs are followed by close-up shots to show the final positions of vehicles, skid and tyre marks and damage to vehicles to establish if possible point of impact, point of contact and speed of travel. Invariably some distance is travelled following the collision before the vehicles come to rest. When photographing damage to vehicles it is as well to include the registration plate if at all possible for identification purposes. Any broken part which was allegedly the cause of the accident should be photographed before the vehicle is moved as further damage may ensue during removal.

Skid and tyre marks may have to be taken from a variety of angles in order to record them

properly as some can only be seen from certain positions.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

At night the photography is relatively short range work, the aim being to record as much as possible and produce that which is recorded in a clear and sharp form. Close-up shots present no difficulty but with general views the light from the flash-bulb falls off rapidly towards the rear of the field of view. Large apertures are no advantage as the depth of field is small, therefore the operator is confined to apertures of *f*11 or possibly *f*8 when using a single bulb in a flash gun attached to the camera. Greater areas can be covered by mounting the camera on a tripod and, by the open flash method, firing a series of flash bulbs at various distances along the field of view. Time exposures where street lighting is of assistance coupled with fill-in flash also produces good results. Flood-lighting and motor car headlights can also be utilized but these latter methods are not easy on busy roads or where time does not permit their setting up. The scene is usually re-visited in daylight and further pictures of the road etc. taken.

Photographs are occasionally taken to corroborate the evidence of an eye witness. In these cases an eye level shot from the position the witness was in and looking in the direction he was looking in will show what he was able to see.

Survey. In road traffic survey work photographs taken at ground level are often supplemented by overhead shots. They are taken at road junctions, black spots and of traffic conditions at peak times, etc., to assist those concerned with road construction or alteration. They also assist in the planning of bus routes, diversions, etc. The plan-type view of the overhead photograph is superior to the ground level one in these cases. Such pictures are taken by means of a roll film camera with a wide-angle lens on a 60 foot extending pole mounted at an angle on a truck, or from a helicopter or light aircraft. A fixed length marker can be placed on the ground and photographed with the scene; this will allow measurements to be taken from the photograph as if it were a scale plan. The helicopter is more suitable for this type of work due to its manœuvrability and range of heights. High shutter speeds are necessary to overcome unsharpness due to a certain amount of vibration in the machine.

Surveillance. Cameras mounted on brackets in patrol cars are used to record incidents of dangerous or careless driving when witnessed by the car crew. Examples of these are vehicles crossing the double white line, overtaking three abreast or overtaking on the brow of a hill or other dangerous place.

Generally 35 mm. cameras are used and they are mounted on a bracket inside the car horizontally and facing square to the front when the car is level. The shutter is set at 1/100 sec. and all the operator needs to do is to select the aperture suitable to the prevailing light conditions and fire the shutter by means of a long cable release when the occasion arises. The photograph should always show the registration number of the vehicle and its position to the road. These photographs may be used in evidence at Court or for road safety propaganda.

Special automatic cameras with motorized film transport have been produced for this work; some types include devices that simultaneously record one or two instrument dials on one part of each frame (e.g. clock time and speed of the vehicle from which the exposures are made).

Photographs for the same purposes are also taken from the helicopter flying overhead or slightly on one side and travelling parallel to the road. H.Sc.

TRAINING AND EDUCATION IN PHOTOGRAPHY

Instruction in photography can be along two lines: pure training in the practical aspects of the craft, and more elaborate schooling covering both theory and practice. The first may involve some sort of apprenticeship under the supervision of a professional photographer. The second is usually connected with study at a special school or course, following a syllabus under one or more instructors.

In considering either methods of approach different requirements must be taken into account. Teaching courses vary accordingly.

The craftsman needs a very practical training in a specific aspect of photography; he gets it during his hours of employment. If he wishes to progress and take examinations he can also attend evening classes, or take a correspondence course in photography.

The technician will require more theoretical background and may be released by his employer to attend college one day a week, or be encouraged to attend evening classes. Alternatively, he may wish to pass examinations before seeking employment in which case he will attend college as a full time student.

The student professional photographer must receive a thorough and comprehensive education in photography rather than be limited to specialization at an early stage in his career. For this reason alone a full-time course of studies at a recognized school of photography is the quickest and surest route. Part-time courses are available to those who need a job to live.

The needs of the photographic technologist are best met by the "sandwich" course, which in other industries has become a recognized method of education and training combined.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Practical training, carefully programmed, is received during the periods spent in the industry and the basic discipline, principles and applications of the subject are studied by the student during College terms.

The dealer in photographic equipment needs training in salesmanship and business. He must still know enough about cameras, equipment and photographic materials to advise customers with assurance.

BRITAIN

Photography is considered to be a subject for further education in Britain. It is practically never taught at secondary school level; a student is expected to have finished his general education before embarking on a vocational course of studies. Students applying to join courses of photography at colleges that offer them, must satisfy certain requirements.

Courses in photography are conducted throughout the country in regional, area and local technical colleges, schools of art and evening institutes. All of these are financed from public funds and come under the jurisdiction of the local education authorities. The latter finance the grades of work up to intermediate level, the higher levels being paid for by the Ministry of Education. Students can apply for financial assistance from their local educational authority. This system makes it possible to offer courses in photography at a comparatively low fee, which would be economically impossible in an independent organization.

Private schools of photography existed before the last war, but conditions are no longer favourable for them. Some private ventures are known to offer specialist courses, e.g. in medical photography and in film technique.

On the whole the British photographic industry does not offer financial assistance to colleges, or present items of equipment on the lavish scale as is done in European countries. However, considerable assistance is given in a less obvious manner, e.g. by granting scholarships on an advanced level and in specialized fields.

Professional Courses. For professional examinations a full-time course is most satisfactory. It requires five days a week attendance at college for two to three years according to the level aimed at. The courses offered vary in entry requirements, course content and standards.

The intention of a full-time vocational course is that the student should enter the course soon after he has finished his secondary education, having passed the necessary examinations. He receives a thorough education in the principles and practice of photography. Usually the courses consist of lectures, demonstrations, tutorials and practical work, on a general level for a period of two years, followed by an intermediate examination.

The third year is usually devoted to concentrated study of a defined area of photography: commercial and industrial, advertising and fashion, portraiture, photography for publications, scientific applications of photography, cinematography. Selected schools of photography, which are equipped for the purpose, prepare their students for the final examination in photography during the third year of the course, the examination being sat at the end of the third year.

Some schools include ancillary subjects in their curricula, as is the case with professional courses in other subjects, e.g. mathematics, physics, design, art appreciation, communication, business studies. These ancillaries are spread over the three years of the courses.

The usual requirements for admittance to professional courses in photography are a minimum age (between sixteen and eighteen), and a minimum number of passes in the General Certificate of Education examinations at Ordinary or Ordinary and Advanced levels. Some schools specify certain subjects for admittance to a full-time day course. English is an essential requirement for all courses which prepare for the professional examinations; mathematics is often required, sometimes also are physics, chemistry and art. Examination equivalents from other countries are usually taken into account, and, if a foreign applicant can furnish evidence of proficiency in the English language, he may be accepted into the course.

Study for the professional examinations can also be conducted on a part-time basis. Students employed by photographers or a photographic department in Government service or industry, may attend college one day a week provided the employer is willing to sponsor them, and facilities are available. In addition, some colleges offer evening courses for the professional examinations. Part-time courses take four to five years to cover the same ground (in abbreviated form) as a full-time course in three. Preparation for the final examination by attendance at night school can only succeed if the student has adequate scope for practical experience and experimental work.

Full-time courses recognized by the Ministry of Education are held at the following institutes in England and Wales:—

Berkshire College of Art, Reading
Birmingham College of Arts and Crafts
Blackpool Technical College
Bournemouth College of Art
Derby & District College of Art
Ealing Technical College & College of Art
Gloucester College of Art
Guildford College of Art
Harrow Technical College
Hull College of Arts & Crafts
Leeds College of Technology
London College of Printing
Manchester College of Science & Technology
Nottingham College of Arts and Crafts
The Polytechnic, Regent Street, London

Salisbury College of Art
Staffordshire Technical College, Wednesbury
Stow College of Printing, Glasgow.
Part-time courses are available at:—
Newcastle-upon-Tyne College of Art
Coventry College of Art
S.E. Essex Technical College, Dagenham.

CC-0. Camarigan Digital Preservation Foundation, Chandigarh

Craft and Technician Courses. These are usually organized on a part-time attendance basis and supplement the training the student receives during his employment. They prepare students for examinations in photography and cover tuition in theoretical aspects as well as a variety of practical procedures. The applicant must be of a certain minimum age (sixteen), employed in photographic work and, for some courses, must also have the General Certificate of Education in a specified number of subjects. The majority of part-time students attend evening classes, but day release courses are becoming popular with employers and employed alike. Duration of courses varies according to the examinations for which students are being prepared. On the average the intermediate level takes two years' study, and the final level a further two years.

Technological Courses. At the present time one course of this character is organized for the employees of the photographic manufacturing companies. Another course, to be introduced at a higher level, will provide suitable photographic technologists, for the photographic manufacturing industry, the wholesale photographic finishing industry and the research and development sections of major industries and Government Departments.

Short Courses. In the colleges these consist of "refresher", specialist, or post-graduate courses. The large manufacturing companies of photographic materials organize short courses. In the main these are intended for professional photographers and instruct in the characteristic features of the manufacturer's own materials, and also how to achieve the best results from these materials.

Non-Vocational Courses. Many such courses exist, especially in schools of art and evening institutes, and can take one of two forms. First, and particularly in the London area, evening classes in photography thrive as a cultural pursuit or as instruction in the hobby. Second, photography is gaining favour as a suitable ancillary subject for inclusion in curricula of art and design courses. Most departments of photography within art colleges are expected to provide such a service. Photography is sometimes also considered a suitable subject for inclusion as an ancillary in science courses in technical colleges.

Cinematography. This subject is incorporated in certain three-year courses; it is now primarily concerned with documentary and industrial film-making, and includes the scientific applications of cinematography. There are also part-time courses in cinematography.

Examinations. In Britain examinations in photography are organized by three examining bodies: The Institute of Incorporated Photographers, The City and Guilds of London Institute, and The Photographic Dealers Association. A few colleges also award their own diplomas to successful students who satisfy the requirements of the courses.

The Institute of Incorporated Photographers (formerly Institute of British Photographers) offers membership only to professional photographers. Candidates for the examinations at intermediate and final levels must be registered student members of the Institute. The Institute holds examinations at three levels: (1) Preliminary, (2) Intermediate, (3) Final. The first two are concerned with the general principles and practice of photography. The Final examination consists of one written paper taken by all candidates, the subject of the other two papers (one written and the other a searching practical test of fifteen hours duration over a period of two and a half days) being selected by the candidate in advance. The areas in which the candidate may choose to be examined are: (*a*) commercial and industrial photography; (*b*) advertising photography; (*c*) medical photography; (*d*) scientific applications of photography; (*e*) portraiture.

These examinations are recognized by the Ministry of Education, and are steadily gaining public recognition and confidence. For the examination at all three levels candidates have to be sponsored by the college or school where they are studying, or by the employer who is training them. For the intermediate and final examinations an additional entry requirement is the General Certificate of Education with Ordinary level passes in English Language or Literature and three other subjects.

The City and Guilds of London Institute is solely an examining body covering a wide range of craft and trade subjects. The examinations in photography are predominantly suited to the needs of the photographic technician, but are fairly closely aligned with the I.I.C. examinations. The C.G.L.I. holds their examinations in photography at intermediate and final levels. There are no educational entry qualifications but students attending courses must be sponsored by their college.

The Photographic Dealers' Association offers examinations solely concerned with aspects of photographic dealing, including however some theory and practice of photography. The examinations are for the members of the Association, i.e. people engaged in the wholesale distribution or retailing of photographic equipment and materials.

Qualifications in Photography. The Institute of Incorporated Photographers awards Associateships and Fellowships. The Associateship is granted to members of the Institute who have passed the Final examinations and have spent two years in photographic practice. Licentiate

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

members of the Institute can also apply for Associateship. The fellowship is a higher qualification. Applications must be accompanied by photographs or a thesis indicating distinction and outstanding ability in photography in a specified field.

The City and Guilds of London Institute grants an Insignia Award which is very sparingly given in recognition of technological advances or developments in the subject in which application is made. Only two awards have been made in photography.

Information on Educational Facilities. In most areas the local education authorities can give information whether there are facilities for studying photography. The Institute of Incorporated Photographers publishes a list of schools recognized by it as providing entry qualifications or exemption for the I.I.P. examinations. Colleges of further education provide information and prospectuses on direct application. This information details entry conditions, application dates, curricula, etc.

UNITED STATES

Photography is recognized at university level in the U.S.A. and degrees are granted in the subject. A number of institutes also have their photographic departments, such as the Rochester Institute of Technology. Such organizations may be members of the American Council on Education and other educational associations. The institutions mentioned in this article are privately-endowed non-government institutions. Some vocational secondary schools have courses in photography.

In addition there are many private schools of photography offering generalized or specialized courses and sometimes sponsored by professional associations. There are also correspondence courses, some of which cover specialized aspects such as camera repairs.

Each institution which offers a course in photography conducts its own examination and awards its own degrees, diplomas or certificates.

The courses range from full-time photographic training to evening classes and refresher courses.

In addition to the degrees, diplomas and certificates conferred by universities, colleges and schools offering courses in photography in the U.S.A., a number of organizations award qualifications to their members who satisfy the required conditions. The largest trade association is The Professional Photographers' Association of America Inc. Members qualify to the Master of Photography certificate.

Syllabus. The first year in a full-time course of photography usually covers photographic theory, technology, practical photography, mathematics and physics. Succeeding stages may offer specialization in photographic science, professional or illustrative photography.

Photographic science courses are concerned with the materials and processes of photography, with special reference to product development, research, and manufacture of photographic material, as well as the application of photography in science and engineering.

The School of Photography at the Rochester Institute of Technology is the only one with both graduate and undergraduate courses in photographic science and instrumentation.

Professional courses embrace the various branches of practical photography as a career, including also photographic technology and business management.

Illustrative photography covers the more creative aspects including design, graphics as well as communication. Press and feature photography for magazines and other publications and also advertising photography come into this category.

Entry requirements stress academic ability evidenced by graduation results in high school with a special accent on science subjects.

There is a great deal of interest on the college level in photographic illustration (expressive photography). There are courses in the Fine Arts or Art in design departments of fifteen to twenty colleges and universities in the U.S.A.

The major institutions where such courses are organized are the University of Ohio, the University of California at Los Angeles, the Institute of Design of the Illinois Institute of Technology, and the School of Art of the Philadelphia Museum. The Department of Cinema of the University of Southern California offers motion picture courses at the same level, while the School of Engineering of Columbia University has special lecture courses in photographic technology.

EUROPE

Many European countries restrict all professional and commercial activities to duly trained and certificated practitioners, often organized in trades and crafts guilds. In the German Federal Republic, for instance, the guild statutes for photographers specify a three year apprenticeship, followed by an intermediate examination, a five-year term as an assistant, and a final qualifying examination. This entitles the newly fledged photographer to registration in the guild and to conduct his own business. Hence apprenticeship training for photographers is still very much in force, often supplemented by evening classes.

Entry into Professional Training. The main possibilities are (1) apprenticeship combined with evening classes; (2) technical school training concurrent with apprenticeship; (3) full-time courses at schools of photography.

The first course is for young people with a full secondary school education who start their apprenticeship at 16 years with a qualified photographer. They may also take evening classes at a technical college. The apprenticeship

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

is followed by a year of practical experience after which the student can enter a school of advanced photography on a full-time basis for two years.

The second alternative is for students who leave school at 14 and then receive a supplementary general education and technical training in a technical school. The apprenticeship training follows on almost the same lines as in the first case but the apprentice attends evening classes to bring him to the secondary school certificate level.

Thirdly, full-time courses in elementary photography at technical colleges take students straight from secondary school at 16 years. These courses are regarded as the equivalent of apprenticeship and are often considered to give a more liberal training in photography.

There are variations in different countries on these three basic systems which are firmly established as methods of providing education and training in photography in the German Federal Republic (West Germany).

Photographic Trade. Germany has courses for photographic dealers and for photographic chemists at certain special schools. Dealers serve a three-year apprenticeship in a photo-retailer's establishment and attend a day-release school during this time. An examination at the end of the apprenticeship leads to a diploma as a commercial assistant, specializing in photography.

A similar three-year apprenticeship for the photographic chemist specializes far more on pharmacy. A number of special schools of pharmacy provide photographic training as part of the general three-year course for photographic chemists. Further specialized training is available at certain advanced schools.

Technical colleges in Germany also have classes for photographic darkroom assistants, but are not listed as special photographic schools.

A wide range of private schools also exists, but are not recognized as professional training for photographers and students cannot therefore set up businesses of their own.

College Courses. Because of the limitations of apprenticeship and the variations in the capacity of individuals to impart knowledge, there is a growing demand for, and facilities of specialized photographic courses in schools and colleges, either as a supplement to apprenticeship or in place of it. Some of the better-known colleges are:

Graphische Lehr-und Versuchsanstalt, Vienna, Austria
Ecole Belge de Photographie, Brussels, Belgium
Ecole Technique de Photographie et de Cinematrographie, Paris, France
Fachschule für Optik und Fototechnik, Berlin, Germany
"Lette-Verein", Technische Berufsfachschule, Berlin, Germany
Staatliche höhere Fachschule für Photographie, Cologne, Germany
Fachschule für Photographie, Hamburg, Germany
Fachschule des Deutschen Photo-und Kinohandels, Kiel, Germany
Bayerische Staatslehranstalt fur Lichtbildwesen, Munich, Germany
Institut for Bildjournalismus, Munich, Germany
School voor Fotografie & Fototechniek, The Hague, Holland
Istituto Professionale Statale "Ceasare Correnti", Milan, Italy
Istituto Statale d'Arte, Rome, Italy
Civica Scuola Avviamento Fotografico "G. Pacchiotti", Turin, Italy
National Institute for Handcrafts, Stockholm, Sweden
Ecole des Arts et Metiers, Vevey, Lake Geneva, Switzerland.

Many of the European colleges which offer courses in photography are financed and sponsored in respect of those courses by the State, the photographic industry and the photographic trade.

Qualifications. The qualifying examination in photography in many European countries comes under the authority of the photographers' guilds, and is recognized as the state final examination. In other countries there is no qualifying examination. In Italy, for instance, it is not necessary to furnish proof of qualifications or training before setting up in business as a photographer.

There is no comparable organization in Europe to Britain's Institute of Incorporated Photographers. Probably the nearest associations of professional photographers are the Swedish photographers' association and the Scandinavian photographers' association. However neither of these organizations hold examinations or grant qualifications.

Higher Photographic Education. Education in photography is being extended in Britain, Europe and the U.S.A. into the higher levels of education by certain major colleges.

At the three best-known colleges of this kind, The Rochester Institute of Technology, New York, the Polytechnic of Regent Street, London; and the Staatliche Höhere Fachshule für Photographie in Cologne, Germany, the subject is covered comprehensively at the professional level. Both science and art aspects are offered either as separate courses or as separate areas of study at the final level. In at least two of these three colleges new courses are being planned with an aim to degrees in photographic science and technology. The schools have the advantage of being independent of any other discipline so that their work can develop on a broad front to a high level. M.F.H.

TRAINING OF PHOTOGRAPHIC TECHNOLOGISTS AND SCIENTISTS

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

A photographic technologist or scientist (PTS), for our purposes, is an academically trained person. In other words, he received his education at an institution which confers a Ph.D degree or its equivalent as its highest award for successful formal education. He is therefore defined as a person with a research degree. He may have taken this in the form of a diploma, where this entails several semesters of work (such as is now general, for example, in the German and Czech Universities) or of a Doctorate. Those trained in technical colleges or institutions of similar standing will therefore not be considered in any detail.

Approach to Training. It is a peculiar fact that facilities for formal training in photographic technology and science (PTS) are limited to a few geographical areas. Notably, the Anglo-Saxon countries have never gone in for this kind of training. There are obvious pros and cons for the various approaches.

Photography, like any other industrial activity, implies, and makes use of, all modern scientific tools. In order to advance any one aspect, chemists, physicists and mathematicians of high calibre are required. Indeed we are at a point, when even in a field as narrow as photographic technology and science, no single person can hope to master the whole subject. People tend to become specialists in one small area, and the most they can do is to have a somewhat superficial knowledge of the rest.

This being so, industry is inclined to engage men with the best possible education in basic sciences and train them up in photography within their own laboratories. Industry has not been particularly interested in men who specialized in photography during their formal courses of study, on the grounds that such specialization was bound to be at the expense of their basic training.

These reasons are behind the fact that (with the possible exception of the U.S.S.R.) no academic institution exists that offers a full-time undergraduate course in photographic science and technology. Such courses are available exclusively at technical colleges. Our photographic technologist and scientist is therefore a man who qualified in one of the basic sciences and who did research on a photographic subject.

Types of Academic Training. Training in PTS can be had in two types of institution: the photographic institutes proper, and in departments engaged in one of the basic sciences, where the head or a member of the staff happens to take an interest in photographic matters. A whole spectrum of attitudes and outlooks exists, resulting in different facilities for training and study. At one extreme is the scientist who will attempt to boil down a photographic problem to a basic one in physics or chemistry. At the other is usually the head of an ostensibly photographic institute, who uses photographic systems and means for his research.

An institute specifically devoted to photography ought to be able to combine these attitudes. Whilst the individual research student could work on a problem—which is basic, although the questions to be answered stem from the photographic field—he should gain some insight into the whole of photography from seminars, colloquia and from observation of the activities of the other students and members of the staff.

It is perhaps remarkable that so few photographic institutes are characterized by an element of purely photographic activity, which is also missing from the usual science department: the taking of photographic records on a routine or service basis, and perhaps even the training of apprentices. Where this sort of work is done, it provides a background, not dissimilar from that of an industrial laboratory, which can be decidedly helpful in training a useful PTS.

Consultation and Servićе. Photographic institutes, technical universities and engineering schools which enjoy the advantages of close contact with industry, are often asked for expert advice, as they are free of manufacturing interests. By participating in consultation and service work, the PTS under training shares the advantages of industrial contact and gets training additional to his research work proper. This develops his feel for industrial work and helps him decide what type of activity suits him best.

Location of Institutes. The considerations above at once provide a clue for the peculiar geographical distribution of training facilities. Where large industrial laboratories exist, such specific training is often regarded as unnecessary or even—from the viewpoint of the potential employer—undesirable. Where the manufacturing units are small, so that they cannot give adequate training themselves, a supply of trained PTS's is desirable. Hence we find photographic institutes at technical universities (Technische Hochschulen) in countries as small as Sweden and Switzerland. There are no less than three in Germany, two of which were established in the lst century, when manufacturing units in that country were still small.

A case which illustrates this point is that of the British Photographic Manufacturers' Research Association which, although not a teaching institution, effectively gave postgraduate training to some of the men now in leading positions in the industry in England. This association was dissolved at a time when industry began to build up its own research facilities and thus became capable of training its own men.

These remarks are strictly historical: it cannot be gainsaid that some of the institutes flourish to this day and fulfil a useful function.

CC-0. Agamnigam. Digital Preservation Foundation, Chandigarh

Syllabi. In very few instances are photographic courses compulsory at undergraduate level; some of the exceptions are students engaged on photogrammetry, cartography, etc., or those wishing to take a research degree on a photographic subject. A typical set of courses the aspiring photographic technologist and scientist could take at undergraduate level might be as follows:

Introductory course of lectures: 2 hours/week for two semesters, or three terms giving a general survey of the process and its applications.

Advanced lectures: 1 hour/week for one semester or 1–2 terms, may be arranged from time to time, on colour photography, radiography, photographic optics, image transfer theory, and emulsion technology.

Practicals: beginners, advanced, special, one semester or term each, 2 to 4 hours per week.

The beginners' practical covers the elementary aspects of the process; the advanced practical may take the student as far as colour printing including masking processes. The special will include the study of unusual processes and advanced sensitometry.

There are, as a rule, no formal post-graduate courses in the European technical universities, at which photographic institutes are situated, a weakness which in time will have to be remedied by following the American example. Attendance of special lecture courses in the field of research of the PTS under training should be encouraged; specifically photographic lectures, seminars and colloquia, in which the students will take over the preparation and presentation of at least some of the lectures, are useful training grounds. Similarly beneficial is attendance at conferences where the young scientist can rub shoulders with more experienced men in his field, take part in the discussions, or even present the results of his own work.

Research projects vary widely according to the interests of the department head, from emulsion technology on the one hand to the mathematics of information theory on the other.

Jobs for the Trained PTS. All the trained photographic technologists and scientists land up in industry, most of them in salaried jobs, a few in independent positions in manufacturing or consultation work, and none, directly, in academic posts.

It is perhaps natural that academic positions in this field should tend to be filled by men with industrial experience, since without this the professor's feet may not be firmly on the ground.

The applicant will, as a rule, have to sacrifice financial prospects; it is nevertheless surprising that at least one chair of photography (Stockholm) could not be filled to the satisfaction of the authorities for several years.

The employment of the photographic technologist and scientist naturally varies with the trends of industrial development. No generalizations are possible beyond the obvious one that the tendency towards advanced instrumentation —*vide* space research—has attracted many into this field.

Here, as in any other branch of technology, there is a great shortage of trained men.

Borderline Cases. A number of departments do not strictly come under the heading of training institutes in this subject, since they do not award a research degree. The outstanding one is the School of Photography at the Rochester Institute of Technology (RIT), which accepts the students as undergraduates and which runs specific courses on photographic technology. Plans for similar courses exist at the Polytechnic in London. A photographic section exists at the physical-chemistry department of Basle University; here again no research work is done. A series of courses on photographic science, engineering and technology is being built up at Columbia University at New York. So far, this does not include practical work or research.

Institutions. Many of the points above result from a questionnaire that set out to obtain answers on various aspects of training. The accompanying tabulation is the result of this enquiry; not all questions were, or could be, answered, and some institutions gave incomplete answers. Hence the detailed figures shown may not be strictly comparable, but they do provide an overall picture. The preponderance of Continental European teaching of photography at academic levels is one of the most remarkable features of the table.

A country which seems to do outstanding work in this field is Russia. The approach is so different, that the information cannot all be fitted into the table.

The Leningrad Institute of Motion-Picture Engineers provides a five-year course in photography. For three years chemical technology is taught as for all students in the college; thereafter, photographic specialization begins. *Year* 3, second half: General photography, 2 hours/week, plus a "short" practical. *Year* 4; Theory of the photographic process, *4* hours/week, two semesters. Practical on sensitometry, 10 hours total/semester. *Year 4*, second half/*Year 5*, first half: Manufacturing technology, 3 hours/week for two semesters; practical, 75 hours/semester. Processing technology, 3 hours/week for two semesters; practical, 75 hours/semester. *Year 4*: Technology of photographic supports, 2 hours/week; practical, 40 hours total/semester.

No fewer than five professors and a lecturer run this course. There is no other formal training to be had anywhere which can compare with this.

Some eleven people took the course in 1960, thirteen in 1961; the aim is to take twenty-five per annum who will be designated as Photographic Engineers. W.F.B.

TRAINS. People photograph locomotives and trains either because they are interested in recording their technical features or because they want to make pictures of them.

The pictorial photographer is usually content to work from a distance so that he can include the setting and exploit the appearance of the smoke and steam from the locomotive. He may be able to get all his pictures without being on railway property. But the technical enthusiast must be able to work close up to his subject. This means getting permission to take photographs from line sides and in and around the locomotive sheds. As a rule, an application for permission addressed to the Public Relations Officer of the Region is willingly granted. When the photographer receives his permit he should regard himself as a privileged guest of the authority and behave accordingly.

No permit is required for taking photographs from the railway platform or on railway property to which the public is normally admitted.

The technical photographer must work to a plan if his prints are to be of any value as records. Generally the characteristic features of a particular class of locomotive or rolling stock call for at least two views (three-quarter front, and side) of each side and one or more views of engines of that type at work.

The steam locomotive, in virtue of its shape, is an awkward problem for the photographer, as the tone range of the subject extends from brilliant reflections off the shiny boiler top to the dull black of dirt-grimed wheels and frames, usually deep in the shadows of the running plate. The smoke deflectors standing out at each side of the smoke box, like huge blinkers, produce deep shadows in which it is easy to lose the details of the black painted smokebox, especially if there is back lighting. Under these conditions the only thing to do is to expose for the shadows or fill in the shadows with a synchronized flash bulb.

It is important to photograph the engine or train from an angle that will show as many important features as possible but which avoids awkward perspectives or depth of field problems. Where it is only possible to get one record picture of a locomotive it is best taken with the subject at an angle of between 45° and 30° to the focal plane. This shows most of the side of the engine quite clearly and also most of the front detail. If more than one view can be taken then there should be at least one broadside view, a view showing the front, and another showing the cab and the arrangement of injector piping and so on, below the footplate.

Moving Trains. The photographer should aim at taking pictures of moving trains with as little blurring of the subject as possible. Three things control the blur—the speed of the train (the faster the train, the greater the blur will be); the direction of movement in relation to the camera position (movement towards or away from the camera gives least blur; movement broadside on to the camera gives most blur); for any given direction of movement, the faster the shutter speed, the less the blur.

As a head-on view is very seldom required (and not very practicable) and a broadside view is almost sure to be blurred (unless the camera is panned), moving trains are best taken with the fastest possible shutter speed when they are approaching at between 30° and 60° to the sight line of the camera. This way records the maximum amount of detail and shows the subject in good perspective.

Photographing a train from the outside of a curve exaggerates the relative movement (and hence the blur) and also causes distortion, as the train is tilted away from the camera by the super-elevation of the outside rail. Pictures taken from the inside of a curve are much more satisfactory because the relative movement is less and the train leans towards the camera.

The height of the camera in relation to the train also affects the appearance of the subject. Normal pictures are taken with the lens at the level of the footplate or a little higher and with the camera held level. The camera should not normally be tilted to include the top of the subject. If necessary, a more distant viewpoint must be chosen, or the photograph taken with a camera equipped with a rising front. When shots are made from above—e.g., from an overbridge—the viewpoint should be far enough to the side to show the side of the engine and train. Low angle shots are best made with the camera on a level with the running rail.

Background. When photographing steam locomotives the pictorial worker relies mainly upon the clouds of steam and smoke to make his picture. Such pictures are, however, increasingly difficult to obtain, and pictorial photography of diesel and electric locomotives depends more upon the beauty and effectiveness of the background setting than upon the train itself. With all forms of motive power, the background can make or mar the picture, and poles, wires, and lamp-posts sprouting from the top of a locomotive or train are highly distracting, and may confuse important technical detail. The photographer should watch carefully for such things and avoid their inclusion in his picture whenever possible. If it is impossible to avoid them they should be manœuvred into the least offensive position by moving the camera one way or another. The unsightly objects may then be removed by painting them out on the negative. Subsequently the sky is reduced on the print until the white outline of the blanked-out object disappears. Iodine cyanide or iodine carbamide reducers are the best to use for this purpose.

Camera. For photographing stationary locomotives, almost any type of camera may be used, so long as the lens will give good definition over the whole field at the fairly wide apertures which are often needed in the murk and grime

CC-0. Panjab Digital Preservation Foundation, Chandigarh

of a locomotive yard, especially in poor weather. It is also possible to photograph quite fast-moving trains with relatively slow shutter speeds if the subject is kept well away from the camera and fairly head-on to it. But this technique will not create outstanding pictures.

The photographer who takes this subject seriously will not be satisfied with this kind of compromise. If he wants to get close enough to take impressively large pictures of moving trains he will need a more specialized type of camera. A shutter speed of 1/250 second is necessary for even slow-moving trains at normal angles of view, and speeds up to 1/1000 second are necessary for real action. A press camera with a focal plane shutter and an open wire frame finder has no equal for the work, although this type of shutter tends to distort fast-moving images.

In the hands of the expert, the high grade miniature can be used to give nearly comparable results but it is not an ideal instrument for train photography. Generally, the simpler the controls the better, but a rising front and swing back are very useful; the latter enables the whole of a long train to be brought into focus when a wide lens aperture is used with the train oblique to the camera.

The lens should have an aperture of at least *f* 4·5 to permit the high shutter speeds necessary even in good light and be of normal focal length for the plate size. Some photographers prefer to use a slightly longer focal length from a more distant viewpoint in order to obtain a slight "bunching up" of the perspective of the train. This is the familiar telephoto effect and it avoids the drawn-out appearance of a long train tapering away to nothing across the whole width of the print. Special care in focusing is necessary when using such a lens as the depth of field is reduced.

Materials. It is safest to use fast films and to stick to one make. In railway work it is often necessary to act quickly, so the photographer must be thoroughly familiar with his camera and film; he cannot afford to experiment.

A soft working developer giving maximum shadow detail is generally the most suitable, and prints should normally be made on glossy bromide paper, properly glazed unless intended as exhibition prints, when a smooth lustre surface may be preferred. Owing to the great contrast between the dark tones of the subject and the bright sky, it is usually necessary to "dodge in" the sky and often also the boiler top and other highlights when printing, but care must be taken to avoid any suggestion of a white "ghost" round the engine.

Colour. Steam, diesel and electric locomotives all make fine transparencies, the first because of the clouds of steam and the latter two on account of their brilliant colours.

Steam locomotives are frequently very grimy, and in colour appear only as an ugly black mass unless extra exposure, which may be as much as four times that required for the rest of the train, is given to show their detail. Usually, a compromise exposure which gives acceptable colour rendering of both locomotive and train must be determined from experience.

Brightly-painted diesel and electric locomotives are less of a problem though even with these some increase of exposure over that given by a general meter reading is often necessary to show the black running gear.

A good lens capable of critical definition at wide aperture is necessary to obtain good colour transparencies of moving trains, and medium-speed colour films in larger sizes have been found to give the truest rendering. P. R-W.

TRANSFER COATING. Transfer coating is suitable for sensitizing any flat and hard surface like metal, wood, and plastic.

The working material consists of a sensitive silver bromide gelatin emulsion layer, coated on a stripping paper. This is transferred on to the surface to be sensitized, exposed and processed. This process is used in various industries for making templates, patterns, and for copying working drawings on to the material to be shaped or machined.

The surface of the support is first lacquered by brushing or spraying on a special white or clear lacquer. White lacquer is used for most surfaces, clear where the surface is light already. Metal articles which might react with the processing solutions must be sealed off with a coat of lacquer on the surface, the back and sides.

When the lacquer coat is dry, it is softened again by applying a special softener, and the sensitive transfer coating paper is immediately squeegeed on to it. After a minute or two the lacquer sets and the paper backing can be stripped off. This leaves the sensitized layer ready for exposure and processing.

When the layer has been exposed, it may be treated like a normal development paper with suitable modifications in processing technique where the sensitized article cannot be immersed in solutions.

See also: *Stripping; Template; Transfer processes.*

TRANSFER FUNCTION. When a waveform is analyzed into frequency components, the effects of any linear transmitting or recording medium may at any frequency be expressed by a simple scale factor. The variation of this factor with frequency is known as the transfer function. The transfer function of an optical or photographic system describes how the system's response to fluctuations in exposure depends on the spatial frequency. It is a much more complete measure of image quality than such concepts as resolution and sharpness.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

TRANSFER PROCESSES. Processes involving the transfer of an image from one emulsion, or support to another. The transfer often involves physical reversal (left—right) and may involve tone reversal (negative—positive). There is a variety of such processes working on fundamentally different principles and used for a wide range of purposes. They fall into the following general groups: chemical image transfer, physical image transfer and emulsion transfer.

Chemical image transfer: the image is transferred by chemical diffusion from one emulsion layer to another placed in intimate contact with it. The image is in fact generated in the second emulsion; the only physical movement taking place is that of the chemicals generating the second image. The latter may be silver (as in various reversal transfer processes) or hardened gelatin (as in bromoil, carbro, and similar processes).

TRANSFER PROCESSES. Top: *Chemical transfer, as used in certain document copying processes for direct positives, in the carbro process, etc. Chemical action in the original images causes image forming reactions in the transfer layer.* Centre: *Physical transfer, as used in dye imbibition and similar processes. A matrix image, charged with dye, is brought into contact with a gelatin layer, and transfers a dye image on to the latter.* Bottom: *Emulsion transfer, as used in a number of colour print processes, etc. The image in its emulsion layer is transferred as a whole from one support to another.*

Physical image transfer: most of these processes involve the transfer of a pigment or dye image absorbed or adsorbed on a gelatin matrix to a plain or gelatin coated paper or similar support. Examples are bromoil transfer (pigment ink), dye transfer (dyes), and various photomechanical and document copying processes.

Emulsion transfer: here the whole emulsion or a gelatin matrix is stripped from one support and transferred to another. This may be necessary with many matrix processes in order to obtain a laterally correct image—i.e., one that is not reversed left to right—or to ensure that the matrix has a firm support—e.g., if the gelatin of the matrix is hardened from the top, the gelatin next to the support would be dissolved on development so the whole layer must be transferred to a temporary or permanent support first.

Another application of emulsion transfer is the preparation of photographic templates. Here the unexposed emulsion is transferred on to the material to be worked, and exposed and developed there. L.A.M.

TRANSFORMER. Electric circuit for changing the voltage of an alternating current. It consists essentially of two coils of insulated wire wound around a closed iron core. If an alternating voltage is applied to the ends of one of the coils it sets up a voltage in the other. The ratio of the voltages in the two coils is the inverse of the ratio of the number of turns in each coil. So if there are ten times as many turns in the first coil (the primary winding) as in the second (the secondary winding), the voltage set up in the second coil will be one tenth of that applied to the first.

A transformer may have more than one primary winding, to provide for input voltages of different values—e.g. 230 and 110 volt—and more than one secondary winding, to provide a range of output voltages—e.g. 6, 12, and 110 volts. These windings may consist of completely separate coils with both ends led out to terminals for connecting to external circuits, or they may be connected as one continuous winding with tappings taken off at suitable points. For example, if a winding consisting of 10,000 turns is tapped at the 9,000th turn, the voltage across the 9,000 turns will be 9/10 of that across the complete winding, and the voltage across the odd 1,000 turns will be 1/10 of that figure. If the input is connected across the 9,000 turns then the voltage available at the ends of the winding will be 10/9 = 1 1/9 times the input voltage. A transformer of this type—i.e. with the same winding for the primary and secondary coils—is known as an autotransformer. The autotransformer principle is used in mains voltage regulating devices and in constant voltage transformers—e.g. to compensate for the small variations in

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

TRANSFORMER TYPES. Top: *Basically a transformer consists of two coils wound around a laminated iron core. A, primary winding. B, secondary winding. C, core.* Centre: *Conventional circuit representation of a transformer, with the same components as before.* Bottom: *Auto-transformer used as step-up* (left) *or step-down* (right) *system. In both cases the lower voltage fed in or drawn out respectively is adjustable by connecting one side of the circuit to one of a series of tappings.*

mains voltage that occur between one district and another or even from one period of the day to another in the same district.

Transformers are used in photography for stepping down mains voltages of 230 and 110 volts to provide power for low voltage equipment such as projector lamps, spot lights, rechargeable batteries and control circuits.

TRANSMISSION. Passage of light through a transparent or translucent medium. The amount passed may be quoted as a percentage transmission; the more scientific term, especially when applied to silver deposits in a photographic image is transparency. A transmission of 100 per cent corresponds to a transparency of 1.

See also: *Transmission efficiency.*

TRANSMISSION EFFICIENCY. When light from an object falls on a lens, it does not all pass through to form an image on the plate. Some of it is lost by absorption and some by reflection. If the lens transmitted all the light—which no lens ever does—it would be 100 per cent efficient.

The absorption of light is reduced to a minimum by using the purest materials for the manufacture of optical glass; most of the losses occur because of reflection at the various glass-air surfaces.

Usually at each glass-air surface only about 96 per cent of the incident light is transmitted, and if the surface is only slightly dirty, the transmission is reduced to about 90 per cent. At first sight, this reduction in the amount of light transmitted may not seem very serious, but a modern photographic lens may contain eight glass-air surfaces, all of which actually reduce the transmission to 70 per cent, even when the surfaces are perfectly clean.

See also: *Coated lens.*

TRANSPARENCY. Positive image on a transparent or translucent support—e.g., glass or film base—intended to be viewed by transmitted light or projected on to a screen. The image may be in monochrome or natural colour.

Transparencies are popular in spite of the extra trouble involved in looking at them, for they can reproduce a greater range of tones than any method of printing on an opaque base.

This is because the tone range of a print is limited at one end of the scale by the whiteness of the paper base and at the other by light reflections from the surface which prevent the attainment of a pure black tone. The tone range of a transparency on the other hand extends from a true black where a completely opaque area of the image blocks out the light altogether, to a highlight which can be as brilliant as the light source itself—i.e., where the emulsion is quite clear. In practice this means that while the contrast range of a bromide paper print can never exceed about 1 : 40, a transparency can reproduce the actual contrast range of the subject which may be considerably more than 1 : 200.

The result is that a lantern slide or film transparency in black-and-white or colour can give a more faithful rendering of the tones and modelling of the subject, and this is the favourite method of presentation among serious workers. Slides and transparencies are popular in camera clubs and societies because, in addition to their superior tones, they are more convenient for viewing by a number of people. Most competitions include classes for slides.

The term transparency is also a measure of the light passed by a transparent or translucent medium. When light rays enter a material and are partly absorbed, the proportion of the original light that passes through unaffected is known as the transparency of the material. So transparency is a figure that may be anything between 0 and 1·0. The transparency

factor is the reciprocal of the transparency. Often the transparency is quoted as a percentage value (from 0 to 100 per cent) and called transmission.

CC-0. Agamnigro Digital Preservation Foundation, Chandigarh

If a material absorbs some of the white light but the light that gets through is still white, then the material is said to be non-selective. But if only certain wavelengths are absorbed so that what passes through is coloured light, then the material is said to be selective. The extent to which the material absorbs the visible wavelengths can be shown by an absorption curve, which is a graph of percentage transmission in relation to wavelength.

The absorption curve is typical of the material, and is in fact an accurate means of identifying it. The power of the absorption depends on the concentration of absorbing material and the thickness of the layer; as these increase, the colour deepens, becoming more saturated.

In photography, the density of the negative—i.e., transparency of the developed silver deposit—is expressed in terms of the logarithm of the transparency:

Density = − log transparency = log 1/transparency where transparency lies between 0 and 1·0. R.B.M.

See also: *Contrast; Projection practice; Projection principles; Slide (transparency); Transparency materials; Transparency viewing and projection.*

TRANSPARENCY MATERIALS. The sensitive emulsions used for transparency materials closely resemble those used for printing papers but they are coated on glass or film instead of paper.

There are three principal kinds of transparency materials:

(1) Lantern plates, which are positive emulsions on glass and used to make lantern slides.

(2) Transparency film, which is a positive emulsion coated on a film base. (The positives must be bound between glass to make slides.)

(3) Positive cine film, which is perforated 35 mm. film used for making film strips.

Lantern Plates. There are three main types of lantern plate: chloride, bromide, and chlorobromide.

Chloride lantern plates are used for making ordinary contact prints from negatives. Chloride lantern plates are coated with the same type of emulsion as contact paper. They give black to blue-black images on normal development for ¾–1 minute in a metol-hydroquinone developer at 65–68° F. (18–20° C.). Like contact paper, they can be handled in subdued artificial light or by a yellow safelight.

Bromide lantern plates correspond to bromide development and are used for projection printing in the enlarger. Their sensitivity is much higher than that of chloride contact plates, and they must be handled by an orange safelight. They give black tones on normal development for 2–2½ minutes at 65–68° F. (18–20° C.) in metol-hydroquinone.

Chlorobromide lantern plates correspond to chlorobromide development papers. They give warm black to reddish brown image tones on prolonged development in dilute and heavily restrained warm-tone developers. They must be handled by a suitable orange safelight.

Transparency Films. Sheet film base, coated on one or both sides with a contact or bromide paper emulsion, is manufactured for making positive transparencies instead of prints. Such films have sensitivity and development characteristics equivalent to those of ordinary bromide or contact paper.

These transparency films are useful, not only for projection, but also in large sizes for direct viewing in suitable illuminated viewing cabinets.

Ordinary non-colour-sensitive negative flat or sheet films may also be used for making positive film transparencies from negatives by either contact or projection.

Positive Cine Film. Film strips are made by contact printing or enlarging the negative on to positive cine film. Positive cine film used for this is a fairly slow non-colour-sensitive silver bromide emulsion coated on perforated 35 mm. film stock.

In its sensitivity and other characteristics 35 mm. positive film is similar to bromide paper.

Colour Films. Many colour materials yield transparencies by direct reversal processing. Certain makes of colour film are also available in the form of positive film for making colour transparencies from colour negatives.

Contrast Grades. Most lantern plates and some positive films are made in several contrast grades to provide for negatives of varying contrast. The range is, however, much more limited than with printing papers, because the contrast of a transparency can be controlled during development in a way that is not possible with printing papers. Where there is only one grade manufactured it is usually contrasty.

Physical Characteristics. The surface of a transparency is always perfectly smooth and flat. Transparency materials are hardly ever made with a base tint. The finished transparency can, however, be tinted afterwards.

The thickness of the glass used for lantern plates depends on their size. Miniature (2 × 2 ins.) lantern plates are usually 0·03 ins. (0·75 mm.) thick and standard (3¼ × 3¼ ins.) plates about 0·043 ins. (1·1 mm.). Stereo lantern plates are available in both thicknesses.

Transparency or positive cine film is coated either on nitrate base 0·003 in. (0·08 mm.) thick, or on acetate safety base 0·005 in. (0·12 mm.) thick.

Manipulation. Lantern slides and film strip material need greater care in handling and processing than paper prints, as the emulsion is more easily damaged, especially when it is

wet. In particular, the temperature of all solutions must be the same or the emulsion may frill and leave the support in places (mostly with plates) or it may reticulate. L.A.M.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Books: *Colour Book of Photography*, by L. Lorelle (London); *Colour Transparencies*, by C. L. Thomson (London); *Making Lantern Slides and Filmstrips*, by C. D. Milner (London).

TRANSPARENCY VIEWER. Various types of viewer are sold for looking at small transparencies without using a projector. There is usually some form of frame for holding the film and a simple optical magnifier through which the observer sees an enlarged image of the transparency.

Some viewers are intended to be held up to the light, others have their own electric light source mounted behind the transparency and supplied from a battery or the mains.

See also: *Viewers.*

TRANSPOSING FRAME. Frame for printing stereoscopic negative pairs. If the negatives made in a twin-lens stereo camera are printed normally and the prints are looked at in a viewer each eye sees the picture that ought to be seen by the other i.e. the effect is a pseudoscopic one, with the space relationships apparently inverted.

This is because the negative images are both reversed and laterally transposed in the camera. The image reversal is restored by the normal printing process, but the lateral transposition remains. For this reason, the printing frame is made so that the negative can be moved to print the right hand image on the left hand print and vice versa.

See also: *Stereoscopic photography.*

TRAUBE, ARTHUR, 1878–1948. German photographic chemist and inventor. Worked in Berlin with Miethe on colour photography and found in 1902 that ethyl red, the first of the isocyanine series of sensitizing dyestuffs, was an orange-red sensitizer (used in 1904 for the panchromatic Perutz Perchromo plate). Also worked on mordanting dye images (Diachrome, patented 1906), invented in 1916 the Uvachrome three-colour transparency process, and in 1925 the Uvatype colour paper print process. Also developed in 1905 (with A. Tellkampf) the Fotoldruck, a blueprint hectograph process.

See also: *Uvachrom.*

TRAVEL PHOTOGRAPHY

Any kind of pleasure or holiday trip, whether at home or abroad, presents excellent opportunities for photography.

The sort of holiday, the method of travel, and the photographer's interests all affect the photographic results, and some advance planning is always advisable whether for the nearest seaside resort or the next continent.

Equipment. Amateur photographers, at least, are apt to carry large quantities of equipment which they never find time or the need to use.

Basically, only a camera and film are necessary for taking photographs. Since, however, the object will be to produce the best possible photographs, it is as well to include an exposure meter, a lens hood and, for protection, an ever-ready camera case. A lens cap adds nothing to weight or bulk and keeps the lens cleaner even inside the ever-ready case which, if velvet-lined, seems to attract dust, sand, fluff and other unwanted foreign matter.

For hikers, cyclists, campers, climbers, and all who have to keep baggage to a minimum—this list represents the photographic minimum.

For motorists, coach tourists, hotel and guest-house residents, more equipment may be comfortably included but even they need not go beyond a couple of filters and a lightweight tripod. The latter is better than a camera-clamp because there is not always a suitable feature situated where the camera might be placed. It is better to be occasionally inconvenienced by an accessory that is usable when needed, than have one that is easy to carry but may turn out to be useless. A light yellow and a deep yellow or green filter should be enough, although in mountain and seaside territories it is advisable to take an ultra-violet-absorbing (UV) filter.

What camera to take is no problem. The camera to be taken on any holiday trip is the one that is completely familiar. The make, type and size matter little in comparison with ease and certainty of operation. Every traveller should carry his own favourite instrument, whatever the size—so long as he can be sure that negative material will be readily obtainable for it.

Holidays and journeys are no occasions for trying out a new camera. Nor is it wise to use a borrowed camera; unless it is one that has been borrowed so often before that all its idiosyncrasies are known.

Much the same applies to accessories. Nothing new or untried should be taken. An incorrect lens hood can cut corners off irreplaceable negatives; unfamiliar filters can produce unexpected effects.

Whilst the majority of people have only one camera and use the two types of material turn and turn about, others carry two cameras, one for colour and the other for black-and-white pictures, which is the ideal method. Accessories and film for both instruments add

to the baggage but the gain in scope is well worth it.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

On a holiday in Britain it is rarely necessary to carry films for the entire trip, as few places are so remote and off-the-track to be ever out of stock of the popular makes, at least. For a foreign trip, however, the only way to be really sure is to take a stock of negative material. Films are undoubtedly as plentiful in continental shops to-day as they are in British shops but it is usually unfamiliar makes that are most freely obtainable, and these are the ones to be avoided. Developing unknown makes of film which are not named in any time-and-temperature tables is an undesirable end to a holiday.

There is a further objection to buying films away from home. Some manufacturers have factories in different parts of the world, each manufacturing the materials under the same brand name. While in theory these materials may have identical characteristics, in practice they may vary widely. The photographer who buys his favourite brand of film in a foreign country may find that it is anything but the same when he comes to use it.

Customs. Foreign holidays involve Customs formalities; and photographic equipment and materials are generally of special interest to Customs authorities everywhere. Unfortunately for the holidaying photographer no two countries appear to see eye to eye on what is and what is not permissible, and Customs departments seldom provide detailed statements of their policy to help the wandering cameraman.

Very broadly speaking, no trouble need be expected if equipment has been honestly come by and if holiday intentions are equally honest. The British Customs are concerned only to see that nothing is illegally imported and that all necessary dues are paid on incoming goods, if they have not already been paid. Many holidaymakers pass unquestioned through the British Customs on leaving the country and on re-entry; others may be examined once; and some twice. The safest and easiest thing is to carry the receipted dealer's invoice as proof of purchase of each camera carried, and to include with this any Customs slips available.

Most countries have rules about the number of cameras allowed per individual, and many countries restrict the quantity of unexposed films. Two cameras, sometimes three, may be taken into and brought out of the majority of European countries. The rules about unexposed films are not rigidly enforced and it is possible to carry a good supply even though the regulations may permit only two or three.

Customs rules and regulations vary from one country to another so it is useful to know that European countries often have consulates in the larger cities in Britain where guidance on the subject can be had from the consular staff of the country to be visited. Travel agents can sometimes supply reliable information, and can in any case provide the addresses of the English offices of all national tourist bureaux operated by foreign countries for the convenience of tourists.

It is always wise to find out in advance the regulations of the country to be visited because the British Customs authorities are only concerned with what may be taken into Britain and not with what happens at the other side.

Technique. Continental holidays in summertime frequently present the British photographer with conditions that he never encounters at home. Intense sunshine, clear atmosphere, white and light-coloured buildings, all present a brilliant picture to the eye. But in the dazzling scene, in spite of the high reading of the exposure meter, are sure to be found some very dark shadows. Such high-contrast subject-matter calls for care both in exposure and development.

Since meter-readings often appear extravagantly high, by English standards, there is a strong temptation to use slow-speed films, yet these have more inherent contrast than the faster emulsions. The latter, being softer, are more suitable for the conditions, and when handled correctly can be expected to give a more workable negative.

It is helpful to develop a film early in the holiday so that the result can be used as a guide to later work. If this plan is to be a success the test film must be processed with the same developer and under the same conditions normally used at home. This means that developing materials and equipment—chemicals, tank and thermometer—must be carried, thus increasing the amount of luggage. And unless a changing-bag is also taken the tank must be loaded under the bedclothes or in the hotel wardrobe or in some such uncertain manner. If really serious work is intended it is certainly wise to pack a changing bag.

Another scheme is to have an early film trade processed, but unless the developing data can be ascertained this course only indicates in a general way how the exposures are faring. If possible, the photographer should try to find a dealer who operates an individual processing service.

Subjects. A holiday trip, especially one abroad, is a source of considerable joy and every chance of recording it for re-enjoyment afterwards should be taken without hesitation. Places are being seen which will probably never be visited again. Any picture—even if it may not be a salon print—is better than none.

It is as well to remember however that in all countries, including Great Britain, there are certain subjects that may not be photographed without permission—e.g., inside many museums, public and private buildings, and churches. Some authorities forbid photography; others allow it by special permission only; still others permit it on payment of a fee, usually small, which goes towards upkeep.

The places for photography are limitless: landscapes, seascapes, street scenes, zoo pictures, beach scenes, all these and countless others by day and by night will offer themselves to the travelling camera enthusiast.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Foreign holidays especially offer vast scope for human-interest photographs. Strange people in exotic settings are irresistible to all photographers, from the casual snapshotter to the ardent exhibition worker.

There are many ways of taking characteristic photographs of people abroad. If a good candid picture cannot be obtained unobtrusively the subject will often agree to pose; this assumes that the photographer has enough knowledge of the language to explain what he is about and to arrange an appropriate pose which gives the subject something to do and prevents self-consciousness and embarrassment. Unposed shots are very much easier to take with the co-operation of a friend or two, to act as a shield. (In taking quick shots of this type the background should be watched carefully because such pictures are often ruined by unsightly objects beyond the subject but in the field of view of the lens.)

People are waiting to be photographed everywhere: in streets and cafés, on river banks and quay sides, at markets and shopping-centres, in parks and gardens, at bus stops and railway stations. But many of them are photographically uninteresting. It is a waste of time to search for the interesting types; the best plan is to be alert and ready to shoot quickly when the right characters appear—as they generally do when they are least expected. The very young and the very old make especially good unposed studies.

Pictures en Route. Rewarding photographs can be taken en route to and from the destination, as well as on excursions made during the holiday.

It is possible to get good pictures from almost every form of transport. Normally airlines do not object and air-to-ground shots are fairly straightforward providing the camera is held just away from the window surface and a fast shutter speed (say 1/250 second) is given. If the traveller has the choice he should select a seat ahead of the wings, where the heat trail from the engine exhausts would not interfere with the negative sharpness. In aircraft having engines mounted at the rear, any seat is satisfactory.

Pictures from fast-moving trains are best taken through an open window whilst standing in the corridor away from the wheels—i.e., midway between the bogies. A shutter speed of 1/250 or 1/500 second is sufficient to ensure a sharp negative when shooting diagonally at an approaching or receding scene. Only the feet should be in contact with the train; the body should be held away from the window-frame and allowed to sway with the motion, arms in to the side and camera at eye-level. Pictures taken from moving trains cannot be composed. They are not seen until a split second before exposure, and a split second later they are gone for ever. The only satisfactory method is to look ahead for likely villages, churches, tree groupings, waterfalls, which will form a centre of interest and to have the camera ready to shoot in an instant. The photographer must simply hope that telegraph poles, embankments, walls, trees, signal boxes, and other obstructions will not spring up to spoil the view just as the shutter is being released.

Shooting from a stationary train is simple and scenes taken in foreign stations can be extremely interesting and sometimes even picturesque. Railway stations abroad are usually bright and airy places, often decorated with flowers; and teeming with character studies ready to be taken easily from the unseen vantage point of the train window.

Taking pictures on board ship, even during a none too smooth crossing, is again a question of using a fairly fast shutter speed and letting the body go with the ship's movement. Shipboard scenes, during embarkation and disembarkation particularly, are a satisfying—and essential—part of any overseas holiday record.

Coaches and motor buses have the drawbacks of more pronounced vibration and less room to manœuvre, but open windows and sliding roofs help; and at stopping places the raised viewpoint is of much use in picturing village scenes, wayside inns and bystanders.

Perfect negatives are easy to take during rides on the funicular railways, and also cable-cars, which take tourists up mountains. From this type of transport, cameras without fast shutters are just as capable of producing good results, as the cars operate in a very steady and slow manner.

Stowing the Camera. If the photographer is a passenger—e.g., by boat, train or motor car—and there are likely to be pictures about on the journey, he can carry his camera at the ready in the normal way. But the driver of a car or motor-cycle and the cyclist will have to stow the instrument somewhere on the vehicle.

In a car, the ideal place for the camera is in a hold-all case on the back seat. The worst place is in the cubby hole at the side of the dashboard where it gets all the vibration and heat from the engine, and is always in danger of being pulled out on to the floor when someone is hunting for a map or a packet of cigarettes. Some cars have a net for small packages stretched across under the roof. This is an excellent place for a small camera, but it should not be left there while the car is parked under a direct hot sun for any length of time.

Cyclists and motor-cyclists are best advised to carry their cameras slung over one shoulder under the jacket or overcoat. There is no place on the machine where it will be as well pro-

tected from rain and vibration. The cyclist can always strap a light tripod along the cross bar of the machine but the motor-cyclist will have to sling it across his back or invest in one of the small pocket-size folding types.

When the camera is packed in a suitcase, the best place is in the centre or near the handle. It should be packed last, and on top of soft clothing. Finally it should be covered with a book or map to protect it from damage through the case.

Precautions. Costly equipment can be safeguarded by insurance for a comparatively small sum, and the surprising thing is that more photographers do not take out a policy. At holiday-time the camera is in use or being carried about for many hours every day, and the risk of loss or damage is obviously greater. The risk can be minimized by a number of commonsense precautions. If cameras have to be packed away they should be placed in a well-protected position in the suitcase or rucksack, where they are still reasonably accessible. On the other hand, if the camera will be carried constantly it will be safer if the strap is kept fairly short so that the camera cannot swing far away from the body.

A foolproof way of carrying the camera is to sling it over one shoulder before putting on the jacket. Once the jacket is on, it is physically impossible for the strap to slip off the shoulder, or for the camera to swing about. At the same time the arrangement offers no hindrance to quick and efficient operation as the case is easily pulled up and forward to the taking position. This idea also makes it impossible for the camera to be left behind anywhere or for it to be left unattended.

When all is said and done most of the information about travel photography boils down to applying common sense, standard routine with slight adaptation, and good manners.

There are certain countries abroad where a stranger carrying a camera is regarded with suspicion, and others where a foreigner is not allowed to take photographs without a special permit. In such places it is foolhardy to attempt to take pictures by stealth—the photographer who is caught at it runs the risk of losing his equipment permanently and his freedom at least for a time. To a camera journalist after a scoop, the risk might be justified; for the ordinary tourist it can never be worth while. The same thing applies to attempts to photograph people—or personalities—who are known to be hostile to photographers. Here the photographer runs the two-fold risk of damage to his equipment and his person. A.H.

TREES. Trees offer unlimited scope to the pictorialist, not only as part of a landscape but as studies in themselves. To be successful, tree photography calls for the ability to make a suitable choice of type or species of tree, lighting, setting, and treatment.

Apart from their intrinsic beauty trees are useful in landscape composition. The foreground use of branches (with or without the trunk) will often mask a bald sky, and will also assist in preserving the impression of space by throwing back a distant hill outline, a valley seen from a ridge, or other open landscape.

A single tree, or group of trees, stunted or weird in shape, will often convey the character or mood of a particular place, as, for example, along the Atlantic coast of Britain, where the south-west wind bends the trees inland at an acute angle, causing the branches all to grow in the one direction.

Type of Tree. Because the composition relies chiefly on balancing masses, the shape of the tree and the distribution of its branches are important. Spreading trees like cedar, oak and chestnut lend themselves to horizontal picture shapes, whilst tall elms, poplars, etc., need the upright format.

The base of the tree is always included in the picture, otherwise the result looks unnatural and top-heavy. Any branches that project towards the camera must be in focus as well as the main trunk, so the taking distance and aperture must be chosen to provide the necessary extra depth of field. Ugly limbs and foliage-shapes are avoided as far as possible by experimenting with different viewpoints.

Lighting. Frontal or flat lighting is rarely used because a tree is a round object and must have modelling. This point is not as serious in mist or fog, where the separation of the picture into planes is more important. Low-angle lighting with its long shadows gives a much more pleasing effect than overhead lighting, and for this reason the best tree pictures are unlikely to be made during June, July and August, between the hours of 11 a.m. and 3 p.m., when the sun is high in the sky.

Backlighting is seldom successful with sparse or small-leafed trees like ash and hawthorn, but it can be very effective with large-leafed trees like chestnut, sycamore, lime, etc. There is little to be said for photographing "open" or bare trees in backlighting conditions because the results are almost bound to be hard and spoiled by halation, caused by spreading of the light into the image of the branches.

Setting. The setting of the subject includes the sky behind it, the other trees around it and the physical features of the landscape. The greatest difficulty usually lies in isolating the one chosen tree or group of trees from its neighbours.

The photographer should always look beyond his subject to ensure that the background is

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

LIGHTING ON TREES. A tree can often be regarded as a sphere, and follows the same rules for the effect of light on modelling. Top left: *Back lighting tends to yield silhouettes.* Bottom left: *Side-rear light produces pronounced rim of light.* Bottom right: *Side lighting gives good modelling, and picks out the pattern of leaves.* Top right: *Front lighting is usually dull.*

free from unwanted objects like buildings, telegraph poles, etc., and he should move his viewpoint if necessary to get rid of them. He should also avoid mixing trees of various kinds; firs do not blend well with oaks, limes, etc., and tall trees should not be surrounded by low, scrubby specimens. The sky generally makes the best background, provided that the area is interesting and not simply blank white paper.

Treatment. Unless the camera is fitted with a rising front, trees will present the same sort of perspective problems as high buildings. If the photographer tries to include the whole of the subject from a close viewpoint, he is forced to tilt the camera up. But if he tilts the camera, the subject will look as though it is toppling backwards because its vertical lines will lean in towards the top.

The answer is to move away to a more distant viewpoint where the camera can be held level and still include the whole subject. This inevitably gives a top-heavy picture in which the lower half consists of empty foreground and all the subject matter is crowded into the top half. But the problem is easily solved by leaving out the unnecessary foreground when the negative is enlarged, or trimming it off the print.

The selected branch or group of branches should be focused sharply at a wide aperture to keep the background out of focus. A sky background of cloudless blue is often better than one covered with patchy cloud. A 3× yellow, or green filter with panchromatic film prevents the green foliage from being reproduced in unnaturally dark tones and gives depth to the blue sky.

A long focus lens is a great help in capturing detail in blossom, and avoids the distortion produced by using a short focus lens at close range.

Trees in Winter. Trees in winter generally call for semi-close or close-up viewpoints which stress the characteristic signs of the season—i.e., snow, rain or mist. Sunshine, no matter how feeble, is necessary for snow and rain effects and the feeling of mist is heightened when there are trees at varying distances from the camera to divide the picture into close, medium and distant planes.

Gaunt, angular trees against an angry sky convey a better impression of the mood of winter than trees with graceful flowing branches, even when they are laden with snow.

Trees in Spring. Spring studies call for close-up viewpoints to show the opening leaves, young buds and blossom. As in so many other branches of photography, the part is generally more effective than the whole.

Often a single branch or spray photographed with care so as to show plenty of crisp detail makes the best picture of all. This demands careful arrangement and viewpoint to make the branch fill the picture area in a pleasing fashion. Fairly strong, oblique daylight improves the rendering of detail and helps to keep exposures short. Shutter-speeds of 1/100 second or faster are usually required to counteract the movement of the branch in the wind.

Trees in Summer. During the summer months, trees are better handled in terms of their masses and shadow effects than as detailed studies. The full, dusty foliage and harsher lighting, characteristic of this season, make it the least interesting to the photographer.

Trees in Autumn. Autumn, on the other hand, with its varied tints and the sparser, lighter-toned foliage of the fall, offers splendid opportunities for photography in both colour and monochrome. Back lighting turns close and semi-close golden leaves into delightful picture material. An orange filter can be used to good effect in this type of picture as it lightens the golden tones.

Large-leafed trees generally provide the best pictures when they are photographed with the sun behind them in this way.

Woodlands. Woodland studies are more difficult, because of their extreme lighting contrasts. The very wide range of tones demands a fast, panchromatic film to give sufficient exposure in the deep shadows without "burning out" the highlights. Slower, more contrasty emulsions are quite unsuitable.

The photographer who is not prepared to

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

take extra trouble in processing to deal with the extreme contrasts of this type of scene should avoid the interior of the wood and make his pictures in clearings or on the outskirts of the wood.

Avenues of limes, elms, horse-chestnut, etc., make natural subjects at almost any time of the year.

Light patches between branch formations should be avoided as far as possible because they tend to irritate the eye.

Camera. Almost any camera can be used for making pictures of trees, but the photographer who wishes to specialize in it should invest in a half- or whole-plate field camera with all the usual camera movements and a selection of lenses of various focal lengths.

For this class of work, while the great depth of field of the miniature camera is an advantage, it lacks facilities for perspective correction and cannot give the crisp detail obtainable with the larger camera. P.J.

TRICHROME CARBRO PROCESS. Method of producing colour prints by the assembly, in register, of a set of three colour carbro images made from separation negatives.

See also: *Carbro colour prints.*

TRICKING THE SUBJECT. One of the difficulties of photographing living creatures, from human beings to insects, is to get the subject to pose for the camera in a natural manner. With human beings—and some animals—there is often the added difficulty of getting them into position and photographing them unawares. The photographer needs to know something about stage management, misdirection and psychology.

Animals. There are many standard tricks for shooting animals, birds and fish. Seagulls in flight, for example, can be enticed into position if a companion stands close to the photographer and throws some morsels of food at the right distance. Fish in an aquarium may be kept in the plane of focus with a sheet of plain glass slipped into the water behind them.

Bait is a great help when photographing birds, animals and insects at liberty. A few crumbs will soon entice all sorts of birds to the desired spot; a single flower that has no other of the same species nearby will attract butterflies, rotting meat similarly attracts flies and other insects. Birds of prey can be attracted by imitating an owl-call, and monkeys can be kept interested with a child's toy.

With dogs and cats there is usually some suitable line of approach suggested by the animal's habits or training. It is often easy to make a placid sleepy dog look bright and alert by rattling his lead or getting dressed as though off for a walk. A cat will generally respond to the clinking of a milk jug. All such stratagems shoutd be introduced immediately before making the exposure; the precious gleam of intelligence soon dulls if the promise remains unfulfilled.

Children. Small children that are too young to be self-conscious also react immediately to a new toy. They are so fascinated by it that they forget all about the photographer standing near by—though he must still make himself as unobtrusive as possible. When making pictures of children indoors it is important never to shine the lamps directly on them at the start. It is best to turn the reflectors away at first, then switch on and swing them carefully round towards the field of view. In this way the children will not be scared by the sudden glare.

Candid Shots. In candid photography there are several tricks that the photographer can employ to avoid drawing attention to himself or his camera. In cold weather the camera may be slung round the neck and concealed under an ample overcoat, worn unbuttoned. When the right moment comes the camera is ready to go into action. In warm weather it is better for the photographer to stroll around casually with his hands behind his back. No one will notice the camera he is holding. For this, however, he must learn to set the camera by feel alone. All adjustments must be made before the camera comes into action.

A right-angle viewfinder deceives the victim by leading him to believe that the photographer is aiming the camera at someone else.

The "swing-round" technique is an excellent method of securing candid shots where the camera cannot be used unobtrusively. Here the idea is to focus on an object at about the same distance from the camera as the intended victim but in a different direction—usually rather more than a right angle. The real subject is observed out of the corner of the eye and, at the last instant, the camera is swung round on to the target and the exposure made right away. Any start of surprise on the part of the subject usually occurs after the shutter has closed.

Portraiture. The following trick saves sensitive material often wasted when the photographic session has been pre-arranged. It is common experience that some time is needed for the model to overcome the initial self-consciousness.

The last exposures of a series are often the best, because by then the model is sufficiently relaxed and at ease and the feeling of stiffness has disappeared.

Why then waste film on the initial exposures? The trick here is not to make them at all, but simply to go through the motions without actually exposing any film. With a plate camera the dark slide can be left in position, and the sitter is led to think by the noise of the shutter that an exposure has been made.

Most photographers know that the sitter appreciates a certain amount of retouching on the portrait. But apart from normal retouching,

one useful trick is worth mentioning: deliberate elongation of the image. The procedure is the same as that used in correcting the distortion of converging verticals, but in this case the object is to make the subject look slimmer. The image is elongated in enlarging by tilting the baseboard. So long as the trick is not overdone, the result will please sitters who have begun to put on weight. O.R.C.

TRICKS AND EFFECTS

Tricks in photography may be executed for their own sake, or as a means to some more serious end. Even when making a photograph by normal procedure, there are occasions when trick methods save time and give a better result.

There are hundreds of situations and subjects where tricks can be used to advantage—e.g., to achieve some special effect or to overcome limitations and shortcomings inherent in the photographic process. In most cases the tricks are simply a matter of applying an established process or technique in an unorthodox manner.

There is scope for tricks at each stage of the photographic process.

OPTICAL TRICKS

Many kinds of trick photography rely on purely optical methods. Generally this is merely a question of using normal equipment in an unorthodox fashion. Once the photographer understands the basic principles the number of tricks he can perform will depend more upon his imagination than his equipment.

Tricks with Lenses. The use of a lens of longer or shorter focal length than normal is not a trick, because these are regular accessories. It is a trick only when some unorthodox optical equipment is used.

A telescope is an example of unorthodox equipment; fitted in front of the camera lens it brings distant objects nearer. There are only two things to watch: the telescope must be rigidly supported, and the coupling between it and the camera lens must be made light-tight—e.g., with electrician's insulating tape. The discrepancy between the small-diameter eyepiece of the telescope and the camera lens is overcome by stopping the camera lens down to *f* 8 or *f* 11.

The resulting photographs resemble genuine long-distance photographs. The slight unsharpness at the edges is in many cases hardly noticeable. One element of a pair of binoculars may be used in the same way as a telescope.

Telescopes and binoculars increase the focal length; the simplest method of shortening it is with a single spectacle lens as used for long-sight. (All supplementary front lenses are fundamentally spectacle lenses of different diopter value: the higher the number, the shorter the focal length.) As all such glasses reduce the optical precision of the camera lens, the latter should be stopped down to *f* 8.

Spectacle lenses may also be used in place of the camera lens. When used in this way as a principal lens they produce a special effect. Being uncorrected, they suffer from all the aberrations. The faults combine to give soft focus.

Ordinary spectacle glasses of from +3 to +6 diopters may be used (concave side out) either to obtain soft outlines, for example to conceal facial wrinkles in a portrait, or to handle an extreme contrast range when absolute sharpness is not essential. The softened focus and lowered contrast are, however, only produced if the lens is not stopped down.

Instead of substituting a spectacle lens for the camera objective, a diffusing disc may be placed in front of the camera lens. This is a piece of glass engraved with a fine texture pattern and used like a filter. It produces very much the same effect as a simple spectacle lens, provided the camera lens is used at or near full aperture.

If the texture pattern engraved in the glass is coarse instead of fine, there is no soft focus effect but instead a multiplication of the image. Thus glasses ground in pyramid form with three, four or more "steps" produce a similar number of symmetrical, overlapping images. (This trick is often used in motion pictures.)

Tricks with Mirrors. A mirror, too, can be made to give multiple images. If an object is placed on a mirror, a double image is formed, the upright image being laterally correct, while the reflected image will appear upside down and laterally reversed. The images form a symmetrical pattern.

If the edge of a mirror is placed against a page of a newspaper, the text appears printed backwards in the mirror. If two mirrors are stood vertically on a newspaper with their reflecting surfaces at an angle of 60°, the newspaper text will be seen multiplied six times.

Every change in the angle between the mirrors will produce a further range of image multiplication.

Curved mirrors make a variety of other effects possible. A cylindrical mirror shortens the image when placed flat and lengthens it when stood up vertically. But it is necessary to focus on the reflection, not the subject. This applies equally whether curved, cylindrical or spherical mirrors are used. If a new silver spoon is held in front of the camera lens and the reflection in it of the surroundings photographed, this will at once show how it is done.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

With this type of photograph, the photographer and his camera will appear in the picture unless special precautions are taken. One way is to turn the reflecting surface towards a plain wall, and set the camera up to the side. The resulting image is then no longer rectangular, but the reflecting surface is blank and the distortion of the mirror frame can easily be corrected when enlarging the negative.

Tricks with Distorting Glasses. All tricks where uneven-surfaced glass plates are interposed between subject and camera can also be classified as optical.

Certain types of ornamental and window glass are designed to give privacy by breaking up images seen through them by a pattern embossed in the glass. Distorting glass of this kind can be used to produce a number of novel effects by taking photographs through it. The effect on the image varies according to the distance between the glass, the camera and the subject.

Tricks with the Enlarger. Some control methods used in enlarging can also be classified as optical tricks.

First there is the soft focus effect, designed to reduce the contrast of an excessively hard negative and conceal obtrusive detail. Instead of placing a soft focus attachment in front of the lens, all that is needed is a sheet of glass rubbed with a smear of vaseline. This, of course, spreads the shadows into the highlights of the picture whereas a soft focus disc or lens used in the camera spreads the highlights into the shadows.

The technique used for correcting converging verticals in the enlarger may be used to bring about deliberate distortion. Distorted lines in the negative are squared up by inclining the baseboard. In the same way all kinds of distortion can be introduced by inclining the baseboard in various directions. A similar class of distortion can be produced by bending the bromide paper into concave or convex shapes and holding it there with pins or tape during the enlarging exposure.

In this way the image may be elongated so as to give an outsize lady a sylph-like figure; or to make a sitter's face look broad or narrow.

IMAGE DISTORTION. Bending the paper under the enlarger distorts the image. Portions farther from lens need extra exposure, also small stop to ensure sufficient depth of focus.

CHEMICAL TRICKS

Trick photographic effects produced by chemical methods usually involve a departure from normal working procedure, often the deliberate production of well-known faults. As chemical manufacturers are at pains to render their products foolproof, such faults are today often hard to induce.

Tricks During Development. If a white or unsafe light is switched on during development, the upper layer of silver already darkened by the developer acts like a negative at the printing stage and masks the light off from the layer underneath which has remained unaffected. At the same time, the clear, unexposed emulsion is exposed, and is darkened by the developer. So a negative and a positive image are formed in the same emulsion, one beside the other. The potassium bromide that is normally formed during development collects along the borders of the image where chemical activity is smallest. Being a restrainer it prevents further darkening there and creates a transparent line in the negative which shows in the print as a dark line around the edge of the positive image. This effect, which resembles a line drawing, is much used as a stunt in modern photography. It is known as the Sabattier effect.

Deliberate alteration of development time can also produce a trick effect. If development is unduly prolonged, it produces an excessively hard negative. From this negative both soft and hard transparencies may be printed on positive film. When separate negatives made from these positives are enlarged in register, the result is a positive with a particularly rich scale of tones, giving a distinctly plastic effect.

Tricks in the Fixer. If the temperature of the fixing bath is raised to 86°–96° F. (30°–35° C.), the emulsion curls up and breaks the picture up into an irregular network of lines like those of a miniature jigsaw puzzle. A wrinkled pattern is thus superimposed on the normal rendering of the subject, giving it a novel texture that can be most effective under certain conditions—e.g., to imitate the brush work of an oil painting.

While the emulsion is still wet and swollen from the final rinse, it will soften and melt if exposed to heat. Here is the basis of a number of photographic tricks. A variety of grotesque distortions may be produced by holding wet plates over a spirit lamp flame (films should be held over an electric cooker or radiator) until the emulsion melts. By tilting the plate one way or another the emulsion can be made to run in any direction. When it cools, it sets permanently in the desired shape.

The normal method of reducing a dense negative is to place it in Farmer's reducer. But the action of the reducer may also be confined to selected parts of the negative by applying it with a brush or a wad of cotton wool. If

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

MELTING EMULSION. This produces distorted images of irregular shape. 1. Soak the negative (must be a plate, not film) in water for 10 minutes. 2. Leave to drain thoroughly. 3. Carefully heat glass side over a spirit burner; when the emulsion starts to melt, tilt the plate to and fro to get the molten emulsion to run in any desired direction.

necessary, the whole of the background or foreground may be removed. This method is one way of making a montage. Or the background may be removed from one negative and the foreground from another, the two negatives being then superimposed and a composite print or enlargement made.

MECHANICAL TRICKS

Mechanical trick effects on the negative are limited to physical alteration of the emulsion surface. Dense areas of the emulsion may either be lightened by rubbing with silver polishing powder (containing oil) or scraped away altogether with a retouching knife. The latter method is used for putting a black border around the picture. To do this the knife is drawn along the edge of a steel ruler until a clear even line has been scraped in the emulsion.

Mechanical treatment of positives covers both cut and paste montage and all methods involving pencil and brushwork.

Cut and Paste Montage. Normal cut and paste montage is the simplest of these methods. Two prints of similar gradation and surface are cut up with the scissors along a particular outline, then pasted together to form a new picture. After copying, any number of prints may be made from the negative. To prevent the cut edges from showing, all prints should be on single weight paper and cut with sharp scissors or a safety razor blade. The cut edges should be dyed or painted black, grey, or left white to match the adjacent print area. O.R.C.

Picture Patterns. Making a pattern from a mosaic of photographs is a good variation of normal cut and paste montage. Very simply the trick is to combine sixteen prints—eight printed the right way round, and eight reversed—to produce a repeating pattern.

The most suitable type of photograph is one with strong geometrical shapes. If the original print consists mainly of flat tones then the finished mosaic will lack interest.

The prints should be about quarter-plate size, otherwise the finished mosaic may be too large. When selecting the composition, an L-shaped piece of card as normally used for composing is required; also a pair of hand-mirrors. Two sides of the print are selected by the piece of card, and the other two sides selected by the mirrors. In this way a combination of four prints can be visualized, two the right way round and two in reverse. In this way it is possible to get an idea of the final effect.

All sixteen prints must be in good register. To ensure this, when making the viewing print, a reversed print of exactly the same size is made. The negative in its carrier must also lie in exactly the same plane for both prints. When the portion of the print has been marked up, the two prints should be placed back to back, registered by viewing them against a strong light, bound together with adhesive tape and trimmed to the marked up area. The reversed print will then have the same area.

Before making the first run of prints, the area of the projected negative is masked according to the viewing print. The exposures should be accurately timed by a clock, and developed to strict time and temperature. A guide print is first made to get the exposure right and then the first batch of prints (ten prints, eight for use and two spares) are given the same exposure. The whole batch are processed by placing them in the developer at 5-second intervals. When the first print has been developed all the subsequent prints are removed after the same intervals. All prints will then be of exactly the same tone. Having made the first batch of prints, the negative is reversed in the enlarger and masked according to the reversed guide print to make the second batch.

The prints can then be trimmed and mounted accurately on card with rubber solution and the joins touched out. L.S.

Drawings from Prints. Most paper surfaces can be worked over with pen and waterproof indian ink, so a light toned enlargement may be transformed into a line drawing by inking it in with the pen, and then placing the print in a strong solution of Farmer's reducer. This bleaches out all photographic detail and leaves only the hand work.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

DRAWING IN THE ENLARGER. This requires no sensitive materials. 1. Project the negative on to a sheet of suitable drawing paper. 2. Shade in the light parts of the projected image with a pencil, gradually working over the picture until the paper is uniform in tone while the image is superimposed on it. 3. Switching off the enlarger reveals a positive pencil image.

Direct Pencil Drawings. Pencil drawings, unlike pen drawings, contain middle tones, but they may be made from photographs by the following method. The negative is placed in an enlarger and focused on a sheet of drawing paper. The bright parts of the enlarged image are then shaded in with the pencil until the image projected on the paper looks a uniform grey all over. When the paper is examined in ordinary light a positive "print" will be found on it. It will be rough or delicate according to the draughtsman's skill, and will display all the characteristics of a genuine pencil sketch.

Endless photographic tricks can be evolved by the imaginative use of such mechanical treatment as retouching and titling.

EXPOSURE TRICKS

Many photographic trick effects are possible at the exposure stage by deliberately disregarding the normal rules.

Long Exposures. Instead of taking an action shot at a shutter speed short enough to arrest the motion, a long exposure may be given. When this is done, highlights become comet-tails that follow the path of the moving object. The more the exposure exceeds the normal minimum the longer the tails will be. Such pictures, though themselves static, convey an unusual impression of movement.

For example: the permissible shutter speed for a man doing a knees-bend would be about 1/50 second. If (after stopping down the lens accordingly) an exposure of 1 second is given, the negative will suggest the whole of the action even though the man performing it will only be seen as an unrecognizable blur. And the work gains a new significance. Instead of being, say, "Father doing a knees-bend", it achieves the status of a study, "Knees-bend by an unknown performer".

Movement offers unlimited scope for trick effects. If, for instance, a small pocket torch is fastened to one hand of an orchestral conductor and a sufficiently long exposure given in a dimly lighted music room, all the conductor's movements will be visible on the negative as a sharp line of light on the dark background and the ghostly orchestra. The photograph no longer shows a particular instant but all the rhythm of a complete cycle.

Records of inanimate objects in continuous motion open up another field of possibilities.

A pendulum, for instance, may be made to swing in an elliptical or circular path, or have its motion interrupted or broken by some obstacle. Its movement will gradually become less and less until it is stationary. An interesting photographic trace of its movements can be made in some such way as the following. A pocket torch is placed in a tin with a small hole in it so that the beam can be seen through the hole. The tin is then suspended from the ceiling by a cord about five feet long. This pendulum is started on any desired pattern of motion in the darkroom and the camera shutter is left open to record the ever decreasing track of the light. A print from the negative will have the appearance of a delicately drawn pattern executed with absolute geometrical precision.

Stars also are moving points of light in the dark sky. An exposure of several hours will record the movement in the same way. After dark the camera is placed on a tripod and aimed northwards towards the pole star. According to the length of the exposure ($\frac{1}{2}$ to 5 hours) the stars will trace their own orbits around the pole as a pattern of arcs of light.

The trick of giving a too-long exposure comes in useful when, for instance, a realistic rendering of running water is required. If a very short exposure is used to photograph a waterfall, the water looks dead and frozen. Longer exposures of the order of 1/5 and 1/10 second produce blur and impart a sense of movement to the whole mass of water.

Photographing a lightning flash calls for more exposure trickery. The camera is directed towards the approaching storm front at night and the shutter is opened after the first flash, as experience shows that a second flash is certain to follow a few seconds afterwards. A succession of flashes may be recorded one after another on the negative if the shutter is left open sufficiently long.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Multiple Exposure. But very long exposures can also be used to eliminate moving objects. The trick can be exploited, for instance, to photograph a busy street as though it were empty. An instantaneous exposure of about 1/100 second would show the traffic clearly. But if, instead of a single exposure of 1/100 second, ten exposures of 1/1,000 second each are made on the same plate, allowing some time to elapse between exposures, the moving objects are recorded so indistinctly at each exposure that the resulting image is overlaid and eliminated by the other nine exposures. The result is a street that appears to be entirely empty of all traffic.

There is another way of using multiple exposure to eliminate moving objects. In night photography out of doors, motor car headlamps appear as lines of light running across the picture. The remedy is to hold a hat in front of the lens whenever a car or other illuminated vehicle passes across the field of vision.

Multiple exposure technique is another way of assembling a photo-montage. Several different subjects may be exposed on the same plate with or without a mask to fill the picture space with either normal images or "ghosts".

Double Exposure Tricks. A number of double exposure tricks are possible with any camera not fitted with a double exposure lock.

The simplest trick of this type is to show a person and his "double" on one plate, against a black background. The same person is placed first on the left of the picture area and one exposure made, then on the right for the second exposure without moving the camera. Trick photographs of this kind (which may even consist of more than two exposures) can show the same person playing cards with himself, drinking his own health, etc.

Ghost photographs can also be made by double exposure. The ghostly outline of the "apparition" is left by the image of a sitter who is present in the scene for the first half of the exposure but absent when the shutter is opened on the same scene the second time.

If persons are to be photographed with their "doubles", the unoccupied half of the set must be masked off each time with a piece of black paper held in front of the lens hood. Otherwise the images will appear as transparent ghosts against the background.

Double exposure is frequently used in advertising and instructional pictures—e.g., a portable typewriter may be photographed so that both the machine with the keyboard, and the cover are visible. Double exposure (once with and once without the cover) produces a "phantom" picture in which the details show through the lid as though it were transparent.

DOUBLES. This requires a matte box or at least a deep lens hood capable of covering up either half of the field of view with masks. 1. Make first exposure of subject with mask covering half of the view. 2. Change mask over to cover other half of view, and also switch round subject. 3. Result shows subject twice, e.g., conversing with himself.

LIGHTING TRICKS

The subject lighting is perhaps the most versatile tool available for trick effects in photography.

Special Light Sources. A simple but powerful concentrated light source for trick effects consists of a hollow glass globe filled with water. When this is placed in a beam of light from an ordinary lamp or spotlight it throws a bright patch of light over a short distance and objects in its path cast a strong shadow. The same effect is produced if a large hand magnifier is held in the path of the rays. The magnifier may be adjusted to any desired position by pushing the handle into a pot filled with sand. A concave shaving mirror may also be used to reflect light on to a small area. The light from the mirror is then brighter, and provides the main illumination, while the lamp itself provides a weaker beam that can serve as a fill-in light. Light may also be concentrated on a small area with a large sheet of tinfoil rolled into the shape of a cone and placed over the reflector. Beyond a certain point, concentrating the light on a smaller area by this means produces no appreciable increase in brightness.

Similar effects accompanied by still more marked shadow formations can be obtained from the light of a miniature slide projector. This type of projector can be used to provide additional lighting effects—e.g., if a piece of fine-mesh net is placed in the slide carrier, it will cast its pattern over the whole subject and make it look as if lit by sunlight shining into

the room through net curtains. Other slides may be inserted to cast a pattern of rings, lines, stars or any other design over the subject at will.

CC-0. Panjab University Digital Preservation Foundation, Chandigarh

Projected Backgrounds. Suitable transparencies may be projected on to a white surface behind the subject, to give the appearance of a natural background. But the relatively weak light from the projector calls for long exposures, and precludes the use of powerful foreground lighting, which would "kill" the background.

Foregrounds. The converse of the above method is foreground projection. A translucent white material such as tulle is stretched over a large frame. The model sits behind it, and behind the model is placed the lamp. The lamp is directed on to the tulle which shines brightly wherever the light strikes it, but remains dark and transparent in the shadow cast by the sitter. All background detail in the bright surround is thus lost, the only visible detail being within the shadow cast by the sitter.

Silhouettes. If opaque white material like linen is used, the same arrangement of material, subject and lighting produces a silhouette. If the sitter is placed immediately behind the screen with the light directly behind him the outlines will be sharp even with ordinary amateur lighting equipment.

Shadowless Lighting. The different lighting tricks described above are mostly intended to provide strong shadows and enhance the sense of depth. But there are occasions that call for flat, shadowless lighting. This can be arranged in several different ways. One way is to put a Photoflood bulb in a lamp socket in the ceiling without a reflector. If the walls are light coloured, its light will be diffused and while powerful enough for short exposures, it will cast no shadows. Photographs taken by such lighting have all the appearances of daylight exposures because the typical contrasts of artificial light are absent.

Such soft lighting is particularly suitable for family group photographs. For still life or other static subjects, a moving lamp is preferable. The lamp is held in the hand throughout the exposure and moved backwards and forwards in an arc, as if to fill in the details in the subject with the light. When photographing china and glass, this trick avoids the bright dots on the subject produced by the reflection of stationary lighting, and the highlights are suitably diffused.

This method of lighting will not serve for bright metal objects, as such surfaces reflect not only light and shade, but the surrounding objects, including the photographer and his camera. The surroundings must therefore be masked off altogether with a "tent". A suitable tent may be made from a cone of tracing paper placed over the subject like a roof. This diffuses the light falling on the subject. The lens is pointed through a small slit and apart from the neutral walls of the tent there is nothing to create reflections.

Shadowless lighting of small objects can be achieved as follows. The seat is removed from a chair and replaced by a sheet of glass. A piece of white cardboard is placed below it, resting across the legs at an angle of 45°, and turned so that it reflects light from the window on to the glass. The object to be photographed is placed on the glass with an empty lamp reflector inverted over it facing downwards. The camera lens is pointed down through the hole in the reflector to make the exposure. The light rays pass from the evenly illuminated cardboard to the inside of the reflector, which in its turn throws them back in a ring-shaped pattern on to the object in the middle. The result is that there are no shadows in the final picture.

An extreme example of shadowless illumination is provided when the object is immersed in a dish of water. This is naturally only possible with waterproof objects.

Photographing Light Sources. Double exposure is usually called for if the light source itself is to be part of the picture. A candle flame, for example, is relatively bright, but its illuminating power is very small, so a still life study by candle light, showing the candle flame itself, is a photographic impossibility. The brightness contrast between the flame and its surroundings is beyond the scope of the sensitive material.

COMBINATION PRINTING. Adding a moon to a night picture. 1. Photograph the moon only with a long focus lens, to obtain a moon negative of the right size and scale. 2. Superimpose the landscape and the moon negatives. 3. Place the sandwich in the negative carrier of the enlarger, and enlarge as one negative in the normal way.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

FAKING SNOW. 1. *Prepare a snow negative, either by spraying a glass plate with red ink, or by photographing salt sprinkled on to black velvet while moving the velvet slightly during exposure.* 2. *Combine the snow negative with a winter landscape (use a spacer between them in the case of the red ink plate).* 3. *Enlarge the two together like one negative.*

Some form of general illumination must be provided, though it must not be bright enough to destroy the atmosphere. The following method gives a natural effect. A preliminary exposure is made with the candle burning in a normally lit room. The candle is then extinguished and a second exposure made, three to five times as long as the first. In the resulting picture, the candle flame retains its typical appearance and the surrounding objects are adequately lighted.

The same trick of giving a short preliminary exposure for the light source followed by a second, longer exposure with the object extinguished, may also be used for photographing electric bulbs, gas flames and open fires.

TRICKS IN THE DARKROOM

There is more scope for photographic trickery in the darkroom than at any other stage of picture making. As with most other branches of trick photography, the effects are produced generally by applying orthodox techniques in an unorthodox manner.

Negative-Positive Combinations. If a particularly plastic rendering of an object is required, two exposures are made on separate negatives, the light being held to the left of the camera for the one and to the right for the other. A positive transparency is then prepared from one of the negatives. The positive transparency is then held in exact register with the other negative, emulsion to emulsion, the two are placed in the enlarger and printed. The dense highlights combine with the empty shadows to give an exaggerated impression of relief and modelling to the positive. (This process sounds very much more complicated than it really is.)

Two further tricks are possible when a positive transparency is made and bound up with its own negative. If the transparency is printed very slightly out of register with the negative, a photographic bas-relief is produced. When the two are in exact register, they combine to form a more or less neutral grey, but slight movement out of register brings out the light and dark edges that are characteristic of a bas-relief.

A number of fantastic and unreal effects can be produced by combinations of two identical negatives, or of one negative and a positive transparency. The effect varies according to the relative position of the two images.

Simultaneous enlargement from two different negatives produces two further useful effects:

Snowstorm Effects. A snowstorm is difficult to photograph; it is easy to print in afterwards. The snow negative is made by sprinkling some granulated sugar on a piece of black velvet. The camera is mounted above the velvet, lens pointing downwards, and a time exposure

PICTURES ON VASES AND TUMBLERS. Left: *For images etched or painted on to glass tumblers, wrap a sheet of bromide paper round the glass. Print the image directly on to the paper by means of a small torch bulb in the centre of the tumbler.* Right: *In the case of a pattern on an opaque vase, wrap the paper round, and illuminate from the back (i.e., a kind of reflex printing).*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

LUMINOUS PICTURES. 1. Coat a sheet of plain paper with luminous paint. 2. Expose for a few minutes under a negative in the enlarger. 3. Switch off the enlarger light, and a luminous image will be visible in the dark.

made. During the exposure the velvet is drawn diagonally across and out of the field of view. A print from this negative shows a mass of bright and slightly blurred lines looking exactly like snowflakes. When printed together with a negative of a landscape, the result looks as if taken in a snowstorm.

Alternatively, a small sheet of glass can be finely sprayed with red or black ink and when dry, bound up with the subject negative with a spacer in between to throw the snow slightly out of focus.

Rainbow Effects. A rainbow can be faked in much the same way. It is drawn in with a pair of compasses in dilute red ink on an unexposed, fixed-out film. To soften the outline of the rainbow, a sheet of clear glass must be sandwiched between it and the principal negative (which is accurately focused in the enlarger to print sharply).

Moon Effects. Moonlight landscapes which include the moon itself are also obtained by combination printing. The moon in a straight print always appears too small. A separate exposure of the moon in a clear sky is therefore made with a lens of two to three times the normal focal length. This negative is then printed in over any night scene, and the result corresponds to the actual visual impression.

Texture Effects. Negatives or transparencies of artificial patterns may also be printed in—e.g., dotted or lined screens, coarse woven cloth, nets, or surfaces with wood-grain or crackle finish. The material itself may even be used. When suitable patterns are chosen, they can add a useful touch of character to the print.

Objects which cannot be inserted in the carrier of the enlarger together with the principal negative may be placed on the bromide paper itself. By laying a piece of netting, grains of rice or sand, or small nails on the paper before exposure, the surface of the enlargement may be broken up according to the nature of the objects used.

Photograms. By laying objects directly on the paper it is even possible to dispense with a negative in the enlarger entirely. This kind of print is called a photogram. A direct print can easily be made from the leaf of a tree, a feather or even a cut-glass dish, provided only that the latter is sufficiently flat. Taller objects such as wine glasses, vases and statuettes lend themselves to more imaginative effects.

The enlarger lamphouse may shine down on the object or be inclined so that the beam of light casts an oblique shadow. The image will be foreshortened and distorted according to the positions of light and paper.

Using the same principle, it is fairly simple to print flat pictures from a curved surface. Where the surface is transparent, such as an etched glass tumbler, a sheet of bromide paper is

SILVER OR GOLD BACKGROUNDS. A metallic surface to the image, in place of a white paper one, enhances the detail and brilliance. 1. Make a thin transparency in the normal way by enlarging the negative on to a slow ordinary plate. 2. Coat the emulsion side with linseed oil, or a suitable adhesive. 3. Stick down a sheet of gold or silver paper foil, and trim to shape.

wrapped round the outside with the sensitized side facing the pattern; the exposure is then made by a small torch bulb inside the tumbler. With an opaque object, such as a vase, the paper is wrapped round in the same way, but the exposing light is placed outside the vase so that it shines through the back of the paper; this produces an image by reflection from the pattern on the vase (reflex printing).

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

Luminous Pictures. An effective way of making pictures that will glow in the dark is to coat a sheet of plain paper with luminous paint. This is left to dry in the dark until it has lost its luminosity. It is then re-activated by long exposure under a positive transparency, which will produce a positive and luminous picture when viewed in the dark. This image is not permanent and will be "fogged" if exposed over-all to light.

A method of producing permanent pictures which have brilliance is to back positive transparencies with gold or silver foil. The transparency must be weaker in density than normal and have no heavy shadows. The emulsion side of the transparency is coated with linseed oil or Canada balsam diluted with a little xylene; one side of the metal foil is treated similarly. The two coated surfaces are then pressed together into firm contact, avoiding air bubbles between them. O.R.C.

TRICOLOUR FILTERS. Set of three filters—red green, blue—used for making the separation negatives in the three-colour process of colour photography.

TRIHYDROXYBENZENE 1 : 2 : 3. Chemical name for pyrogallol or pyrogallic acid. One time very popular developing agent.

TRIMMER. A trimmer is a tool for making a straight cut through a print or mount and leaving a clean edge. It is used principally for removing distracting objects lying near the edges of the print, or for giving the picture more pleasing proportions. It is, in fact, a useful means of improving the composition.

Scissors make poor trimmers because they cannot cover the whole edge in a single cut, and each shift of the blades jags the edge of the paper—unless the scissors are unusually long, or the print is very small.

Prints can be trimmed quite well with a sharp pen-knife or a safety razor blade in a holder. The blade must be steadied against the edge of a steel ruler and enough pressure used to cut through the paper at a single stroke. The print should be on a piece of stiff board; cutting on to a sheet of glass soon blunts the edge of the blade. A strip of medium sand-paper glued to the lower face of the steel rule prevents it from slipping about.

But for those who can afford it, the commercial print trimmer is the best tool for the job. There are two types of trimmer—the desk trimmer, and the guillotine.

Desk Trimmer. This type of trimmer consists of a board, hinged to a base and kept raised an inch or so at the free end by a spring. A cutter blade runs the length of the free edge of the board and is fixed, edge upwards, on the base. A steel strip is fixed along the raised edge of the board, leaving a slit just wide enough to allow the edge of the print to be pushed under.

In use, the print is laid on the board so that the piece to be trimmed off projects under the steel strip. The board is then pressed down against the spring pressure and the fixed knife slices off the surplus paper against the edge of the steel strip. When the board is released, it automatically springs up into position ready for the next cut. Desk trimmers are not usually made to cut prints longer than twenty-four inches.

Some models also have a small ruler fixed along one edge of the board (at a right angle to the blade). This serves as a guide edge for cutting the print squarely; it may also be calibrated in inches or centimetres (or both) so that it indicates the length the print will be after the cut is made.

Guillotine Trimmers. The guillotine type of trimmer can be more easily made to cut prints up to any size. It is a board with a metal edge

DESK TRIMMER. The top board is hinged to the base at the far end. The paper protrudes over the near edge against which the blade bears. Downward pressure on the board cuts the paper.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

GUILLOTINE TRIMMER. The trimming blade is hinged at one end, and is pushed down to cut off the paper protruding over the edge of the board. The blade may have a return spring.

INTEGRAL TRIPACK FILM. A, blue-sensitive layer. B, yellow filter layer. C and D, green and red sensitive layers. E, anti-halo layer containing an even silver density. F, film base.

which has a knife blade fitted with a handle hinged at one end. The paper is held on the board overlapping the metal edge where it is to be cut. When the knife is pulled down it makes a sharp, clean cut. The advantage of a guillotine is that it will easily cut several thicknesses of paper, and can also be used for trimming cardboard mounts.

Guillotine trimmers are also made to cut with a deckle edge. Whilst a deckle edge is out of place on large prints, some people like it for prints of about postcard size or less.

For mass production trimming, such as in D. & P. work, the cutting mechanism is operated by a treadle so that the operator has both hands free to move the print as required.

When using either type of trimmer, it is essential that the print is held in firm contact with the trimmer board when the cut is made Otherwise the action of the blade is liable to pull against the print, displacing it and causing a crooked cut or else tearing the paper if the blade is not dead sharp. F.P.

TRIOXYMETHYLENE. Hardening agent used instead of formalin.

Formula and molecular weight: $(CH_2O)_3$; 90.

Characteristics: White crystalline powder. Unlike formalin, it is odourless.

Solubility: Freely soluble in water.

TRIPACK. Combination of three separate emulsions, each coated on its own base, used in some early colour processes under the name "tri-pac". The object is to secure the three separation negatives with a single exposure. The usual form of tripack consists of a front film carrying a blue-sensitive emulsion which is dyed yellow and placed with its sensitive surface in contact with an ortho emulsion on another film. The latter has a transparent red backing in contact with a red-sensitive emulsion on a third film.

The exposure is made through the blue sensitive emulsion layer. The layers are then separated and developed normally to give separation negatives. Unfortunately, although two of the three emulsions can be placed in contact, the remaining emulsion is slightly out of focus. The process is no longer used.

The modern development of the tripack is to coat all three emulsions and the intervening filter layer on a glass or celluloid base. This composite material, called an integral tripack, is developed to form the three colour separation negatives in the respective layers. It is then further processed to leave only three corresponding dyed positive images which combine to produce a natural colour transparency. Alternatively, it may be processed to yield a colour negative for printing on to another tripack coated on a paper base.

See also: *Bi-pack; Colour photography history; Colour materials; Colour printing.*

TRIPLE EXTENSION. Amount by which the front of a field, technical or similar camera can be extended—e.g., to three times the focal length of the normal lens. It is primarily required for taking close-ups. A triple extension enables a camera to be used for reproducing to a scale twice as large as life—i.e., a subject 1 in. high can be reproduced 2 ins. high.

See also: *Extension of camera.*

TRIPLET LENS. Popular form of lens assembly consisting of three single glasses: a converging front crown glass lens, a diverging flint glass lens and a converging crown glass lens. The elements are air-spaced.

The first lens of this type, the Cooke Triplet, was developed by H. D. Taylor in 1893 and it was subsequently widely adopted.

See also: *Lens history.*

TRIPOD. Support for camera, consisting of three legs usually hinged together at one end to a component which carries a tripod screw.

See also: *Camera supports.*

TRISODIUM PHOSPHATE. Alkali, used mostly in fine-grain developers as it is to some extent self-buffering.

See also: *Sodium phosphate (tribasic).*

TROPICAL PHOTOGRAPHY

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Heat, moisture, insects, air-borne sand and dust are the main factors which complicate photography in the tropics. There are two characteristic combinations of heat and moisture: a high and widely varying temperature accompanied by a low relative humidity such as is found in desert regions, and a very high humidity with comparatively low maximum temperature, i.e., the conditions that may be expected in the rainy season or on tropical islands. Owing to these great variations in both temperature and humidity, general photographic data may not apply in the tropics. The fullest use possible should be made of any available local information.

Materials and Equipment. The construction of tropical equipment is important. Aluminium and unprotected iron are liable to corrosion. Where wood is used, teak or mahogany are to be preferred, with all joints fastened by rustless screws. Glued joints should be avoided.

Modern plastic or light metal non-folding cameras, which minimize the entry of moisture into the air-space of the body, are particularly suitable for tropical use. Collapsible lenses are best left permanently extended.

Between-lens shutters are normally more trouble-free than the focal-plane shutter.

Sensitive material should be ordered in tropical packings. The packages of sensitized materials should be kept as cool and dry as possible. A cold store should be used if available, but as the humidity in a cold store or a refrigerator is usually high, all packages so stored must be made completely waterproof. Materials required for use must be removed from the cold store about twenty-four hours before use, and allowed to warm up gradually to air temperature.

Colour films should be purchased in hermetically sealed tropical packings. The seals should not be broken until the films are required for use, and all colour films should be sent for processing as soon as possible after exposure, and should on no account be stored.

Should no cold storage be available, unventilated buildings and the top floors of uninsulated buildings should be avoided, and materials stored well away from outside walls and steam pipes. Storage pits are the next best to a cold store.

Photographic chemicals should always be purchased in tropical packing. In general, anhydrous forms are preferable to crystalline. Chemicals which deliquesce (i.e., absorb so much water that they dissolve in it), such as sodium sulphite, sodium hydroxide and potassium carbonate should be kept in corked bottles and wax-sealed. Efflorescent chemicals, such as sodium carbonate and sodium sulphate, must be similarly treated. After mixing, solutions should be stored in dark bottles filled to the neck, and kept in a cool, dark place.

All apparatus should be kept as cool, dry, and clean as possible. In humid regions, all metal parts should be greased regularly, and leather parts treated with a wax polish. In dusty or sandy regions, lenses should be protected, when not in use, by a lens cap, and during use by a clear glass "filter" or a haze filter. In such places no grease or oil should be applied to metal parts.

Processing Films and Plates. Films and plates should be processed as soon as practicable after exposure because of the possible fading of the latent image. Should delay in processing be inevitable, the materials should be dried before repacking in their original containers.

To dry materials, a quantity of indicator silica gel should be placed with the material in a sealed air-tight container. The silica gel should be replaced every 24 hours until there is no change in colour from blue to red. The drying properties of silica gel may be revived by heating to 400° F. (205° C.) and cooling in an air-tight container.

The hands must be kept as dry and free from perspiration as possible by soaking them in iced water or spirit and thoroughly drying them afterwards. To avoid fingerprints, film clips, film hangers, plate racks and print forceps should always be used.

High-temperature processing affects the photographic characteristics of emulsions, giving rise to an increase in fog and a decrease in gamma. Loss of gamma is especially noticeable with process materials normally developed in caustic developers which are too alkaline to use above 75° F. (24° C.). Use of an anti-fogging agent tends to lessen the fog. With high-speed emulsions there is also an increase in graininess together with a decrease in resolving power.

A wetting agent may be added to developers, but must not be added to fixing baths. If fresh water is restricted, chlorinated or sea water may be used for mixing developers. Any sludge formed should be allowed to settle, after which the clear decanted liquid may be used. Acid hardening-fixing baths are quite satisfactory if made with sea water. Washing in sea water must be followed by two or three short rinses in fresh water to remove residual salts. This may be done at a later date.

If all solutions can be maintained below 75° F. (24° C.), standard formulae and processing technique may be used for processing plates and films. Should the washing water be above 75° F., an acid hardening-fixing bath must be used, and the washing time should not be excessive.

With processing solutions and wash water between 75° F. (24° C.) and 90° F. (32° C.) any normal developer loaded with sodium sulphate may be used. Up to four ounces of sodium sulphate may be added to 20 ounces of

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

solution (up to 200 grams per litre), the maximum quantity being required at the higher temperature. To compensate for the resultant slowing down of development, 20 per cent should be added to the normal tropical development times. Highly alkaline M.Q. formulae should be avoided because they tend to form fog with prolonged development times.

A special tropical developer of the following type may also be used:

Metol	100	grains	5·7	grams
Sodium sulphite, anhydrous	3½	ounces	90	grams
Kodalk	33	grains	1·9	grams
Sodium sulphate crystals	4½	ounces	105	grams
Water to make	40	ounces	1,000	c.cm.

The average development times are:
6–8 minutes at 75° F. (24° C.).
3½–4½ minutes at 85° F. (29·5° C.).
2½–3 minutes at 90° F. (32° C.).

Development should be followed by a 3-minute immersion in a chrome-alum stop bath. Fixing is then carried out in a tropical acid hardening-fixing bath for 10 minutes.

Tropical acid-hardening fixing baths may be mixed from packed proprietary brands, or made up to the following formula:

Sodium thiosulphate, anhydrous	6	ounces	150	grams
Sodium sulphite, anhydrous	265	grains	15	grams
Acetic acid, glacial	300	minims	17	c.cm.
Boric acid	130	grains	7·5	grams
Potassium alum	265	grains	15	grams
Water to make	40	ounces	1,000	c.cm.

If the processing solutions exceed 85° F. (29° C.), and a very humid atmosphere has caused the emulsion to become excessively swollen the materials should be dried, as described above, before development is attempted.

When all solutions, including the wash water, are at a temperature higher than 90° F. (32° C.), a tropical pre-hardening bath in conjunction with a sodium sulphate loaded developer should be used. In this case the chrome-alum stop bath should be omitted.

Pre-hardening baths may be mixed from packed proprietary brands, or made up to the following formula:

Sodium sulphate	8	ounces	200	grams
Formalin (40 per cent solution)	1	ounce	25	c.cm.
Water to make	40	ounces	1,000	c.cm.

The materials should be fixed in a tropical acid hardening-fixing bath for 10 minutes.

Where running water is available, washing time should not exceed 30 minutes for temperatures of 75–90° F. (24–32° C.), and 20 minutes for temperatures of 90–105° F. (32–41° C.). Alternatively, the material may be immersed for 5 minutes in each of three changes of still water, allowing 16 ounces (450 c.cm.) of water per square foot of material in each bath. If the emulsion is very soft, a 2–3 minute wash in still water should be given, and the material refixed and rewashed as above within three days. Washing times can be reduced by the use of proprietary hypo-eliminators.

The final rinse, or a proprietary fungicide bath if used, should contain a wetting agent.

Before drying, the emulsion may be carefully wiped down with a viscose sponge or a chamois leather, provided the emulsion is not very soft, and there is no appreciable frilling or stripping. Drying may be assisted by the use of a spirit bath diluted with 30 per cent water. Fungicide baths may be precipitated by alcohol, and the two treatments should not be given at the same time. Drying can be accelerated by placing the material in a current of air—e.g., from a fan. Whatever method of drying is used, negatives must be protected from insects and dust by the use of gauze or mosquito netting. Suspending films from a wire gives protection from cockroaches which might eat the wet gelatin off the film or plate.

If maximum permanence is desired, films and plates should be given the following treatment within twenty-one days of processing, in solutions preferably at about 75° F. (24° C.).

(1) Soak in water containing a wetting agent for 5 minutes.

(2) Fix in a freshly prepared tropical acid hardening-fixing bath for 10 minutes.

(3) Wash in running water for 30 minutes.

(4) Soak in a 0·03 per cent (by volume) solution of ·088 ammonia for 5 minutes.

(5) Wash for 5 minutes.

(6) Immerse in a fungicide solution for 5 minutes before drying.

Processing Paper. For processing paper at temperatures between 75–95° F. (24–35° C.), a standard print M.Q. developer may be used without pre-hardening. The development time will become appreciably shorter as the temperature increases. When development is complete, the prints should be rinsed for a few seconds in an acid stop bath before transferring to an acid hardening-fixing bath. Two fixing baths should be used, the prints remaining in each bath for 5–10 minutes. A maximum of sixty-five whole-plate prints, or the equivalent area, per gallon may be fixed in the first bath, which should then be replaced by the second bath, and a fresh second bath made up.

Single-weight prints should be washed for 40 minutes and double-weight prints for 60 minutes. If prints are required quickly, or it is necessary to conserve water, a hypo eliminator may be used, provided the solution temperature is brought below 75°F.

Prints may be dried by heat, or laid out to dry in a dust-free atmosphere.

For maximum permanence, prints should be toned with either a selenium or a hypo-alum toner.

For selenium toning the prints are fixed normally, using two baths in succession, washed (single-weight prints for 40 and double-weight prints for 60 minutes) in running water, toned in a selenium toner, and re-washed.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

For hypo-alum toning the prints are fixed normally, using two baths in succession, washed in running water for 10 minutes, and toned in a hypo-alum toning bath. This should be followed by sponging in luke-warm water to remove any sediment, and washing (single-weight prints for 40 and double-weight prints for 60 minutes) in running water.

Storage of Processed Material. Negatives and prints destined for storage in the tropics should be specially treated during processing, as detailed above.

All processed materials should be stored in conditions with a relative humidity below 60 per cent and as cool as possible.

An air conditioning system, if available, helps to ensure favourable and consistent storage conditions.

Films to be stored may be given a coating of film lacquer which will prevent fungus growths in the emulsion and will also protect the surface of the film from abrasion in handling. Most proprietary makes of film lacquer contain a fungicide.

Prints and negatives in fairly regular use may be stored in fungicide envelopes. Single kraft paper envelopes impregnated with a fungicide (a 2 per cent solution of sodium pentachlorphenate is most effective), are satisfactory for this purpose. The envelopes should have narrow edge seams, rather than a centre seam, and carry a folding flap. Certain pastes are very hygroscopic and envelopes secured by these should be avoided. All material stored in this way should be examined regularly and any signs of deterioration dealt with immediately.

Colour transparencies must be kept as cool and dry as possible, and preferably stored in a dark place.

Materials for long term or archival storage should be dried out thoroughly and then placed in laminated foil envelopes, which can be hermetically sealed, and stored in as cool a place as possible. Care should be taken to ensure that packages to be re-opened are allowed to condition to normal room temperature before the seal is broken.

Cine films to be stored in the tropics should be specially washed after processing to remove any residual traces of processing chemicals. A lacquer coating is recommended for all valuable negative material and prints intended for archival storage. If air-conditioned storage space is not available, the films should be carefully dried out and then stored in cans which should be tape-sealed to prevent the entry of humid air. A drying agent may be included in the can, but care must be taken that the film does not become so dry as to make it brittle. The cans should always be laid horizontally so that the weight of the film rests on the edge of the roll. A.E.S. (L.G.F.)

Books: *Camera in the Tropics;* by G. C. Dodwell; *Photography on Expeditions,* by D. H. O. John (both London).

T-STOPS. Aperture values measured on a scale based on the actual transmission of light at different stop diameters instead of on the relation of the diameter to the focal length of the lens (*f*-stops).

See also: *Diaphragm; Transmission efficiency.*

TUNGSTEN FILAMENT LAMP. Electric lamp consisting of a filament of tungsten in a glass envelope containing an inert gas. The filament is rendered incandescent by the passage of an electric current. Lamps of this type are among the most useful light sources.

See also: *Filament lamp; Light sources.*

TUNGSTEN IODINE LAMP. Term preferred by some lamp manufacturers for the quartz-iodine lamp because this type of lamp is also made with an envelope of heat resisting glass.

TURRET HEAD. Rotary multiple lens housing on cine cameras and some experimental miniature still cameras. The head holds several lenses of different focal lengths and permits them to be rapidly interchanged. The required lens is brought into the taking position by simply rotating the turret.

See also: *Cinematography.*

TURRET HEAD. Special type fitted on 35 mm. still camera. Any of the three lenses (wide angle, standard, long focus) can be brought into use by the turret.

TWIN LENS CAMERA. Camera consisting of two compartments, each with its own lens; the top compartment carries a focusing or viewing screen and the other the sensitized material. The focusing movement is usually common to both lenses so that when the image

appears sharp on the screen it is also focused sharply on the sensitized material. The system has the advantage that the lens of the viewing camera remains fully open while that of the taking camera can be stopped down as required. So the screen image is seen at full brilliance all the time.

A number of early workers had the idea of coupling two identical cameras in this way. In 1864 Disderi constructed a "double appareil" on this plan and there was a camera of this type manufactured by Marion in 1888.

There have been twin lens reflex cameras since 1891, the upper, viewing half of the instrument being equipped with a reflex mirror and a focusing screen in register with the focal plane of the taking lens. In particular, Dr. Heidecke built a twin lens plate reflex in 1908. But such cameras were extremely bulky and the idea did not become popular until it was applied to the small-format roll film camera in 1928 by the manufacturers of the Rolleiflex, and subsequently by a number of other firms.

TWO-BATH DEVELOPMENT

Two-bath development, as its name implies, is carried out in two solutions, and two separate stages.

In the first solution, the emulsion layer is saturated with developer. At this stage, some development may or may not take place.

For the second stage the material is transferred to another bath which may be a dilute alkali solution or even plain water. Here the image starts to develop (or continues developing) until the developer carried over in the emulsion becomes exhausted or too diluted to have any further effect.

Water Bath Development. The simplest form of two-bath development uses a normal developer for the first stage, and plain water for the second.

Generally, most of the development takes place during immersion in the developer. When the material has been in the developer for about two-thirds to three-quarters the normal time, it is transferred without rinsing to a dish or tank containing plain water. No agitation must be given at this stage.

The developer which was absorbed by the emulsion continues working in the water bath. It soon becomes exhausted in the dense highlight portions of the negative, but it goes on much longer in the thin shadow areas. After a time the developer diffuses out of the emulsion layer and the whole process comes to a stop.

The net result of the water bath method of development is that the shadows are developed up fully as they would be in the normal way, but the highlight density is lower. In other words, the over-all tone range is shortened.

The local contrast of the image is, however, not decreased in either the highlights or the shadows. Since the developer still goes on working for a while, the contrast will, if anything, become higher. This is particularly so in the shadows where the developer diffuses out of the emulsion and is diluted long before it is exhausted.

On the other hand, the developer is used up so quickly on the highlight areas that they stop developing before they have a chance to block up. Flattening of the tone gradation occurs mainly in the middle tones and produces an effect akin to tone separation.

This result cannot be achieved by shortening the development time, since that would reduce the contrast all over, particularly in the thin shadow tones.

The method is most useful for negatives which have a well-defined range of highlight tones, an equally well-defined range of shadow tones, but nothing much in between, like shots against the light and indoor photographs which include parts of a view through the windows. If carried to excess, staining will result.

Although the main use of water bath development is in processing negatives, it can also be applied to prints. There it reduces the contrast and so enables an ultra-hard negative to be printed on a paper that would not otherwise accommodate the negative tone range.

To obtain a noticeable effect in practice, it is necessary to use a hot water bath for prints, transferring the print to the water as soon as the image begins to appear.

Intermittent Development. The effect of water bath development depends to a large extent on the amount of development allowed to take place in the developer. The sooner the negative is transferred to the water bath, the greater the compression of the extreme tones, but the softer the final image.

But the effect of the water bath can also be controlled by intermittent development. This procedure is mainly suitable for development by inspection, as it depends to some degree on judging the partially developed image.

The material is immersed in the developer until the first highlights begin to appear. It is then transferred to the water bath, and left there for 2 minutes. After this time development will have stopped almost completely. The negative is placed again in the developer for about two to three minutes, followed by another two minutes in the water bath. The procedure is repeated until the negative has built up sufficient density. The contrast can be increased by extending the time in the developer.

A fairly energetic developer—e.g., a concentrated contrast metol-hydroquinone for-

mula gives the best results. Easily oxidized developers, like pyro or caustic hydroquinone, are less suitable as they are apt to stain.

CC-0. Sgpc Digital Preservation Foundation, Chandigarh

Alkaline Two-bath Development. Two-bath development is similar to water bath development in principle and results, but the water bath is replaced by an alkali bath, e.g., 1 per cent borax or sodium hydroxide.

The first bath—i.e., the developer itself—is often made up with little or no alkali so that hardly any development takes place in it. The gelatin emulsion merely becomes soaked with developer solution which is not activated until the negative reaches the alkali bath. Here development soon stops in the dense portions while it goes on in the thin shadow areas for much longer until the solution diffuses out of the emulsion.

One of the advantages of alkaline two-bath development is that neither time nor temperature are critical. Both baths must be kept at the same temperature to avoid reticulation and similar troubles.

Immersion in the first bath should last about three to four minutes. After that there is practically no increase in the amount of solution absorbed by the gelatin. But the time is not critical.

The immersion time in the second bath should again be three to four minutes. By that time most of the developer solution has diffused out of the gelatin and further immersion only softens the emulsion layer. Since development stops altogether, the negative cannot be over-developed and the time of immersion in the second bath also is not critical.

There must always be enough alkali solution in the second bath to "swamp" the developer carried over and diffused out by the film, or development will continue instead of stopping after about three to four minutes. At least ten to twenty ounces (250–500 c.cm.) of alkali bath should be used and for the same reason it should not be used for more than one session.

At higher temperatures the developer acts more rapidly, but it also diffuses out of the emulsion sooner. These two effects more or less neutralize each other, so the exact development temperature is not important.

The concentration of the first bath is usually varied to compensate for the increased or decreased development speeds of different materials. Slow developing materials are given a concentrated first bath so that the developer will continue working for a long enough time in the second bath. Rapid developing materials are given a more diluted first bath.

The concentration of the alkali bath also influences the rate and thus the amount, of development, but in practice it is usually kept constant.

A normal metol-hydroquinone negative developer, made up at about two to four times its normal strength, makes a suitable first bath. Since practically nothing happens in this

TWO-BATH DEVELOPMENT. 1. Negative material exposed to subject of extreme contrast. 2. First bath of comparatively slow acting developer. The material remains in it long enough so that the gelatin layer soaks up a certain amount of solution. 3. Second bath. The developer in the gelatin, sometimes activated by alkali in the bath, carries on developing the image. 4. After some time, the developer in contact with heavily exposed areas becomes exhausted, while the developer in the lightly exposed parts still carries on working. 5. Finally, development stops when all developer has diffused out of the emulsion layer. The tone difference is, however, less than it would have been with straightforward development.

solution, it may be used as long as it lasts.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Two-bath developers made with highly concentrated solutions and a concentrated alkali bath are used for high-speed processing.

Two-bath Fine Grain Development. Any developer of the low energy type can be made up in the normal way and used as the first bath of a two-bath formula.

Therefore fine-grain developers like D-76, etc., will serve as two-bath developers, with a borax or Kodalk solution as the second bath. The amount of development that takes place in the first bath during the soaking time can be ignored.

To compensate for the different development speeds of different negative materials the strength of the first solution may be varied.

Meritol-Caustic. A special type of fine-grain two-bath developer is provided by the Meritol-caustic series of formulae.

The special advantage of Meritol-caustic developers is that they give fairly fine grain without loss of emulsion speed.

The procedure is the same as with a normal alkaline two-bath developer: the film is first soaked in a solution of a Meritol fine-grain developer for three to four minutes, and then transferred to the caustic bath (a 1 per cent solution of sodium hydroxide).

The caustic bath may also contain about 5 parts per 100 of formalin solution to harden the film. Because the caustic alkali solution tends to soften the gelatin, a hardening fixer, preceded by a thorough rinse, must be used after development.

The strength of the first bath again determines the degree of contrast obtained. For average films, the Meritol developer (e.g., Meritol Super Fine Grain, or M.C.M. 100 without alkali) is diluted with an equal volume of water. Slow developing films need a stronger first bath, rapid developing films a weaker one.

There is a fixed relationship between the strengths of the two baths for any particular degree of contrast. Strong developer and a weak alkali bath (say 0·5 per cent) give the finest grain, but this is offset by a certain amount of fog, and loss of shadow detail. A weak Meritol bath with a stronger alkali solution (over 1 per cent) gives better shadow detail, but slightly coarser grain.

The backing dyes on roll films may interfere with the action of the Meritol. They must be removed before development by soaking the film in a 1 per cent solution of sodium sulphite for about one to two minutes. After this fore-bath the Meritol has to displace the sulphite solution already absorbed in the gelatin. The film must therefore be left longer—up to five minutes—in the Meritol bath.

Developer improvers can also be added to the Meritol bath in the proportion of about 1 part in 200. These give slightly lower emulsion speeds, but considerably less fog. L.A.M.

TWO-COLOUR PHOTOGRAPHY. A passable representation of natural colour can be produced by analysing the spectrum into only two parts instead of three, and combining the images with printing colours which are approximately complementary to the taking colours. It is not possible to reproduce the whole spectrum by such methods, but there are many subjects which do not include the whole spectrum—e.g., blue is absent from normal flesh tints and in many scenes where the sky does not appear.

In the 1950's Dr. E. H. Land claimed that full-colour sensations could be produced by practically any two wavelengths from the visible spectrum, provided they were separated by at least 10 mμ. He made negatives of a coloured subject through a green filter (short wave) and through a red (long wave). From these, two transparencies were made, and projected in register, the short record by white light, the long record by red. Instead of an overall pink shade, a full colour reproduction resulted.

It was shown that colour sensations were not stimulated in the eye by the overall relative intensities of the two records, but by *differences* in the relative intensities from point to point in the picture. Moreover the pattern of intensity ratios had to be haphazard rather than orderly.

Although certain wavelength combinations produced an incomplete colour range, this could be rectified by broadening the wavebands. Wavelengths over much of the spectrum could act as both long and short records, when matched with shorter or longer wavelengths respectively. However, when the short (green) record was projected by red light and the long (red) record by white, colour reversal occurred.

Land showed that the eye could experience the same colour sensations simultaneously from several sets of wavelengths. He concluded that, in sunlight, the eye sees many "colour worlds", separating the wavelengths into long- or shortwave stimuli about a balancing wavelength of 588 mμ in the yellow region. P.B.M.

U

ULTRA-MINIATURE CAMERA. Type of camera which takes films narrower than 35 mm., such as perforated or unperforated 9·5 or 16 mm. cine film.

Some types take a number of exposures (usually 8) on round discs of film about 1½ ins. in diameter.

An ultra-miniature camera is usually much smaller than any other type, varying from matchbox size to about 4 × 2 × 1 ins. Many ultra-miniatures are derived from spy cameras which were popular at the beginning of the century.

Scope. There are two distinct groups of ultra-miniatures: very simple cameras, and precision models. The former are comparable with box cameras in performance and standards of construction. The precision models have the refinements of a normal precision miniature.

The negative sizes of the ultra-miniature cameras range from about ¼ in. square to around ½ × ¾ ins. so if the negatives are to be enlarged to any degree, the optical and mechanical requirements have to be very strict. With the best instruments of this kind, the largest print size for acceptable quality is around whole-plate or 6 × 8 ins., but in most cases postcard size enlargements seem to mark the limit. For this reason the simple ultra-miniatures are little better than toys, and very few models of even the intermediate specifications can compare with a typical medium priced camera of the normal roll film type.

The commonest shape is that of an oblong rectangular box, similar in appearance and dimensions to a cigarette packet. Ultra-miniatures have also been designed in other forms, occasionally based on the layout of an amateur cine camera. The latter type sometimes takes normal 16 mm. cine film in standard 25 foot spools, yielding several hundred exposures at one loading.

Features. High-class ultra-miniatures are, despite their small size, fully equipped as serious photographic instruments, and are built with the precision of a watch.

Most cameras use film in special cassettes, holding up to 50 exposures. These cassettes are often made to be reloaded by the photographer in his own darkroom.

There does not exist a standardized frame and film size or packings for ultra-miniatures as there are for 35 mm. miniature cameras. Attempts at standardization have, however, been made both in Germany and in Japan; the German standard suggests a 12 × 17 mm. frame on unperforated 16 mm. film, the Japanese a 10 × 14 mm. frame on single perforated 16 mm. film. Neither of these standards is universally adopted, and other sizes are also in use.

Accordingly, films are often made in packs for specific camera models (sometimes marketed by the makers of the camera) and only a limited range of films exists for any one camera.

The lens generally has a focal length of ⅓ to 1 in., with a maximum aperture in most cases around *f* 3·5. Even at full aperture such a lens will give a depth of field extending from infinity down to about 3 feet.

The focusing range generally starts as close as 20 ins.

Interchangeable lenses are very rare in ultra-miniatures, mainly probably because the mechanical tolerances in positioning different lenses in a minute lens changing mount are liable to be too great to preserve the utmost precision necessary for maximum image quality. (Making more substantial lens mounts would increase the bulk of the camera.) Some ultra-miniatures take afocal wide-angle and tele lens attachments to provide effective alternative focal lengths.

Shutters are mostly of the sector type working either in front of or behind the lens, and speeded to 1/1000 second.

Interlocked shutter tensioning and film transport, and a built-in rangefinder are common features on these cameras. Other features sometimes included are built-in coupled exposure meters, built-in filters and automatic film transport.

CC-0. Kamakura Digital Preservation Foundation. Siddhanta

ULTRA-MINIATURE CAMERA. Ultra-miniature cameras vary from fancy toys to precision instruments built on the lines of a high-class watch. The model shown comes into the latter category, and takes 50 exposures 8 × 11 mm. on unperforated 9·5 mm. film in special chargers. A, lens in focusing mount. B, built-in filters. C, shutter. D, window in front of lens when camera is open. E, shutter release. F, camera lid, extends for use. G, viewfinder. H, take-up magazine. I, spring loaded shaft of magazine. J, film. K, spring-loaded pressure plate; under pressure only when camera fully open for shooting. L, film guide, keeping film correctly positioned. M, feed magazine.

Systems. Since originally standard developing tanks and enlargers for 35 mm. film did not accept narrow-gauge ultra-miniature films, most such cameras were brought out with a complete system of accessories including their own developing tank, film loading equipment, enlarger, and so on. These, together with the comprehensive range of accessories offered by manufacturers of the leading types of ultra-miniature form a self-contained camera and equipment system akin to that of the classical miniature cameras.

More recent developing tanks are frequently adjustable to take 16 mm. film as well, and there are special attachments and accessories to adapt normal enlargers to ultra-miniature films. Complete processing outfits for specific makes of ultra-miniature camera are therefore nowadays less frequent.

See also: *Miniature camera; Spy camera.*

ULTRASONIC IMAGE RECORDING. Production of visible images formed by high-frequency sound waves in the ultrasonic region (20,000 to 1,000,000 cycles per second). Such sound waves resemble light waves in their ability to undergo reflecton, refraction and diffraction, and can form acoustic images and shadow images analogous to optical ones.

Since no photographic materials are directly sensitive to ultrasonic vibrations, the effect of the latter is made visible by their action on the process of photographic development. Sound waves can agitate processing solutions; if such agitation is sufficiently localized, it can lead to differential action on different areas of the surface of a film or plate. The resulting image is thus based on local under and over development.

Method. One set-up for producing ultrasonic images consists of a water tank containing an ultrasonic generator (a quartz crystal oscillator). An evenly fogged but undeveloped photographic plate is immersed in dilute developer solution contained in a perspex tank. The latter is placed in the water tank. A suitable object (for example a plastic saucer with a prominent relief pattern) is placed close in front of the photographic plate, so that the sound waves produce an acoustic image in the plane of the plate. This image causes differential agitation of the developer on the emulsion surface, yielding a reproduction of the pattern of the saucer (due to diffraction) in the form of a developed image.

Similar physico-chemical sound images can be obtained by immersing a uniformly fogged and developed plate in a silver solvent solution (for example acid potassium bichromate). This selectively dissolves away the silver image according to the ultrasonic agitation of the solution.

ULTRASONIC SHADOWGRAPH FORMATION. A, fogged plate. B, Perspex tank containing developer. C, shadowing object (for example a plastic ribbed saucer). D, water tank. E, ultrasonic generator. The sound waves from the latter are held back to a greater or lesser extent by the object and so produce local variations in the agitation of the developer, leading to the development of a shadow image of the object on the fogged plate.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Images and image patterns can also be obtained by using ultrasonic acoustic lenses and by placing the photographic plate in the path of standing waves produced in the tank.

The Ultrasonic Image. High sound frequencies (usually above one million cycles) are necessary to yield any sort of resolution. The resolving power is limited by the wavelength; at one million cycles this is 0·3 mm., and the resolution at such frequencies is of the order of one line per mm.

Ultrasonic Projector Control. Ultrasonic sound signals have been used for remote control of slide projectors and other equipment. This requires a transmitter (in effect an ultrasonic whistle) and a receiver built into the projector which responds to these signals and closes a relay to change the slide, etc.

ULTRA-VIOLET (U.V.). Beyond the violet end of the spectrum there is a band of invisible radiation to which the term ultra-violet or U.V. is applied. The region includes rays with a wavelength from 4,000 down to a few hundred Angstrom units, but below about 2,000 A. both gelatin and air cease to be transparent to the rays. Sunlight is rich in ultra-violet rays of the 3000–4000 A. region, although the greater proportion and all radiation below 3000 A. is filtered out by the upper layers of the atmosphere before the sun's rays reach the earth.

Carbon arc and mercury vapour lamps are the commonest artificial sources of ultra-violet light; and if necessary, the visible rays can be removed completely by a special filter of deep violet glass.

Filtered ultra-violet light is used in photomicrography because its short wavelength gives better definition of fine detail. The microscope lenses must be made of quartz for this work; ordinary glass does not transmit ultra-violet.

Ultra-violet light is highly photo-actinic and it is the U.V. content of sunlight which causes sunburn.

Some inorganic substances (e.g., uranium salts), many synthetic organic ones (e.g., eosin—as used in red inks) and most animal and plant materials (except blood) fluoresce strongly under ultra-violet radiation. Most materials fluoresce to a greater or less degree according to their composition. This fact is exploited in various ways in science, medicine, forensic science when dealing with forged documents, etc., examination of precious stones, industry, etc.

See also: *Spectrography; Spectrum; Ultra-violet and fluorescence photography.*

ULTRA-VIOLET AND FLUORESCENCE PHOTOGRAPHY

The limits of the colours visible to the human eye lie between violet at one end of the spectrum and red at the other. Beyond these limits, however, there are radiations that the eye cannot see—i.e., ultra-violet and infra-red rays, both of which are made use of in photography. Ultra-violet (or U.V.) radiations are often loosely and incorrectly referred to as U.V. "light" and sometimes "black light".

Ultra-Violet Radiations. The U.V. region of the electro-magnetic spectrum adjoins the short wavelength end of the visible spectrum at about 4,000 A. and extends to about 140 A. Only the "near" U.V., i.e., between 2,000 to 4,000 A. is accessible without special apparatus and techniques, for beyond 2,000 A. the gelatin of the photographic emulsion absorbs all the radiation and beyond 1,800 A. the air begins to absorb the rays.

Conventional optical glass absorbs all U.V. of wavelengths shorter than about 3,500 A.; quartz lenses must be used for the shorter wavelengths. Therefore, in the absence of special equipment, photographs are normally restricted to the 3,500 to 4,000 A. band.

Fluorescence. Fluorescence may be described as the property of some substances of absorbing radiation of one wavelength, and in its place emitting light of another wavelength or colour. The phenomenon ceases immediately the source of radiation is cut off. As used here the term fluorescence refers to the visible "glow" which results when invisible U.V. rays impinge on certain substances. Fluorescence may be of any colour from violet to red and this feature may be of analytical importance. Since all materials also reflect some U.V. rays, fluorescence will be masked in a photograph unless unfiltered U.V. radiations are prevented from reaching the emulsion.

Some substances have the property of continuing to glow for a time after the exciting rays (light, U.V. or X-rays) are shut off; this glow is known as phosphorescence and is often mistaken for fluorescence. In some instances it may be difficult to detect as the afterglow may last for only a fraction of a second. The luminous clock dial and the coating of fluorescent light tubes offer two examples of phosphorescence. The phenomenon is of little photographic importance.

There are two ways of making photographs by the agency of U.V. radiations: U.V. photography of the reflected radiations and fluorescence photography.

Sources. Sunlight provides only a 5 per cent U.V. emission as compared with 40 per cent visible light and 55 per cent infra-red. Carbon arcs have a strong emission at about 3,900 A. but are inconstant in operation. This is especially true of the enclosed variety. The most practical, convenient and constant source is some form of mercury vapour arc-lamp because mercury vapour emits a strong and

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

MERCURY LAMP SPECTRUM. The spectrum of the high pressure mercury vapour lamps used for ultra-violet photography is concentrated in one line in the yellow and yellow-green regions, two in the violet, and one in the near ultra-violet. In practice, all the visible light is filtered out, so that only invisible ultra-violet radiation reaches the subject.

photographically useful radiation at 3,650 A. Visible radiations can be subsequently filtered out by a suitable screen.

A convenient lamp is made by at least one firm. Essentially it is a mercury-vapour discharge lamp enclosed in a glass envelope, which restricts its U.V. emission, but having the advantage of a built-in 60° reflector.

One very suitable make of lamp is run in series with a choke and is designed to operate continuously; it takes about ten minutes before it reaches full brilliance and after it is once switched off it will not "strike" again as long as it is hot. It is convenient to mount this lamp in a light-trapped, ventilated box with slots in front to accept the various screens as required. Two sources may be used to advantage, but this necessitates greater capital outlay on equipment which is not merited for occasional use.

Low-pressure sources similar in form to domestic fluorescent tubes are available with emissions at 3,650 A., 3,100 A., and 2,537 A.

Electronic flash offers a useful and readily obtainable source of U.V. radiation especially in the 3,650 A. band. If living or moving. objects are involved, this may be the most appropriate source. Ultra-violet flash may be applied effectively to both ultra-violet and fluorescence photography, although in the latter instance a continuously burning source will also be required, for visual inspection.

U.V. lamps must be used with great care. Wavelengths around 3,000 A. have a stimulating effect on the skin but too much exposure causes a painful "sunburn".

As U.V. lamps will probably be left burning for a considerable time during photography, the eyes of anyone engaged in this work should be protected by goggles of U.V.-absorbing glass as a matter of routine, more particularly if there is appreciable transmission at 3,130 A. U.V. may cause severe inflammation of the eyes (conjunctivitis) which only becomes noticeable some hours after exposure and which is both dangerous and unpleasant.

Screens. The U.V. transmitting filters which are used to screen off unwanted visible light are called U.V. screens or Wood's glass screens. If they are used over the radiation source instead of the lens, both reflection and fluorescence work may be undertaken with the same basic set-up. Some lamps possess an integral screen: with lamps that do not, a special U.V. passing screen should be used. These screens transmit a very narrow band of U.V. from roughly 3,000–4,000 A. (with a maximum at 3,600 A.). They are thus well matched to the 3,650 A. mercury line. A home-made liquid filter of a 1 cm. layer of saturated cobalt chloride (in a suitable glass cell) can also be used.

Filters. The term U.V. filter is applied to the U.V. absorbing filters used in the photography of the visible fluorescence emitted by some substances when exposed to U.V. radiation; they are always used over the camera lens. These filters vary according to make and type, but are generally designed to begin maximum cut at anything between 3,800–4,800 A. A home-made liquid filter can be a 1 cm. layer of 10 per cent sodium nitrite solution.

General U.V. Arrangement. In the practice of U.V. photography there may be some difficulty or confusion in the exact interpretation of results, so a control photograph is made by half-watt light wherever possible. To make the examination complete, it may also be necessary to make an additional record by the fluorescence method and, until the user is thoroughly familiar with U.V. techniques and subsequent interpretation, these three steps should be taken as a precaution.

An inexpensive set-up for both reflected and fluorescence photographs consists of the following items:

(1) A mercury vapour lamp as the source of U.V. radiations.

(2) A U.V. screen that can be placed in front of the source for cutting out visible light when taking fluorescence photographs.

(3) A U.V. filter for use in front of the camera lens for cutting out all but U.V. radiations when taking reflected U.V. photographs.

(4) A U.V. absorbing filter for use in front of the camera lens to absorb U.V. radiations when taking fluorescence photographs.

It should be remembered that if a glass-fronted lamp and a glass lens are used the recording range is restricted to radiations of 3,500–4,000 A.

Reflected U.V. Photography. This method requires U.V. radiations falling on the subject, and only U.V. radiations entering the camera. This is achieved by using a screened or unscreened source, and a filter over the camera lens which passes only U.V.

Use of an unscreened source has the advantage that focusing can be done by the visible emission of the source without the camera filter in position. The latter is then placed over the lens for the exposure.

Any normal camera may be used. After

initial setting-up the normal room lights should be extinguished.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

As most of the normal sensitized materials are sensitive to U.V. radiations, there is no particular point in using panchromatic materials for this reflected U.V. photography; although they may be faster, speed is not usually of any great importance.

Fluorescence Photography. This method requires U.V. radiations only (and no visible light) falling on the subject, and visible light (but no U.V.) entering the camera. The source must be screened, and an U.V. absorbing camera filter is essential.

The same set-up described above for U.V. photography can be used with the addition of a U.V. absorbing filter over the camera lens. Thus, theoretically, any U.V. radiations reflected by the subject are absorbed by the filter so that, in the absence of a fluorescing substance, no photographic image should be formed. Polished metal will reflect U.V. radiations without fluorescing as well and can be used to test the efficiency of the screen/filter combination. Any image obtained is probably due to a violet component passing through the filter and it is useful to know the extent of this "background" exposure. It is sometimes produced deliberately to obtain a faint orientating image for reference in studying the finished record.

As in U.V. photography, the actual exposure should be made in the absence of room lighting.

Where the fluorescence is gross and of one colour, a black-and-white record may suffice but a colour photograph is more satisfactory in every way. Even when the brightness range extends beyond that acceptable by colour materials a better idea of relative brightness and colour is obtained. If 35 mm. transparencies are adequate, there is little difference in cost.

For black-and-white records a panchromatic emulsion may be necessary as the fluorescence is often reddish in colour. A contrast filter of the same colour as the fluorescence will help to separate a dimly fluorescing subject from its background.

General Applications. The uses to which reflected U.V. and fluorescence photography have been put are numerous. Many of these applications will not even concern the practical photographer in his daily work. The appearance of an object photographed by U.V. and/or fluorescence may be quite unrelated to its normal visible appearance. There is no general rule as to which is the particular method to use for any particular purpose: if the detail which is to be shown can be seen (by presence or absence of fluorescence) then the fluorescence method may be used, but otherwise, only experiment will show whether the required information can be revealed by U.V. photography.

Some of the commoner applications of U.V. and fluorescence photography are:

ULTRA-VIOLET PHOTOGRAPHY SET-UP. The main difference between reflected ultra-violet and fluorescence photography is that an ultra-violet absorbing filter is essential over the camera lens for fluorescence photographs. A, mercury vapour lamp. B, visually opaque, ultra-violet transmitting filter. C, ultra-violet absorbing filter (for fluorescence). D, object plane.

Forensic science: for the examination of forged or altered documents; reflection may reveal the character of erased writing and fluorescence may show up the defaced paper surface or indicate the presence of invisible inks, chemical erasers, etc. Fingerprints on confusing backgrounds may be made to stand out clearly by fluorescence if they are first dusted with a fluorescing powder like anthracene. Sealing waxes differ in fluorescent properties and any tampering with seals may be detected by fluorescence photographs. Some precious and semi-precious stones can be differentiated from paste counterfeits and natural pearls can be distinguished from artificial by fluorescence. Seminal and other body fluid stains fluoresce brightly. Traces of oil and greases can be characterized by their fluorescence, especially after partial fractionation by absorption in filter paper.

Philately: removal of cancellation marks and authenticity of watermarks may sometimes be established by comparison under U.V. irradiation. Watermarks are often forged with oils which may fluoresce, whereas the true watermark would photograph normally.

Industry: textiles, dyes, stains and markings may be compared by fluorescence. (The "invisible" laundry mark which becomes visible under U.V. is a familiar example of such an

application.) Adhesives may also be compared or even identified by U.V. Certain chemical compounds can be traced and identified by their known fluorescent emissions.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Fine art: examination of paintings may be aided by U.V. photography since recent restorations or addition of pigments can be shown up vividly by their increased fluorescence. In such cases the evidence is nearly always confirmed by other means such as chemical analysis and radiography.

Medicine: the presence of body fluids on clothing can often be demonstrated by a change in the general level of fluorescence. U.V. irradiation of the scalp is an important diagnostic test in the detection of ringworm and certain other fungi which have a characteristic fluorescence. Porcelain jackets and artificial dentures are quickly shown up by their lack of fluorescence compared with normal teeth. In the laboratory, U.V. methods have been extended to the examination of bacterial colonies and certain aspects of chromatography. Finally, fluorescence is of importance in revealing traces of industrial oils in the skin crevices, and skin blemishes are rendered more visible by reflected U.V.

It may be necessary to supplement many of these and other methods of U.V. examination by radiography, chemical analysis and even infra-red photography, and in any case interpretation of the results calls for special experience because they present differing visible translations of invisible states.

Surface texture: perhaps the least obvious use of reflected U.V. photography is the rendering of any surface texture. In general, within the spectral range from infra-red to U.V., the shorter the incident wavelength, the more it tends to become reflected from a surface without penetration. Thus infra-red radiation is mostly used to reveal detail beneath surfaces which it can penetrate and U.V. for recording the fine detail of a surface itself. Fluorescence, however, can be excited within some structures by penetration.

Special Applications. The foregoing techniques and applications require normal equipment and make use of only a narrow spectral band. This type of work is within the reach of any competent photographer. A few more precise techniques requiring specialized apparatus involve microscopic methods:

U.V. microscopy: very high magnifications and resolving power can be attained by microscopes designed to utilize U.V. radiation in place of visible light. Because of the selective absorption of the rays, structures can be differentiated without staining, and negligible depth of field makes "optical sectioning" possible—i.e., the photography of thin sections selected simply by focusing and not by actual cutting.

Since glass absorbs all radiations shorter than about 3,500 A. every optical component, including slides and coverslips, must be made of quartz for this type of work. And because it is difficult to achromatize objectives for more than a single waveband, a cadmium arc is commonly used as the source of U.V. radiations. This source gives strong emission lines at 2,750 A. and 2,573 A. either of which can be selected to illuminate the specimen by a monochromator.

The optical system is first centred and focused visually using a mercury-vapour arc as the illuminant. After changing over to the cadmium high-tension spark system the image is no longer visible and final adjustments are made by means of an "artificial eye" consisting of a fluorescing uranium glass screen over which is mounted a strong field lens. This separate focusing system presents a small visible image and bears a definite relation to the true focal plane at which the actual exposures are made. Optical sections of the preparation are photographed by making a series of exposures between which the microscope focusing control is advanced by a known small amount.

In this way it is possible to make extremely detailed studies of planes $\frac{1}{4}\mu$ thick at magnifications ranging from 1,000 to 3,000 diameters.

Colour translating U.V. microscope: an ingenious elaboration of normal U.V. microscopy has been developed in recent years. The system was originally intended to provide coloured images of unstained biological specimens, the colour differences being related to the chemical constitution of the material under investigation.

Three U.V. photomicrographs are prepared of the same field using wavelengths of 2,630, 2,580 and 2,370 A. respectively. Differing selective absorption in these three bands produces corresponding differences in the three negatives. These three photographs are then projected through red, green and blue filters, the individually coloured images being superimposed for final examination. In the original system the negatives obtained by the shortest U.V. band were projected through a red filter and the longest through a blue filter, thus inverting the sequence of wavelengths, but other combinations are possible.

Fluorescence microscopy: the general principles of fluorescence photography may be applied with equal effect to microscopy.

Normal microscope equipment may be used, although any mirror should be made of polished aluminium as silver is a poor reflector of U.V. For best visual results a heavy yellow (minus blue) filter is placed within or over the viewing eyepiece; but for photography it may be preferable to allow a certain amount of visible blue and violet light to be transmitted to give a direct indication of the relationship between the specimen and the fluorescence. This technique is now in general use, and is applied to the examination of unstained material (primary fluorescence), or to preparations

stained with specific fluorochrome dyes (secondary fluorescence).

In some instances fluorescence can be excited merely by placing a deep blue filter over the normal microscope lamp, in which case a green or yellow absorption filter is used at the eyepiece. All such techniques should be regarded as a supplement to normal photomicrography. P.H.

UNDER-DEVELOPMENT. Fault indicating that the developing solution did not act long enough on the sensitized material to produce an acceptable result.

Negatives. An under-developed negative looks thin and lacks contrast. All the detail is clearly visible, but the highlights lack density. It is easy to distinguish from an under-exposed negative which has been correctly developed. The under-exposed negative is thin also, but in this case there is no shadow detail, and the brightest highlights may be somewhere near maximum density.

A normal print from an under-developed negative is flat, lacking in contrast and with no real black tones.

Assuming that the developer is correctly mixed and fresh, under-development may be caused by a mistake in working out the time of development for the sensitized material in the particular developer used or it may be simply due to faulty timing or to insufficient agitation. Other possible causes are that the developer concentration was too low, or exhausted, or that the time of development was not adjusted to allow for a drop in temperature or for the number of films already developed in the same solution.

When developing by inspection, under-development may be due to the photographer's inability to judge the appearance of a fully developed negative.

An under-developed negative may be bleached and redeveloped as in intensifying. This treatment can result in a negative indistinguishable from one correctly developed in the first place. If the amount of under-development is slight, the remedy may simply be to print it on a harder grade of paper to restore the contrast.

Prints. An under-developed print looks pale and washed out. If it was correctly exposed, it will show detail in both highlights and shadows, but there will be no black tones even in the deepest shadow areas. If anything, the tones will be mottled, tinged with a trace of reddish brown. The image will tend to show up more strongly in some parts than in others.

An under-exposed print, that has received normal development, looks quite different. In this case the image is weak, but there is no highlight detail and the shadows are light in tone with only a few, if any, real black areas.

Since prints are developed by inspection, the only reason for failing to leave the print in the solution long enough is sheer inability to recognize a fully developed print. Most beginners tend to lift the print out too soon: the tones always look darker when the print is in the developer than when it is finally dried and looked at in daylight.

Contact paper requires a more concentrated developer than bromide paper, and under-development will result if contact prints are developed in a solution mixed in error to bromide paper strength.

If the temperature of a MQ developer is allowed to fall much below 60° F. (15·5° C.) it will produce under-development.

See also: *Developing negatives; Developing prints; Faults; Under-exposure.*

UNDER-EXPOSURE. Fault indicating that the image formed on the sensitized material was either not bright enough or was not allowed to act long enough during exposure to produce an acceptable image on development.

Negatives. The appearance of an under-exposed negative is characteristic: the shadow areas are clear emulsion without any trace of detail or gradation and only the highlights show a black silver deposit. It is easy to tell the difference between an under-exposed negative and one that has been correctly exposed, but under-developed. The under-developed negative will bear a distinct but thin image of shadow detail, but the highlight areas will lack density and appear greyish. An under-exposed negative looks contrasty but generally gives flat contrast in the shadows. An under-developed negative looks flat and gives a soft, flat print with no strong contrast at either end of the scale.

The commonest cause of under-exposure is simply failure to estimate or measure the light intensity accurately, and to adjust the shutter speed and lens aperture to give an adequate exposure to the sensitized material in use.

In flash photography it may be the result of faulty synchronization or of wrong calculation of the stop and subject distance.

In the first place, the method of estimation may be faulty, or the exposure meter may be faulty, or it may not have been set for the right speed of sensitized material. It is also possible that the meter has been used incorrectly—e.g., pointed too much towards the sky—or that the correct allowance has not been made for such additional factors as subject brightness and contrast, the filter in use, the direction or colour temperature of the light, and the developer

which will be used—some fine-grain developers reduce the effective emulsion speed and call for a substantial increase in exposure time.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

Finally, the shutter itself may be faulty.

There is very little that can be done about an under-exposed negative. If the exposure has been insufficient to record detail in the shadows, no subsequent processing can put it there. Continued development simply increases the density of the highlights, making them print out whiter and whiter, while the shadows remain a featureless black.

Intensification is no more likely to succeed than over-development, and the results are similar. The only aftertreatment likely to yield a better picture is optical intensification—i.e., the negative is set up against a white background and copied by reflected light. Even this method is useless unless there is some slight suggestion of detail in the shadows.

Prints. An under-exposed print looks pale and washed-out. The shadows are grey and the highlights are featureless areas of blank paper. Such a print cannot be improved by being left in the developer.

An under-exposed print can be distinguished from one that has been correctly exposed but under-developed by the fact that in the under-developed print all the detail in both highlights and shadows is visible but there are no good black tones anywhere. If anything, the tones in an under-developed print tend to be of a warm or muddy colour and in extreme cases may be mottled. In an under-exposed print, most of the detail is absent and all visible tones are a light grey except in the extreme shadows.

The print has not been left long enough under the printing light. If a test strip was used, then the section selected as giving the best reproduction may have been too pale. It is important to remember that the image tones always look darker under the safelight, especially a deep orange one, than they do in the finished print in daylight.

In enlarging, the trouble may be that the scale of enlargment has been increased without making a corresponding change in the exposure. Or the lens may have been opened up a stop and the exposure halved when, owing to the concentration of light rays at the centre of the lens, very little reduction should have been made.

If an automatic timer is used for the exposure, it may not be giving times that correspond with the times of the test strip.

Nothing can be done to improve the tones of an under-exposed print.

The remedy for under-exposure is to make one or more tests on strips of paper from the same packet and to choose the section that looks just too dark under the safelight. If a big change is made in either the magnification or the lens aperture, a fresh test should be made.

Both the test strip and the finished print should be developed for the full time recommended by the maker of the paper to obtain the best image quality.

UNDERWATER PHOTOGRAPHY

Underwater photography remains a somewhat esoteric art despite the fact that most people are now familiar with underwater photographs. The reason for this is probably that it is a branch of photography that must be embarked upon wholeheartedly or not at all. The would-be underwater photographer must obviously be able to dive, and if using a standard camera, he must be prepared to expend some effort in preparing it for a sub-aquatic environment.

History. Underwater photography was first attempted in 1856 by William Thompson at Weymouth, England. The camera, in a watertight box, was lowered from a boat to the seabed 18 feet below, and the drop shutter held open for 10 minutes by pulling a long string from the boat. A passable picture of seaweed and sand was obtained. Ten years later a French photographer named Bazin went down in a diving bell with watertight port-holes through which he photographed by electric light from a Bunsen battery. His purpose was to make the reclamation of sunken ships easier. In 1893 Louis Boutan photographed in a diving suit in the Mediterranean. He used a magazine plate camera sealed in a metal box with a glazed opening for the lens. Exposures of ten to thirty minutes were necessary, depending on the depth. Below 15 feet, artificial light was needed. After experimenting with two forms of magnesium light, Boutan in 1899 used with greater success submarine searchlights charged from a dynamo on board a boat, and a camera with an electro-magnetic shutter operated from the boat, with which instantaneous pictures could be taken and greater depths explored. Boutan wrote the first book on underwater photography *La Photographie Sousmarine* (1900) in which he foresaw that one day underwater photography would be practised by amateurs as a new sport.

EQUIPMENT

Underwater Cameras. As the result of the increasing popularity of underwater photography, cameras designed specifically for this purpose are available.

The bodies of such cameras are constructed of pressure- and corrosion-resistant materials, with the controls operating through water-

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

SELF-CONTAINED UNDERWATER CAMERA. This type of design needs no separate pressure proof-housing. The main parts of the camera—the fim holder and transport unit A, the outer housing B, and the lens unit, C—fit together with pressure-tight seals. The interchangeable lens unit incorporates the aperture and distance controls which connect through water-tight glands. A single lever, also working through a gland, operates the fim transport and shutter release.

tight glands. Standard lenses are usually hermetically sealed behind flat glass portholes. This enables the cameras to be used above and below water without modification.

Standard Cameras. Because of the limited range of underwater cameras, the majority of divers use a standard camera enclosed in some form of waterproof housing. As the cost of such cases is linked with the number of controls, and the ease with which they can be remotely manipulated, the choice of camera is of considerable importance. Rigid housings have to withstand considerable pressures underwater and are kept as compact as possible.

The number of controls necessary to operate the camera should be kept low as possible. These have to operate through watertight glands in the case and are therefore possible sources of leakage. Also, they are susceptible to mechanical malfunction. Thus a small camera with a coupled exposure meter and a mechanism that advances the film and cocks the shutter is preferable to a larger model that requires four separate manipulations to operate the same number of controls. These parameters are satisfied by a wide range of 35 mm. cameras. So 35 mm. models are the most popular size of still camera used underwater. The same criteria can be used to judge the suitability of cine cameras for underwater use.

The range of waterproof housings used to accommodate standard cameras for sub-aquatic use can be divided into three basic categories: pressure-compensating, pressure-resistant, and internally pressurized.

Pressure-Compensating Housings. The simplest type of case employs the pressure compensating principle used by Boutan. His first camera housing had a small air-filled balloon attached to a short length of tubing that connected with the inside of the case. As the diver descended the increasing water pressure compressed the air inside the balloon, which in turn transmitted the pressure to the inside of the camera case. The build up of considerable pressure differences between the inside and outside of the case was thereby prevented, and the possibility of water leaking into housing reduced.

Nowadays, however, the pressure compensating device has a dual purpose. It usually takes the form of a rubber glove through which the diver manually operates the camera controls. The advantage of this type of housing is that it does not have to be tailored to a specific camera. As the controls are operated by hand, a range of cameras can be used in a single case.

There are two main disadvantages: one is the relatively fragile and perishable nature of the thin rubber components. The second, and perhaps more important, reason is that the limiting depth to which such cases can safely be taken is usually in the region of 30 feet. The reason for this is that the air enclosed inside the housing decreases in volume according to Boyles Law. At a depth of 33 feet the pressure is double that on the surface. At this depth, therefore, the volume of air inside the case is reduced by half when the pressures equalize.

Pressure-resistant Housings. The most widely used type of case consists basically of a rigid box capable of withstanding the pressures encountered under water. The forces to which such housings are subjected are quite considerable, as the pressure increases by 14·7 pounds per square inch for every 33 feet the diver descends. An 8-in. cube, for instance, is subjected to a force of over 3 tons at a depth of 60 feet.

A sphere is the ideal shape to withstand such pressures, but the inherent difficulties of construction usually preclude its use. Instead the housing takes the form of a rectangular box with a removable side or lid. The camera is fixed inside the box and "looks" through a glass or Perspex window. The camera is operated via

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

UNDERWATER HOUSING. Usually underwater housings have to be designed for individual cameras. This model for a twin-lens reflex has outside controls for all the camera operations, and will also take a flash unit. The controls are linked to a suitable coupling mechanism inside the case, and pass through water-tight glands in the body.

controls that pass through watertight glands in the body of the housing. A variety of methods are employed to provide these watertight seals. One popular method utilises a greased string packing compressed round the shaft of the control rod. A more sophisticated method is to use "O" ring seals upon which the compression can be varied. The seal between the box and its gasket is achieved with the aid of a continuous flat rubber gasket, or an "O" seal.

A considerable range of materials is used for the construction of such housings. Perspex is popular because it is transparent and has the advantage that the camera settings and controls can be inspected visually. Wood, metal and fibre glass are also used.

Rigid housings are often fitted with valves which enable them to be internally pressurized with a hand pump. Increasing the internal pressure serves two purposes. Firstly it helps to balance the external pressure when the camera is taken deep. Secondly, it acts as a leak detector. For if the camera is immersed in water a tell-tale stream of bubbles issues from any leaking seals.

The weight of a housing is usually adjusted so that it is slightly negatively buoyant when it contains the camera. This enables it to be comfortably carried by the diver with the aid of a neck strap.

A fairly wide selection of rigid camera housings is now commercially available. In addition to models designed for specific cameras, these include several general purpose types that can be tailored by the manufacturer, or the purchaser, to suit the camera in question.

Automatic Internal Pressurization. The most elaborate type of underwater housings are automatically pressurized internally. This principle is only warranted in large housings, where the dimensions render the construction of a rigid housing impractical. In such units the case containing the camera is connected to an air cylinder fitted with a device similar to a diver's demand valve. As the unit is taken deeper, air passes from the cylinder into the case until the internal pressure is slightly greater than the external pressure. As the diver ascends the excess air leaks from the case via a one-way valve. As no great pressure differentials are built up, large housings of this type, of relatively light construction, can be used to any depth accessible to the aqualung diver.

Portholes. Cases made of opaque materials must be fitted with a transparent window or porthole for the camera to "see" through. When light rays pass from water to air they are bent due to refraction. This results in a reduction of the field of view when a camera is used behind a flat glass porthole to photograph an underwater subject. Special portholes have

USE OF UNDERWATER CORRECTION LENS. Top: Difference of refractive indices together with flat window causes distortion and reduces angle of view. Bottom: The Ivanoff correction lens eliminates aberrations caused by refraction in water, and compensates for reduced angle of view and for apparent reduction in subject distances. Beyond the wavy line (the "blue wall") water turbidity makes sharp images impossible.

been designed to overcome this effect. They are, however, expensive, and have to be accurately aligned with the camera. They are seldom used. Most housings are fitted with optically flat portholes made of glass or Perspex.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Condensation. As the temperature of the water is generally lower than that of the air at the surface, there is always a tendency for moisture to condense on the inside of the viewing and taking windows in plastic containers. This is particularly so with the flexible pressure-equalizing types when the air becomes compressed. One way of counteracting this is the inclusion of a dehydrating agent—e.g. capsules of silica gel—in the housing. In a metal container any condensation takes places on the metal which is colder than the glass.

Viewfinders. If the diver can see through the viewfinder when the camera is encased in its underwater housing there is no reason why he should not use it underwater, as it will indicate the true field of view accepted by the camera. Housings for reflex cameras may include prism and other devices for direct observation of the screen image. Usually, however, it is impracticable to use the viewfinder in this way. Most underwater camera housings are therefore equipped with an external direct vision frame finder. The separation of the front and back sights is increased to compensate for the reduced field of view. The need to correct such viewfinders for parallax is also important because of the increased separation of the viewfinder from the camera. This is usually achieved by making the back sight adjustable. When located above the camera the rear sight is raised for close-up shots.

Rangefinders. As with viewfinders, it is usually impossible to use a rangefinder attached directly to the camera when it is enclosed in its watertight case.

The refractive index of water is 1·33. This has the effect of making underwater objects appear closer to the diver. As the lens of a camera behaves in much the same way as the lens in the eye it must be focused at the apparent, and not the real distance of the subject, to obtain a clear picture. If a rangefinder can be used, the camera lens should be set at the distance indicated by the rangefinder as it will automatically correct for the foreshortening effect of the water.

Distances greater than 3 feet can usually be guessed by the photographer with sufficient accuracy. Distances of less than 3 feet can be measured with the aid of a focusing stick. This is a stick 4 feet long, marked to represent 3 underwater feet.

Underwater Lighting Equipment. When light strikes a water surface some of it passes into the water, and a fraction of it is reflected. The percentage of the light reflected varies with the angle of the source, and is a minimum when the light rays are perpendicular to the interface. The intensity of light just below the surface is therefore always less than it is above water. The light that passes into the water can be attenuated in a number of ways; by bubbles, suspended particles, and absorption by the water itself, which absorbs various colours to different extents. The overall result of these effects is that the light intensity underwater is lowered, its intensity decreasing with increasing depth. In addition, there is a pronounced change in its colour balance. As a result it is often necessary to supplement the natural lighting in some way to obtain adequate exposure for black-and-white films. To take colour films with a full colour range it is essential to use additional lighting below a depth of 20 feet.

For the still photographer, additional lighting can be achieved cheaply and simply by the use of expendable flash bulbs. The bulbs can be used in direct contact with water. They can be placed in an external reflector and changed by hand. The reflector should be positioned as far away from the camera as possible to reduce the particle illumination effect to a minimum. The electrical components of the flash gun can be located inside the camera case. Some underwater housings have special compartments for this purpose.

The low voltages used to fire flash bulbs will do no more than make the photographer jump should he accidentally get a shock. The same cannot be said of the circuits used to energize electronic flash tubes which operate at much higher potentials. The voltage from these could be lethal. So when electronic, or strobe, flash is used under water, the entire unit must be enclosed in a reliable watertight housing.

The use of electronic flash underwater was pioneered in the 1950s by Dimitri Rebikoff who housed the components in a long metal tube. The flash tube was placed in the nose, and the unit named the "torpille", or "torpedo". As a result of the current trend in miniaturization, it is now possible to construct, or buy a much more compact unit. It is a practical proposition to incorporate an electronic flash unit into a small separate housing.

The cine photographer must have a continuous source of lighting, which has to be of considerable power if it is to be of any use under water. For lighting large areas, waterproof lamps connected via heavy cables to generators on the surface are useful. For close up work, self-contained, battery-powered units can be used. Rebikoff utilized a torpedo, containing silver-zinc batteries, with a projection lamp located in the nose. The batteries were also used to power a propeller at the rear end of the torpedo. With the camera, enclosed in its case, mounted on the side of the torpedo, he had a mobile, self-contained, filming unit. Underwater lighting units containing standard batteries and highly efficient, cool running, tungsten iodide projection lamps are now commercially available.

Diving Equipment. An obvious prerequisite to

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

UNDERWATER TORPEDO. The complete casing incorporates an electronic flash unit, and on some models an electric driving motor which even pulls the swimmer along. The front of the torpedo carries the flash tube, the centre the capacitors and accumulators, and the rear portion holds the controls as well as the camera in its own pressure-proof casing.

taking underwater pictures is that the photographer should be able to dive. The use of standard diving equipment—consisting of a rubber suit, and a copper helmet into which air is pumped from the surface—is becoming obsolete, and is not suitable for underwater photography. The alternatives are snorkel diving, and free diving.

When snorkel diving, the underwater swimmer uses only basic equipment, i.e., facemask, fins, and snorkel tube. The facemask enables the diver to see clearly underwater, the fins increase his swimming power and manœverability, leaving his hands free to operate the camera, and the snorkel tube enables him to breath with his facemask submerged—permitting him an uninterrupted view of the underwater scene. Some divers can attain depths of 100 feet using such equipment. The duration of their stay underwater is governed by the length of time they can hold their breath.

The free diver can use either an oxygen rebreathing set, or an aqualung. Oxygen sets, which were developed for military purposes, can be used to a maximum depth of about 40 feet. They can be hazardous and are not therefore recommended.

The most suitable diving equipment for the underwater photographer is an aqualung. This consists basically of a cylinder of compressed air fitted with a valve that supplies the diver with air at the pressure of his surroundings. It is simple to use, and perfectly safe, providing the diver follows a well-defined code of rules. Before commencing with his photography, the diver should master the use of the aqualung so that he can deal confidently, and automatically, with any situations that he is likely to meet under water. Once this is achieved he can give all his attention to photography.

MATERIALS AND TECHNIQUES

Only in very foggy conditions does the visibility above water fall below 40 yards. Underwater a visibility in this region would be regarded as very good. It is usually much less. This, coupled with the change in colour balance and considerable variations in light intensity, present the photographer with a challenging and rather unique set of conditions which require a special approach.

Films. The underwater world is one of soft diffuse lighting and low contrast subjects. The use of the slow films which usually produce a negative of high contrast is therefore indicated for black-and-white photography. Unfortunately, the low light intensity usually precludes the use of the slowest films. A compromise choice is the slowest film commensurate with the depth and lighting intensity of the underwater scene.

The equivalent difference in colour brilliance between slow and fast colour films is not so apparent. Thus a fast colour film is recommended. The speeds of some colour films can be considerably up-rated by modifying the development procedure. This factor can sometimes be used to the photographer's advantage by extending the maximum depth at which colour photographs can be taken.

Filters. Minute suspended particles reflect and scatter light underwater, thereby reducing the visibility and producing a hazy effect. The scattered light lowers the contrast and definition of monochrome pictures, tending to give them a flat and lifeless look. As much of the scattered light is in the blue end of the spectrum it can be partially eliminated by the use of yellow filters. Although the use of yellow filters enables brighter pictures to be taken when conditions are poor, they cannot be regarded as a substitute for good visibility. Collectively, suspended particles present a physical barrier through which light cannot penetrate, and filters cannot increase transmission. As a general rule, clear pictures can be taken when the distance between the subject and the camera is less than one-third of the underwater visibility.

The use of filters in colour photography is a controversial subject. With increasing depth underwater there is a change in colour balance in addition to the overall lowering of light intensity. As no red light penetrates more than 30 feet underwater, photographs taken below this depth have a monochrome blue-green

appearance. The photographer can therefore either reproduce the scene as he sees it (by not using filters), or he can try and reverse the change in colour balance and give his pictures an "on the surface" colour rendering. The loss in red light can be corrected for by the use of CC-R filters which have a high red transmission. The strength of filter to give full correction is determined by the total underwater path length of the light, approximately four filter units being added for every foot. A CC 5OR which should be used when the path length is about 12 feet requires an increase in exposure of one stop. It is impossible fully to correct for the loss of red light at depths below 20 feet. Only supplementary lighting can yield pictures with a full colour range below this depth.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Exposure. The percentage of light penetrating to a given depth depends upon many variables. The use of an exposure meter is essential unless the diver is very familiar with conditions. The meter is used in the usual manner. It can either be located in the camera case, or in its own separate housing. It is sometimes advisable deliberately to underexpose monochrome films and prolong the development in order to obtain a higher contrast negative.

Flash. When using flash above water the exposure is derived from the flash factor, which assumes the flash is the sole source of illumination. The attenuation of light under water, and the general lack of reflecting surfaces, considerably reduces the illuminating power of a flash bulb. The loss depends upon the prevailing conditions, but as a general rule dividing the normal flash factor by five gives a reasonable correction.

When the flash reflector is located near to the camera, small particles suspended in the water close to the camera are relatively intensely illuminated. As they are usually out of focus they appear as unsightly circular white blotches on the final print. The flash reflector should therefore be positioned as close to the subject as possible—but out of the field of view of the camera. In this position the illuminating power of the flash is increased, and the particle-illuminating effect is reduced to a minimum. The haze produced by scatter of the flash light can be reduced by the use of yellow filters. With colour film, however, such filters give the picture an unnatural yellow cast.

Flash bulbs for use with colour daylight films are normally coated with a blue filter to remove some of the excess red light. However, water itself preferentially absorbs red colours tending to balance the spectral distribution of the light. Colourless bulbs are therefore preferable for colour pictures under water.

Subjects. The underwater world abounds with subjects. An obvious one for the diver is his diving companions. The weightlessness of the diver under water can be used to advantage by the photographer as it enables the subject to assume a great variety of positions. If the model is wearing an aqualung, wait until a plume of bubbles is rising from the demand valve before releasing the shutter. The play of light on the bubbles not only has an intrinsic beauty, but it does gives a picture a truly underwater atmosphere. The use of wide angle lenses enables the camera to get closer to the subject. This greatly enhances distortion due to perspective. Divers should therefore move parallel to the camera and keep their hands by their sides.

A flat sandy seabed is usually relatively lifeless, and is not very photogenic. A rocky area contains more abundant life and a greater variety of natural backgrounds. Caves, gulleys and arches can all be exploited to provide a framework in which the major subject can be posed. Wrecks are ideal objects for exploration and can provide the cameraman with a wealth of exciting material.

With increasing experience the diver subconsciously acquires the lore of the underwater world. He can find and photograph the habits and haunts of underwater animals that pass unnoticed by the novice. A cardinal rule when photographing fish is to swim as quietly as possible. Most fish can swim much faster than a diver and they will quickly take flight if the diver makes vigorous erratic movements. Many fish are naturally inquisitive, and will swim right up to the photographer if he sits quietly and patiently on the bottom. Fish can

COLOURS UNDER WATER. Water acts as a strong filter and cuts out some of the colours of white sunlight. At 3 feet below the surface, half the red is filtered away; at 16 feet all red, at 33 feet all orange, at 66 feet all yellow and violet. At 100 feet everything looks blue-grey. Electronic flash or other artificial light will of course show a full range of colours.

often be attracted to a specific site by scattering pieces of broken-up shell fish in the area. This practice, known colloquially as chumming, was used by Boutan who could not readily move his cumbersome camera housings.

CC-0. Agamnam Digital Preservation Foundation, Chandigarh

The problem of the small size of the subject can be solved only by working close to it and producing a large image in the first place. Working with a long-focus lens from a distance is not satisfactory because of the murkiness of the water; for the same reason the quality of a small image taken from a normal viewing distance is too poor to give a good enlargement.

When selecting a subject for underwater photography it is the result that counts, not the risk to life and limb that goes into procuring it. The diver will find that his best results with natural lighting are obtained in shallow water where the light is brighter and the subjects have a much greater contrast than when photographed at depth.

Darkroom Techniques. Increasing the development time will give negatives of greater contrast. If the photographs were taken in dull conditions the film should be developed to a gamma of 0·8 to 1·0. The development times necessary for this can be found in the data sheets available from the film manufacturers.

Underwater negatives are often too soft to produce a bright print on normal printing paper, and very hard papers may be necessary to obtain the desired result. As such papers have a limited exposure latitude, differential shading of various parts of the print may be called for.

CINE

For underwater filming, 8 mm. cameras with fast wide-angle or zoom lenses, and coupled exposure meters are ideal, and underwater cases for many such cameras are available.

The shorter focal length of lenses used on 8 mm. cameras yields a considerable depth of field, even at the widest apertures. This gives well-defined pictures over a wide range of camera-to-subject distances. Fixed focus lenses are therefore quite adequate for most purposes.

An 8 mm. camera, with a fixed focus lens and a coupled exposure meter, is very simple to use above and below water. It is the ideal medium for recording people and the natural world that lies beneath the waves. Weightlessness gives the underwater movements of man and fish an intrinsic grace and beauty that can never be captured in a still photograph. 16 mm. film should be used when the product is intended for showing to large audiences, or for television.

It is sometimes advantageous to fit horizontal fins to the camera case. They help stabilize the camera, and enable the diver to take smooth tracking shots.

It is often difficult to keep the camera steady in shallow water where there is a strong tidal swell. One solution is to attach the camera to a tripod. An alternative is for the diver greatly to overweight himself so that he can sit, or kneel, on the bottom with some stability. A somewhat safer alternative is for the diver to provide himself with a rigid support of some kind about which he can entwine a leg or arm.

As in normal cine filming, underwater sequences should be planned beforehand. As it is impossible to communicate verbally underwater, the photographer must give the participants in the film clear directives on the surface. A prearranged code of simple hand signals can be used underwater.

The photographer should bear in mind that a large portion of his audience is likely to be unfamiliar with the underwater world. He should therefore hold his underwater shots for much longer than above water sequences. The audience can be prepared for the sub-aquatic sequences by being shown the divers getting ready to enter the water. Underwater, the scene can be set by showing a group of divers leaving the surface and heading towards the sea bed. This can be followed by a sequence showing a single diver reaching the sea bed. The photographer can then show the natural inhabitants of the underwater world in close-up.

Fast-moving fish are best photographed at a faster camera speed. When the film is projected at normal speed the movements are slowed down.

This has the double advantage of prolonging the sequence and of enabling the audience to appreciate more fully the artistry of movement of those ever-mobile inhabitants of the sea.

DEEP SEA PHOTOGRAPHY

When discussing underwater photography one generally thinks in terms of photographs taken by divers. The depth to which divers can safely descend with a standard aqualung varies with the individual. The maximum is in the region of 300 feet. The greater part of the sea bed lies at depths much greater than this. Cameras have been developed that can be operated by remote control in the deepest oceans of the world.

Foremost in the field of deep sea photography is Professor Harold E. Edgerton, of the Massachusetts Institute of Technology. He has developed a photographic unit capable of withstanding pressures in the region of 17,000 pounds per square inch. Working in conjunction with a pioneer of underwater exploration, Commander Jacques Cousteau, Professor Edgerton has provided conclusive proof that life does exist in the depths of the ocean.

One of the cameras developed by Professor Edgerton can take up to 2,000 pictures on 35 mm. film stock at signalled time intervals. For use at great depths, the camera is mounted on a frame and lowered by cable from the research ship. The frame also carries an electronic flash unit that is synchronized with the

camera. The height of the camera above the sea floor is determined by a sonar (radar) gauge on the camera. The pinger simultaneously sends a pulse, or signal, downwards, and another upwards. The camera to bottom distance can be determined by the difference in time it takes the pulse bounced from the bottom, and the direct signal, to reach a receiver under the ship. In this way it is possible accurately to position the camera a few feet above the sea bed despite the fact that it may be more than 15,000 feet from the surface. H.E.D.

UNIFORM SYSTEM (U.S.) System of stop numbers proposed in 1881 by the Royal Photographic Society. Based on *f*4 as the unit, a stop requiring twice the exposure was marked 2; three times the exposure, 3; half the exposure, $\frac{1}{2}$, and so on. The idea never became popular and has not been used for at least twenty years.

However, the practice of marking enlarging lenses to indicate relative exposures is on the increase. These lenses are marked with numbers in the series 1, 2, 4, 8, 16 and so on, taking the larger stop as equal to 1.

UNITED STATES OF AMERICA

Towards the end of September, 1839, less than a month after the public disclosure by the French Government of Daguerre's invention, daguerreotypes were being taken in the United States. Of the several scientifically-minded men who re-created Daguerre's technique from the detailed specifications contained in his instruction manual, the most prominent was Samuel F. B. Morse (1791–1872), best known for his work in the development of the electric telegraph.

Daguerreotypes. Morse showed his first successful daguerreotype, a view of a church in New York taken with an exposure of 15 minutes, on 28th September, 1839. Most early daguerreotypes, like Morse's, were views of buildings, to judge from the accounts of them. Only one has survived; a small ($1\frac{1}{4} \times 2$ ins.) and imperfect view of the Philadelphia Mint, taken by Joseph Saxton in October, 1839. Not until François Gouraud (died about 1848) arrived from Paris in November, to teach and demonstrate the process, did daguerreotyping become firmly established in America. His first step on arriving in New York was to arrange an exhibition of daguerreotypes taken by Daguerre himself. The display was a revelation, for Americans had no idea of the potentials of the process, and the pictures on view were vastly superior to anything which had been done in America. Gouraud gave private instruction in daguerreotype; S. F. B. Morse was one of his first pupils.

Within a matter of months, Americans began to improve the process, particularly with a view to making portraits. In New York, Alexander S. Wolcott (1804–44) and John Johnson (active 1839) patented a new kind of camera, in which a mirror was used instead of a lens, and with their invention they were able to take miniature portraits. It is hardly possible, owing to lack of documentation, to single out any one of the pioneer daguerreotypists as the first to make a portrait. There is evidence that Wolcott, Morse, John W. Draper (1811–82), and the Philadelphian Robert Cornelius (1809–1903) all took portraits before the year 1839 had come to a close. The question is academic, for portraiture was not practical. The sitters had to suffer the direct sun for minutes on end and the results were very small.

The world's first public portrait studio was opened by A. Wolcott in New York, March, 1840. By 1841 portraitists opened galleries in all leading American cities. Yankee ingenuity overcame many of the problems of preparing plates and making them more light-sensitive, and soon American daguerreotypes received critical acclaim abroad; in the London Crystal Palace Exhibition of 1851, for example, more prizes were awarded for photographic displays to Americans than to any others. Daguerreotyping was not limited to portraiture, and magnificent daguerreotypes of city views, landscapes, buildings, locomotives, ships, steamers and even news events exist.

The daguerreotype lingered longer in America than in England or on the Continent, and was not entirely displaced until the late 1860's.

The paper negative technique published by William Henry Fox Talbot in London just before the disclosure of the daguerreotype was hardly used at all in America. The only professional use of Talbot's calotype was by the Philadelphia firm of William Langenheim (1807–74) and Frederick Langenheim (1809–79), who bought the American rights for the patent. They had, however, small success in promoting the process, perhaps because Americans preferred the brilliant detail of the

daguerreotype, and perhaps because photographers resented having to pay a licence fee when the daguerreotype could be practised at no cost.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Two glass plate techniques were patented in 1850, both apparently identical with the albumen plate process of the Frenchman Niépce de Saint-Victor. The Langenheim brothers showed, at the London Crystal Palace, positives on glass which they called hyalotypes, and in Boston John Adams Whipple (1823–91) launched his crystallotypes. Although neither process was suited to portraiture, owing to extreme lack of sensitivity of the albumen emulsion, they proved useful for lantern projection and making copy negatives of daguerreotypes from which an unlimited number of paper prints could be made.

Collodion Process. To the nineteenth century American daguerreotypist, photography meant but one thing: the collodion process of Frederick Scott Archer, invented in England in 1851. One by one, and not without real regrets, daguerreotypists gave up the silvered copper plate, buff stick, coating box and mercury bath for the glass plate, collodion vial, and silver bath of the wet plate worker.

The new collodion process was first used in America to make imitations of daguerreotypes. The ambrotype was simply a direct positive, made on a collodion plate, backed with black. The technique, unsuccessfully patented in 1854, was in use through the Civil War. The tintype, called the ferrotype or the melainotype when it was patented in 1856, was identical with the ambrotype, except that a sheet of iron, japanned black, was substituted for glass. Because the materials were inexpensive, the technique simple and the processing rapid, tintypes became extremely popular for cheap portraiture.

The first widespread use of the collodion process for making negatives was by portraitists who supplied cartes-de-visite and by travelling photographers who made stereoscopic views.

Stereoscopy. If stereoscopic photography was slow in starting in America, it quickly grew into a major part of the photographic industry. Following the publicity of the stereoscopic daguerreotypes shown at the Crystal Palace in London in 1851, a few experiments were tried in America. Southworth and Hawes in Boston built a mammoth Wheatstone viewer to take whole plate ($6\frac{1}{2} \times 8\frac{1}{2}$ ins.) daguerreotypes, and charged admission. A daguerreotype case, with viewing lenses set in a flap inside the cover, was patented in 1853. But the daguerreotype was not suited to stereoscopic work, because it was difficult to view the mirror-like images.

At the time the Civil War broke out, stereo was part of the American scene. Oliver Wendell Holmes (1809–94), physician, philosopher and writer, devised a simple skeleton-type viewer and wrote on the pleasures of collecting in the *Atlantic Monthly*. The stereoscopic camera became an important tool for showing America to Americans.

Documentary Photography. The value of photography as a means of preserving for the future the very look of a place and a time was early recognized in America. Portraits of famous Americans were collected to form National Galleries of Daguerreotype Miniatures. One of the first to form such a collection was Mathew B. Brady (1823–96), a maker of leather cases for instruments and miniatures, who became interested in daguerreotypes when he began to make cases to hold them. In 1844, he opened a daguerreotype gallery in New York, which became the fashionable place to have one's likeness taken. Soon he had a gallery in Washington. He published a folio volume of lithographs made from daguerreotypes which he had collected. It was a failure, but Brady was established as a photographic historian.

When the Civil War broke out, Brady determined to make an historical record by means of photography. Collodion plates had replaced the daguerreotype, and Brady sent out operators into the field with a travelling darkroom. The result of this undertaking was the creation of a vast record of the war. Thousands of pictures were taken, which Brady published. His cameramen were equipped with both view cameras and stereoscopic cameras, so that the record exists in three-dimensional form as well as in large single prints. The scheme was a bold one, but it was the financial ruin of Brady. After the war people did not want to be reminded of what the country had been through and did not buy prints. One part of his collection was sold for non-payment of storage and acquired by the War Department; it is now in the National Archives. Another part eventually found its way into the Library of Congress.

Some of the photographers who had created Brady's project went West with government surveys to photograph the unknown parts of the country and the building of the transcontinental railroad; from their photographs we have a vivid picture of the opening of the American West.

Eadweard Muybridge (1830–1904), an Englishman who had emigrated to California, was the first successfully to photograph a horse in full gallop. He was asked to undertake this seemingly impossible assignment in 1872 by Governor Leland Stanford, who owned extensive stables in California and was a great student of hippology as well as a racing man. Muybridge succeeded in the summer of 1878 by using a battery of cameras, a white-washed background, and a track sprinkled with powdered lime.

Although he was using the slow wet collodion process, he secured remarkably detailed photographs showing clearly the position of a horse's feet in the gallop, the trot, the walk and the pace. In 1885, using dry plates and perfected cameras, he produced nearly 800 sequ-

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

ence photographs of the human figure and all kinds of animals. They were published in Plates as *Animal Locomotion*. His analytical photographs of action were at first disbelieved. In 1880, to prove their validity, he reconstructed the original action by projecting each photograph of the sequence on a screen in rapid succession. The result, though crude, was the first moving picture.

Dry Plates. American photographers shared with their overseas brothers impatience with the wet-plate process, which chained the photographer to a dark tent, in which to prepare the fugitive sensitive material. Attempts to increase the sensitive life of collodion by the addition of hygroscopic materials to keep the emulsion moist were not successful. Carey Lea of Philadelphia (the first American photographic scientist to win international recognition) devised a dry collodion technique, but the plates were very slow.

Gelatin dry plates, which eliminated all drawbacks of the collodion process, were invented by the Englishman, Richard Leach Maddox, in 1871 and soon improved by others. The first American known to have used this process was a Rochester, New York, bank clerk named George Eastman, who in 1877 imported gelatino-bromide emulsion in shredded form (known as pellicles) from England. He had taken up photography as an amateur, and quickly became dissatisfied with the collodion process. Reading in English periodicals of the new dry plate experiments, he at once began to investigate the process. Within a year he was making his own emulsion, following Charles Bennett's formula. His friends found his plates so good that he decided to go into the business of making them. He visited England in 1879 with drawings for a plate-coating machine which he patented, and on his return began to build a factory. In 1880 he was in business for himself.

Roll Film. Before many years, Eastman had devised a substitute for glass plates: rollable sensitive material to fit into a roll holder that could be put on any standard camera. He called this new material American Film. It was paper, coated with, first, a layer of soluble gelatin, and second, light-sensitive gelatin. After development and fixing, he stripped the layer of gelatin which bore the camera image from the paper support, dried it in contact with a piece of clear gelatin, and thus produced a transparent negative. It was an awkward technique so far as the processing was concerned. But it enabled him to design in 1888 a small, hand-held camera, loaded with material for one hundred pictures, which was simple to operate. After the last picture had been taken, the entire camera was returned to the Eastman factory, where the film was processed by experts, and a hundred mounted prints were returned. Eastman named this new camera of his the Kodak, a word invented by him.

The Kodak was typical of the many hand cameras which made possible a new kind of photography. No skill was required, and anybody could take pictures of a sort simply by pressing a button. Within a year, Eastman introduced a much superior sensitive material, a true film of transparent cellulose nitrate, coated with gelatin emulsion. It was this film which Edison used in his motion picture system. The first inventor of celluloid roll film was, however, the Rev. Hannibal Goodwin.

The Amateur. The dry plate and film developments led to an enormous increase in amateur photography, which had begun in America with the introduction of the collodion process. A lively Amateur Photographic Exchange Club flourished just before the outbreak of the Civil War in 1861. But the new dry processes of the 1880's so facilitated photography that more and more people were attracted to it as an avocation.

It was the amateur who established pictorial photography in America. One man was responsible for focusing the attention of American photographers on the aesthetic: Alfred Stieglitz (1864–1946). He first became interested in photography in Berlin, where he became a student of Hermann Wilhelm Vogel, the great photographic scientist who discovered spectral sensitizing of photographic materials by the use of dyes. Under Vogel's instruction, Stieglitz gained a thorough technical knowledge and put this to use in making photographs which instantly won critical praise. England was the home of artistic photography in the 1880's, and Stieglitz's photographs appeared in every exhibition. P. H. Emerson, the founder of the "naturalistic photography" movement, awarded him the first prize. Critics were so enthusiastic over his work that they regretted he was not an Englishman.

On his return to America in 1890, Stieglitz was disappointed to discover that artistic photography hardly existed in his native land. He urged the formation of an American salon, became the leader of the New York Camera Club, made its periodical one of the finest in the country and through his energy brought into being what was dubbed the New American School. In 1902 the Photo Secession—a society based on the Linked Ring of England—was formed, and Stieglitz began the publication of the famous magazine, *Camera Work*, which won for him the Progress Medal of the Royal Photographic Society.

The Modern Style. Around the time of the outbreak of World War I, photography all over the world reached a turning point. If the established styles did not imitate painting, they certainly emulated that medium. Photographers now became aware that the camera had an aesthetic of its own. Except for occasional experimental departures, Stieglitz had always used the camera direct, without distorting the image. Edward Steichen (1879–),

his close associate in the Photo Secession and a leader of the New School of 1900, changed his style completely at the end of World War I, preferring the sharp, unaltered image of the lens to the soft-focus effects on which he had built his fame. Charles Sheeler (1883–) painter and photographer, began to use his camera to document American forms with a direct simplicity that had almost been forgotten. Paul Strand (1890–) exhibited, at Stieglitz's gallery in 1916, photographs in which abstract form was emphasized by choice of viewpoint and the use of extreme close-ups. Alvin Langdon Coburn (1882–) showed that the camera could produce abstractions as readily as the painter's brush.

In the late 1920's this new spirit found another champion in Edward Weston (1886–1958), a Californian with an international fame for his soft focus, atmospheric portraits and figure studies. Weston abandoned this style for the image of a well-stopped anastigmat printed by contact on glossy paper. An organization was formed in San Francisco in 1932 of photographers who shared this point of view. They chose the name "Group *f* 64", held exhibitions and fostered the new approach.

A distinct contribution made by America has been the use of photography for sociological purposes. In 1888 Jacob Riis (1849–1914), the author of *How the Other Half Lives*, took a series of photographs of slum areas to supplement his verbal descriptions of the plight of the under-privileged. Lewis W. Hine (1874–1940), a trained sociologist, produced in the first decade of the twentieth century photographs of child labour which led to the adoption of legislation. The term "documentary photography" was applied to photographs taken from this standpoint. Later, in the 1930's, the Farm Security Administration of the Government, under the direction of Roy E. Stryker, used photography to document agricultural conditions. The project, as it developed, became a vast documentation of rural America and some of America's leading photographers were employed: Walker Evans (1903–), Dorothea Lange (1895–), and Arthur Rothstein (1915–).

Two technical innovations from Germany exerted a powerful effect upon American photography: the 35 mm. miniature camera (1925) and the electric photoflash bulb (1929). The frontiers of photography were pushed farther than ever before, especially when, in 1938, sensitizers were discovered which greatly increased the speed of film. News photography became increasingly important, and magazines began to develop a new use of pictures. *Life*, for example, founded in 1936, demanded photographs which were unposed and realistic, and established definite styles of picture taking.

Colour. In 1935 the Eastman Kodak Company announced Kodachrome film. The invention of Leopold Mannes and Leopold Godowsky, this film differed radically from other colour material. On a single support were three coatings of light sensitive emulsion, which recorded the red, blue, and green components of the scene. By the technique of dye coupling development, each coating was converted from metallic silver to the complementary dye (cyan, magenta, yellow). This film, which was quickly followed by Ansco Color, could be used in any camera. Sheet film monopack material was introduced and commercial photographers adopted the new material in preference to the older forms of colour photography which involved the taking of three separate negatives, or the use of material with ruled or mosaic screens.

A further development was the production of colour negative material which yields, upon processing, a negative in which the brightnesses and also the colours are inverted. From these colour negatives, prints can be made on transparent material or on paper.

Equipment Trends. Enormous strides have been taken in increasing the sensitivity of both black and white and colour films. In 1947 the fastest film available of domestic manufacture was 200 A.S.A. Today black and white film is available at A.S.A. 1250 and colour film at A.S.A. 160. Although this is partly accounted for by a change in the method of determining speed rating by the American Standards Association, the increase is still significant.

Chester F. Carlson's Electro-photography, a dry, non-chemical process, by which an image on an electrostatic field is produced and then dusted with powder, was introduced commercially for document copying as *Xerox* in 1950 by the Haloid Co. (now Xerox Corp.) of Rochester, N.Y. A similar system, *Electrofax* was announced by the Radio Corporation of America in 1956. While perhaps not a branch of photography, the tape-recording of electronically transmitted images (video tape), first demonstrated in 1951, became commercially practical with the *Ampex* system in 1954.

In 1947 Edwin H. Land announced at a meeting of the Optical Society of America his invention of a one-step photographic system, and by the end of 1948 cameras and sensitized material were put on sale. With this Polaroid Land camera, processing took place within the camera. Originally processing was complete in one minute but in 1960 the time was reduced to 10 seconds. Sensitized material in sheet form, to yield pictures 4 × 5 inches in size and to be used in a special holder fitting most 4 × 5 press or view cameras, was introduced in 1958, and a further improvement followed in 1961 when a negative-positive film packet was announced, enabling the photographer to obtain both a film negative and a positive in one operation. The speed of the Polaroid-Land film was increased to 3,000 A.S.A. in 1959. In 1963 a new colour material, based on the diffusion through triple emulsions,

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

of dye developer molecules, was introduced. Named *Polacolor*, this system enables colour prints to be made in one stage within the camera, the whole process being complete within 50 to 90 seconds of the exposure.

Cameras equipped with aperture and/or speed setting controlled automatically for light conditions by a photo-electric cell became popular in the late 1950's. In 1963 Kodak introduced its *Instamatic* magazine-loading camera taking 12 black-and-white negatives, or 20 colour transparencies or negatives per loading in the format of 28 × 28 mm.

American Photography Today. The two largest societies are the Photographic Society of America (membership largely amateur) and the Professional Photographers' Association (membership strictly professional). Specialists have their own organizations: the National Press Photographers Association, the American Society of Magazine Photographers, the Biological Photographic Association, the Society of Motion Picture and Television Engineers, and the Society of Photographic Scientists and Engineers. Three societies are active on behalf of photographic manufacturers, dealers, and photofinishers: N.A.P.M. (National Association of Photographic Manufacturers), P.M.D.A. (Photographic Manufacturers and Distributors' Association, Inc.), and M.F.D.F.A. (Master Photo Dealers' and Finishers' Association). Every city and town has its camera club, ranging from large organizations with well equipped darkrooms and studios, down to small groups of enthusiasts who meet at each other's homes. Four magazines, with a total circulation of well over a million copies per month, are directed primarily at the amateur: *Popular Photography*, *Modern Photography*, *U.S. Camera* and *Camera 35*.

In 1961 sales in the United States of photographic equipment and supplies totalled $1·18 billion. Of an estimated 40 million still cameras in use, 28·7 million were of the simple box type. Some 52 million Americans were taking photographs, including 2·5 million advanced amateurs, and 92,000 professionals. Photographers had a choice of 440 different cameras, of which 53 were fully automatic. $355 million was spent on photo-finishing, and 624·7 million flash bulbs were shipped by manufacturers. Of the 2·3 billion photographs taken during 1961, 41 per cent were in colour.

If the bulk of consumers of photographic goods are amateurs, the most significant progress is being made by professionals, especially in the field of what has been called "photo journalism". Both magazines and newspapers have made a greater use than ever of photography since World War II, and notable picture stories have been produced for *Life* magazine and others by W. Eugene Smith, Henri Cartier-Bresson, Alfred Eisenstaedt, etc. The recent trend in news as well as feature photography has been away from the 4 × 5 in. hand camera to 35 mm and 2¼ in. square formats, the single-lens reflex camera having become particularly popular. The many picture magazines absorb a great quantity of photographs, and demand that these pictures have vitality and style.

The Museum of Modern Art, the George Eastman House, and the Art Institute of Chicago hold frequent exhibitions. Under the direction of Edward Steichen, the Museum of Modern Art held in 1955 a mammoth photographic exhibition, *The Family of Man*, of 500 photographs, mostly of unusually large format; the exhibition was later shown throughout the world. The United States Information Agency displayed an equally large exhibition *A Nation of Nations*, organized by Nancy Newhall, designed by Herbert Bayer. *Photography in the Fine Arts*, a movement to encourage the exhibiting and collecting of photographs, sponsored by the *Saturday Review* and directed by Ivan Dmitri has circulated four exhibitions since 1959 through leading art museums.

Another important field of work is photographic illustration for advertising purposes. Studios are maintained which rival the motion picture studios of Hollywood. The natural scene is reproduced indoors, and artificially lighted—for advertisers cannot wait for the seasons and for good weather. A great deal of ingenuity goes into the making of the sets, and the success of a photo illustrator is judged more by his skill as a stage manager than as a master of the photographic medium.

In contrast to these commercial uses, the direct simplicity, aesthetic integrity and masterful technique of such creative photographers as Edward Weston, Ansel Adams, Brett Weston and Paul Strand have set standards which are recognized internationally. There are few photographers in any land whose work is consistently of equally high artistic value. B.N.

Industry. The United States possesses the world's largest photographic industry, both in terms of production value and the number of manufacturers, which in conjunction with the general expansion of the national economy has shown continued strong growth over the past five years. The scope and volume of output is sufficient to fulfil most of the needs of the domestic market, and consequently the exports and imports of photographic goods, although considerable by European standards, are of relatively minor importance.

The Census of Manufactures held in 1958 recorded that there were then in existence 158 photographic manufacturing establishments with twenty or more employees each, which together provided employment for 61,200 persons, of whom 39,300 were classed as production workers. About two-thirds of output is accounted for by producers located in New York State, whilst other important centres of production are Illinois and New Jersey.

The largest photographic manufacturer in

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

the United States is the Eastman Kodak Company of Rochester, New York, which produces still and cine equipment and all types of sensitized materials, and also has interests in the manufacture of chemicals, plastics, and synthetic fibres, being the parent of a chain of subsidiary companies and distributors throughout the world. In 1963, the company employed 46,000 persons in the U.S.A., and the total value of sales reached $1,106·7 million, of which amateur photo products accounted for about 25 per cent, and commercial and professional photo goods for some 32 per cent.

Among other leading manufacturers are Bell and Howell, producers of high quality still and cine cameras and other equipment, employing approximately 8,600 persons and having a sales figure of $150·0 million in 1963, and the Polaroid Corporation who invented and market cameras and film using the unique Land on-the-spot developing process, with 3,600 employees and 1963 sales of $110·0 million.

Mansfield Industries is one of the largest photographic manufacturing groups, with plants in both the U.S.A. and Japan, undertaking the production of 8 mm. cine equipment. This group acquired the Argus Cameras Division of Sylvania Electric Products, making still and cine apparatus and accessories. The combined annual sales of these exceeded $40 million in 1963, whilst the number of employees was about 1,100.

Important companies in the field of sensitized materials include the Dynacolor Corporation, which derives the major part of its income from the processing of Kodachrome film but also manufactures its own film and sensitized papers, with a sales figure of $15·0 million in 1963, and the General Aniline and Film Corporation, a Division of which is concerned with the production of film, papers, and chemicals and photographic equipment marketed under the trade name of Ansco, having an overall 1963 sales total of $190·0 million.

The industry is served by its own trade body, the National Association of Photographic Manufacturers.

Production. The value of photographic goods produced in the United States has risen by over one-fifth since 1959 to reach a total of $1,460 million in 1963. Approximately one-third of this is now accounted for by apparatus which, in contrast to the considerable growth shown by the output of sensitized materials, has followed a gradually declining trend during the period.

The largest group among apparatus consists of still picture equipment, within which the major product appears to be still cameras, whilst cine cameras, projectors and accessories are a close second in importance.

No breakdown of the totals is available beyond the 1958 Census, but the figures for that year showed the output of roll film cameras of 35 mm. or smaller format as 239,600 units valued at $9·2 million, and that of other types larger than 35 mm. as 535,900 cameras worth $34·6 million. At the same time, the production of slide and film-strip projectors totalled 654,900 units with a value of $24·1 million, whilst among cine equipment the output of 8 mm. cameras reached 1,093,700 units valued at $45·6 million, and that of 8 mm. projectors attained 684,600 units worth $36.1 million.

The total of $1,040 million reached by sensitized materials in 1963 continued the rising trend of output over recent years, the leading item being film and plates, followed by sensitized paper and cloth. Again, the only breakdown available for individual products is that of the 1958 Census, which showed the production in that year to be as follows:—

	Million sq. feet	*$ million*
X-ray film	218·3	78·4
Plates, Sheet and Graphic Arts Film	171·1	58·5
Other Still and Cine Film	514·1	257·9
	869·5	394·8

Imports. Imported photographic equipment and materials totalled $88·6 million in 1963. The greater part of this continued to be attributable to apparatus, among which still and cine cameras are the chief products.

Still cameras imported in 1963 reached 1,287,800 units with a value of $19·9 million, of which 875,100 cameras worth $10·6 miillon came from Japan and 144,200 units valued at $7·9 million from West Germany. These two countries supply nearly all of the models with a declared value of $10 or more each, and are also important sources together with Hong Kong of the other types.

Imports of cine cameras have shown rapid growth in recent years, due very largely to the activities of Japanese producers, to reach 311,100 units with a value of $10·9 million in 1963.

Of these, Japan supplied 272,000 cameras worth $7·6 million, the bulk of which were 8 mm. models, whilst Switzerland supplied 16,000 cameras with a value of $1·8 million.

Lenses form another important item among imports, with a total of 508,100 units worth $5·8 million in 1963. Japan and West Germany are the chief sources of these, the former supplying 393,700 lenses worth $2·5 million and the latter 94,100 units valued at $2·0 million during the year.

Imports of sensitized materials have risen one and a half times in value since 1959 to a total of $40·1 million in 1963. The leading product is photographic paper, the silver sensitized type accounting for $10·1 million of the $15·7 million total in the year, the principal suppliers of which are Belgium ($6·9 million's worth) and West Germany ($2·9 million's worth).

X-ray film is another important item, and

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

imports have registered a noticeable increase in the value during the period 1959 to 1963 to reach $11·6 million in 1963, of which $5·8 million's worth came from Belgium and $4·1 million's worth from the U.K. Cine film imports also rose substantially during the year, resulting from an increase in stock of less than one inch in width (to 154·8 million linear feet worth $1·5 million) whilst the broader gauge type expanded slightly (to 210·5 million linear feet valued at $2·3 million). The main sources of both types are Belgium and Italy, with Japan in third place.

Exports. Photographic goods exported by the United States have risen by 65 per cent in value over the last five years to a total of $148·2 million in 1963.

Two-fifths of this amount was accounted for by apparatus, among which still cameras are an important product. Exports of these reached 1,166,900 units with a value of $9·2 million during 1963, of which the hand-type fixed focus models amounted to 986,000 cameras worth $3·7 million. The largest single market for all types of still cameras is W. Germany, which received 246,600 units valued at $1·4 million in the year, whilst France took 232,900 cameras worth $1·3.

Exports of cine equipment have shown little change during the period from 1959 to 1963. In the latter year those of cameras totalled 74,800 units with a value of $4·1 million, whilst cine projectors reached 58,400 units valued at $4·9 million, the greater part of both being represented by 8 mm. models. The leading market for 8 mm. cameras is France (22,800 units worth $0·7 million), whilst the U.K. is the major purchaser of this gauge projectors (16,400 units with a value of $0·6 million).

Among other products exported an important place is held by microfilm and photocopy equipment and also processing and finishing

equipment. The principal market for both of these in 1963 was Canada, which received $2·5 million's worth of the former and $2·0 million's worth of the latter item.

Sensitized materials have shown a substantial growth in value since 1959, to reach a total of $89·6 million in 1963. The principal product is cine film, which rose to 783·6 million linear feet with a value of $22·6 million during the year, of which 35 mm. gauge stock accounted for 287·2 million linear feet worth $11·3 million. Leading markets for all types of stock are Japan and Canada, whilst Australia, the U.K. and West Germany are also large purchasers.

Other major items which have recorded considerable growth in the period are photographic paper and roll film, reaching respective totals in 1963 of 430·0 million square feet worth $20·8 million and 24·6 million square feet valued at $17·7 million. The principal destinations of these products are shown in the accompanying table.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

In contrast to these, exports of X-ray film have shown relatively little increase since 1959, totalling 32·0 million square feet with a value of $9·8 million during 1963. Important markets are Canada (6·0 million square feet worth $1·9 million) and Brazil (3·4 million square feet valued at $1·0 million). G.R.H. & A.G.B.

UNIT VALUE. Single number assigned to lens aperture or shutter speed settings of a camera in accordance with a logarithmic exposure function. Each increase of 1 in the unit value halves the light transmitted through the lens opening or the shutter. Unit values are used in certain exposure calculation systems.

See also: *Apex system.*

UNIVERSAL DEVELOPER. Name given to the many proprietary—usually M.Q.—developers intended for use with all types of black-and-white negative and positive materials.

URANIUM NITRATE. Uranyl nitrate. Used in toners and intensifiers.

Formula and molecular weight: $UO_2(NO_3)_2.6H_2O$; 502·2.

Characteristics: Greenish yellow salt.

Solubility: Highly soluble in water at room temperature.

UVACHROM COLOUR PROCESS. A three-colour dye transfer process invented by Dr. Arthur Traube in collaboration with Prof. Adolf Miethe in 1904. Named after Dr. Traube (Latin *uva* = grape = Traube (German)). Commercialized by Uvachrom A.G., Munich. From the three separation negatives of a coloured object, three diapositives were made on a silver bromide gelatine film. In a bleaching solution the metallic silver was converted into silver iodide. After rinsing, they were put in three different dye solutions: the one taken from the blue filter negative, in a yellow dye; that taken from the green filter negative in a red dye; and that from the red filter negative in a blue dye. After further rinsing the diapositives were fixed, and then superimposed to form a colour transparency. There was a great deal of control to obtain perfect colour balance by locally adding or removing the dye according to need.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

V

VACUUM BACK. Holder for sheet films, especially in process cameras, or for flat originals in copying set-ups. It depends on the use of a vacuum to hold the sheet in position and flat.

The vacuum back consists of a flat plate carrying recessed grooves which are joined to a suction pump. When the pump is started it draws the air out of the grooves and so pulls the film or other sheet perfectly flat against the back.

This is also the ideal way of ensuring intimate contact between two sheets of material such as a negative film and a contact screen used in photo-mechanical reproduction.

See also: *Process camera.*

VADAS, ERNÖ, 1900–62. Hungarian photographer. Founded Magyar Fotomüvészek Szövetsége (Association of Hungarian Artistic Photographers); had leading influence on pictorial photography in Central Europe. Won Emerson Medal and was honoured by Hungarian Government.

VALENTA, EDUARD, 1857–1937. Austrian chemist, professor and later director of the Graphische Lehr-und Versuchs-Anstalt (Graphic Arts Institute), Vienna. Used stereo radiography as early as 1896. Discovered the red sensitization of ethyl violet and the green-yellow-red sensitization of glycine red for silver bromide emulsions. Worked on isocyanine sensitizers (1903), silver chloride printing-out papers, toning, platinum printing, silver phosphate emulsions, tracing papers, printing materials, photochemistry and spectroscopy. Wrote numerous books.

VALENTINE, JAMES, 1815–80. Scottish landscape photographer from mid-1850s. Founder of firm in Dundee still in existence as one of the largest producers of photographic postcards in Britain.

VANISHING POINT. Point to which parallel lines converge when they recede from the observer. When the parallel lines are horizontal, the vanishing point lies on the horizon. All lines parallel to a given line converge towards the same vanishing point—e.g., the roof, eaves, window-sills, etc., of a rectangular building seen in perspective have a common vanishing point. There is a vanishing point for each of the visible sides of such a building.

Once the vanishing point of a set of parallel lines has been determined—graphically or by observation—it gives the inclination of any associated parallel lines. The conception of a vanishing point, therefore, is perhaps more important to graphic artists than to photographers.

See also: *Perspective.*

VAPOUR DISCHARGE LAMP. Type of electrical lamp which derives its illumination from an electrical discharge through a vapour or gas—e.g., mercury vapour—instead of through a wire filament.

See also: *Discharge lamp.*

VARIABLE CONTRAST PAPER. Certain bromide papers are made in a single variable contrast grade.

These papers carry two sensitized emulsion layers, one coated on top of the other. One emulsion is very contrasty and sensitive to yellow-green light. The other emulsion is soft and is sensitive only to violet and blue. (The sensitivities can equally well be reversed: soft yellow-sensitive and hard blue-sensitive.) An alternative method is to mix two emulsions, so that the sensitive layer contains silver halide grains of the different sensitivities side by side. The image is then all in one plane, but this makes no noticeable difference.

With such an arrangement, the contrast of the resultant print depends on the colour of the printing light. Exposure to blue light—e.g.,

through a blue filter held in front of the enlarging lens—affects mainly the soft emulsion and yields a print of low contrast. Used in this way the paper is suitable for hard negatives.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Similarly, exposure to yellow light, with a yellow filter in front of the enlarging lens, affects only the yellow-sensitive, contrasty layer and gives a print of high contrast. Used in this way the paper is suitable for printing from soft negatives.

The print can be given any intermediate degree of contrast by exposing it for part of the time through the blue, and the rest through the yellow filter. The final contrast is decided by the relative exposure times through each filter.

The filters themselves may be held in a filter slide or turret which brings the selected filter in front of the enlarger lens. Annular filters are also used, in which a yellow filter has a central clear aperture. The contrast there depends on the lens aperture employed; at the largest lens opening most of the light passes through the yellow filter, yielding high positive contrast. At small lens apertures the light through the yellow filter is largely cut out, leaving only light passing through the clear centre of the filter and leading to lower print contrast.

Some advanced enlargers incorporate variable density filters of the two colours in the lamp house. Setting an appropriate control there selects the proportion of light passing through each filter, mixing the light of the two colours thoroughly before it reaches the negative.

Where continuous variation of contrast is not essential, filter sets for variable contrast papers may include three or more intermediate filter densities between the maximum blue and maximum yellow. In that case the filter corresponding to the actual paper grade required is fitted in front of the lens.

An alternative method of obtaining a range of print contrasts from a single paper grade involves pre-exposure or flashing. This method is popular in automatic photo finishing printers where a single high-contrast paper grade is used. By varying degrees of pre-exposure to a fogging light, the effective print contrast is reduced. The actual pre-exposure must be balanced with the image-forming exposure for the print. This is frequently done semi-automatically.

See also: *Flashing; Papers.*

VARIABLE FOCUS LENS. Lens system in which the focal length can be changed continuously by mechanical displacement of one or more lens elements. Such a lens can thus replace a range of interchangeable lenses of fixed focal length.

See also: *Zoom lens.*

VARNISHING NEGATIVES. Particularly valuable or heavily retouched negatives can be given extra protection against scratches or other injury by varnishing.

APPLYING NEGATIVE VARNISH. Varnishing protects the emulsion layer against damage, and also provides a retouching surface for pencil work. 1. Choose a suitable varnish, either hot or cold. 2. Clean and thoroughly dry the negative. 3. Pour a pool of varnish on to the centre of the plate. 4. Carefully tilt the negative so that the varnish flows towards one corner. 5. Tilt in the opposite direction to cover the second corner. 6. Cover the third corner in the same way by further tilting of the negative. 7. Drain off the surplus liquid from the last corner of the negative into the bottle. 8. Lay down the negative to let it dry and to give the varnish a chance to settle in an even layer and harden completely.

There are two types of negative varnish, hot and cold.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Hot Varnish. Hot varnishes are suitable for plates only, since they must be applied to a rigid surface, and the hot solvent may attack the film base.

They usually consist of shellac or other resin dissolved in alcohol. They are coated on to the negatives while hot. These varnishes dry very quickly, and are usually hard as soon as they are cold, by which time virtually all the solvent has disappeared. After a further drying out time of a day or two, the varnished negatives will stand a higher degree of rough treatment. A formula for a hot varnish is:

White shellac	5 parts
Sandarac...	5 parts
Gum mastic	1 part
Oil of turpentine	1 part
Methylated alcohol to make	40 parts

The methylated alcohol should preferably be the colourless (industrial) variety, or the denatured but clear type sold by some chemists as surgical spirit.

For hot varnishing the plate negative should be quite dry, and slightly warm to the touch. The plate, emulsion side up, is held level by supporting it on the finger tips of one hand, and a pool of hot varnish (heated up on a water bath) is poured on to the centre.

The plate is then tilted each way in turn, so that the varnish flows over the whole negative surface.

When the whole of the surface has been wetted with the varnish, as much as possible is drained off at one corner, and the plate set level again to dry.

Cold Varnish. Cold varnishes are usually suitable for films and plates. The finish they produce is as hard as that of a hot varnish but they may take several hours to dry. They are thus more likely to pick up dust particles than the quicker-drying varnishes. Film varnishes never contain alcohol, since it tends to soften acetate film bases.

A formula for a cold film varnish which is perfectly safe is:

Celluloid	1 part
Amyl acetate	50 parts

The celluloid can be obtained by boiling old film negatives in 5 per cent sodium carbonate solution to remove all gelatin. The films are then cut up into small pieces and dissolved in the amyl acetate. The solution is very inflammable and should therefore not be handled near a naked flame.

The negatives are immersed in the varnish, immediately drained, and hung up to dry in a dust-free place.

A 5–10 per cent solution of gum dammar in benzene or petroleum spirit (lighter petrol) can be used in the same way. A formula for a cold plate varnish is:

Canada Balsam	1 part
Benzene or benzole	15 parts
Sandarac...	15 parts
Methylated alcohol, to make	100 parts

This mixture is brushed on to the plates and allowed to dry in the usual way. L.A.M.

VECTOGRAPH. Composite stereoscopic positive in which the pairs are bound up with a polarizing filter and a metal reflector. The light reflected from the pairs is differentially polarized and when seen through spectacles fitted with suitable polarizing lenses, the pictures fuse to a three dimensional impression.

See also: *Projection Practice.*

VEIL. Alternative name for fog; a uniformly distributed silver deposit or density in a negative, transparency, or print not forming part of the image itself.

See also: *Fogging.*

VERIFAX. Proprietary transfer method of document copying, utilizing a paper which produces a dyed gelatine matrix on exposure to the original and processing. The original is usually copied by the reflex method, and the processed matrix pressed into contact with a specially prepared but non-sensitized paper to which the pigment image is transferred.

See also: *Document copying.*

VERTICAL ENLARGER. Type of enlarger in which the head assembly—lamphouse, negative carrier, and lens—is attached to a vertical column so that the negative image is projected downwards on to a horizontal easel.

VESICULAR IMAGE. Image with density variations derived from the differential scattering power of microscopic bubbles in a transparent layer. Usually obtained by a diazo process.

See also: *Diazo processes.*

VIDAL, LÉON, 1834–1906. French photographer, professor of photography at the Conservatoire National des Arts et Métiers (National School of Arts and Crafts), Paris. Described in 1861 one of the first plate-changing cameras, the Autopolygraph. Worked in the 1870's on three-colour pigment pictures, chromolithography and later on three-colour additive projection. Founded the Association du Musée des Photographies Documentaires (Museum of Documentary Photographs Association), Paris.

VIDEO TAPE. Magnetic tape used to record electric impulses of a television scanning system and to reproduce these, through suitable equipment, as a television image. The term Videotape (written as one word) is a trade mark.

See also: *Television recording.*

VIEW CAMERA. American equivalent of the British field camera; in each case usually a camera of quarter-plate size or larger, and designed to give the main camera movements. Originally intended for outdoor "views", these cameras are also used by many commercial photographers for subjects like formal groups, school photographs, architecture and general technical work.

VIEWERS

Very small photographic positives cannot be viewed with comfort unless some apparatus is used to increase their apparent size. Optical projection gives the most pleasing result but, when the positives are only to be viewed by one person for short periods of time, something simpler is needed.

For this purpose, various types of viewers are made.

Mostly they are intended for viewing transparencies—partly because it is this form of photograph which is too small for viewing in other ways and partly because the transparency needs to be viewed by a transmitted light.

Holding the transparency up to the window or the sky or another light source is not normally satisfactory: it neither provides the even illumination necessary nor is the light quality usually the best to show the colours in their correct tones.

Viewing under the right conditions not only brings out the true beauty of a transparency, but shows up an even greater brightness range than is seen on projection. This is because some light scatter inevitably takes place on projection, so that the darker parts of the image on the screen receive some light from the brightest areas and so get slightly degraded. On viewing by transmitted light in a properly designed viewer no such scattering occurs. In a viewer with a directional light source (lamp and condenser) the brightness range may even be enhanced by the Kallier effect (the preferential scattering—and hence loss—of light in the dense areas of a transparency). This is particularly pronounced with black-and-white silver images.

Magnifying viewers for prints are rarer. On the one hand when an enlarged view of a part of a print is required, it is quite sufficient to look at it through a normal magnifying glass. A positive print, if enlarged to the right degree, can only be taken in as a whole without any viewing aid, anyway. Apart from that, magnification of a positive print brings out detail of the image structure (grain, the paper grain, etc.) rather than additional image detail. The latter is best obtained by enlarging the print to a higher degree.

OPTICAL PRINCIPLES

The apparent size of an object depends upon its distance from the eye; the closer the eye comes to the object, the bigger it looks. But there is a limit; when the eye is very close, it can no longer focus the object. By using a magnifying lens, however, objects can be examined at distances that would be too close for the unaided eye.

Ten ins. is the normal comfortable unaided viewing distance, so, by using a lens of 5 ins. focal length, we can see an object distinctly when it is only 5 ins. away. (Such a lens would have a magnification of 2 × and, in the same way, the magnification given by any lens can be found by dividing 10 by its focal length in inches. When the power of a lens is given in diopters, its magnification can be found by dividing the figure by 4, i.e., a lens with a power of 12 diopters has a magnifying power of approximately 3.)

Effect of Aberrations. The human eye can accept considerable amounts of aberration in magnifying lenses but, after a certain point, astigmatism, field curvature and distortion set a limit to magnification and field of view. The best shape for a single magnifying lens is a meniscoid with its concave surface towards the eye. Weak lenses of this form are used in spectacles. If plano-convex lenses only are available, the plane side should be towards the eye.

Double convex lenses suffer badly from astigmatism and are only usable over a narrow angular field.

Limitations. A magnification of 3 is about the limit for a single lens covering a reasonable field, and 5 where only a small area has to be examined. Higher magnifications call for a more complicated design which must be specially computed. The corrections in such lenses have to suit an imaginary stop positioned in the centre of rotation of the eye. Camera lenses are not always suitable as magnifiers because the eye is not close enough to the internal stop and the head must be moved about to see different parts of the field.

One objection to the use of monocular viewers is that both eyes are not relaxed. This causes a form of eye-strain because it is impossible to relax with one eye held shut. Viewing is much more comfortable if both eyes are open and if the amount of light falling on them is about the same. This may be a little difficult at first but the knack is easy to acquire by practice.

Binocular Viewers. Binocular viewers can only be used with comfort if they allow the eyes to converge naturally in accordance with the apparent distance of the object. If both eyes are to focus comfortably on an object which is

apparently 10 ins. distant, their lines of sight must converge to a point at that distance.

CC-0. Jangamwadi Math Collection. Digitized by eGangotri. Digital Preservation Foundation, Chandigarh

A simple form of binocular magnifier consists of a low power lens (giving magnifications up to about 2) made wide enough for both eyes to look through at once. In this case the lens itself provides the correct relationship between apparent viewing distance and convergence.

Binocular magnifiers using separate lenses can incorporate deviating prisms to provide the necessary convergence, but their use, especially when they are mounted in the form of spectacles, is not recommended. The reason is partly psychological and partly due to optical aberrations and the difficulty of fusing two images with opposite forms of key-stone distortion.

Binocular viewers of a special kind are used for looking at stereoscopic pairs. In this case there is no problem of convergence because the eyes are looking almost straight at two objects, not turned to look in at one.

Magnification. The magnification required from the viewing lenses is related to the focal length of the camera lens. When the eye views the positive through a magnifier with the same focal length as the camera lens, it sees a scene exactly as the camera saw it.

If the separation between the two camera viewpoints is the same as the distance between the human eyes, and if the two positives are mounted so that each eye sees the appropriate image, they will fuse to give a stereoscopic effect corresponding exactly to the effect created by the original scene.

If the viewing lenses are of shorter focal length than the camera lenses, the stereoscopic effect will be increased. At the same time, the scene will appear larger in proportion so that the net effect is that of looking at the original scene from a closer viewing distance. The perspective will not be true, but otherwise there is no unnatural representation.

Exaggerated stereoscopic effects are obtained by varying the separation of the two camera viewpoints. They are not caused by the design of the viewer or by enlarging the positives. G.H.C. (L.A.M.)

The Transparency. The correct density for a transparency for viewing depends upon the type of viewer to be used. Some viewers call for a relatively thin positive, others may need greater density. In general it is better for an image to err on the side of weakness than for it to be very dense. The power of the light source can be reduced to deal with a thin image where a very dense positive simply cannot be seen at all.

Transparencies are usually looked at in a magnifying viewer which inevitably magnifies any defects present. So it is more important than usual to avoid, or conceal, any blemishes, however small. Pinholes and dust are particularly noticeable faults.

In the same way irrelevant detail, which may not be noticed on a small print, is apt to attract undue attention in a transparency, and has to be toned down or, better still, avoided.

A transparency has no mount to help it out; as a rule there is just a large black area round the picture. This is not pictorially suitable for all subjects, but there is no alternative. In a positive transparency made by contact or reversal, masking takes the place of trimming, so if the original includes too much of the subject, the unwanted portions are cut out by the mask, even though this means a smaller picture.

Transparencies are not considered as ready for viewing until they are properly mounted, titled and spotted (i.e., have a white spot placed on the mount to show proper orientation). The standard system of spotting is a single spot in the left-hand lower corner, when the transparency is viewed upright and the right way round. Transparencies for projection are always mounted between sheets of glass of standard thickness to avoid variations in focusing.

Conditions for Viewing. The only light allowed to reach the viewer of a transparency should be the light used for illuminating the image. All other light either distracts the eye or degrades the picture.

The power and colour of the illuminant is chosen to suit the transparency. A viewer designed for mixed types of transparency, which vary greatly in density from one to another, should incorporate a control for increasing or decreasing the brilliance of the light source.

With any method of viewing there is a limit to the number of people who can see a picture of good size and quality; the method adopted is decided by the size and distribution of the audience. In general, if the width of the picture is about a quarter of the distance from the spectator the result will be satisfactory, although much smaller images are often used with success.

Transparencies are viewed directly to the best advantage when they are mounted in the centre of a large black mask—far larger than the size usually supplied for the purpose. A diffusing screen between the light and the transparency and a few inches away from it greatly improves the character of the illumination. M.K.K.

CONSTRUCTION

Most viewers are designed for 2 × 2 ins. mounts to accommodate 35 mm. transparencies $1\frac{5}{8} \times 1\frac{5}{8}$ ins. (4 × 4 cm.) superslides, and size 828 (28 × 40 mm.) transparencies. There are also viewers for $2\frac{3}{4} \times 2\frac{3}{4}$ ins. slides. Special models are made for viewing narrow gauge film transparencies of 10 × 14 mm. and 8 × 11 mm. formats, in 2 × 2 ins. or smaller mounts, certain models can be adapted for viewing slides of smaller dimensions than those

for which they are designed, and some can be adopted for viewing uncut lengths of film.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Most viewers are much cheaper than projectors, but they give only a limited magnification. There are occasions however, when a viewer is more convenient than a projector. It can be more easily carried about and can be used at a moment's notice without any of the preparation associated with the projection of transparencies on a screen.

There are many different kinds of viewers ranging from folding types that fit unobtrusively into the pocket to the larger and more elaborate viewer which is used on the desk or table. Special viewers are made for showing stereo slides and films.

Illumination. Daylight is the illuminant for inexpensive viewers, but has a number of limitations. One is the variable strength and colour. Most colour films for miniature transparencies are designed to yield the best colour compromise when the transparency is viewed or projected by a light source of a colour temperature of around 3,200°K. On viewing by daylight such transparencies therefore tend to appear too bluish. This is particularly pronounced if the picture is held up against the blue sky. Colour films intended for larger transparencies—especially sheet films—are, however, usually balanced for viewing by a daylight-quality illuminant. This is because they are mostly intended for display in light boxes lit by fluorescent or similar tubes.

Most slide viewers therefore have some sort of artificial light source built in. A miniature bulb fed from a torch battery, as used in cheap viewers, also suffers from variable colour quality. As the battery runs down, the light becomes progressively weaker and more reddish. In any case, the light of a torch bulb is considerably more reddish (lower in colour temperature) than the ideal illumination.

With mains-operated viewers the light source is at least constant in quality, though even there often too red. The use of high-power lamps for a whiter light is rarely practical, because then the intensity becomes too great for comfortable viewing. One possible correction is to interpose a very pale bluish filter (best found by experiment) in the light path of the viewer. Behind the diffusing screen is usually the best place.

Even illumination is also important. The only way of achieving this in a daylight viewer is by a diffusing screen placed behind the transparency. Flashed opal glass or opal plastic are best since they have virtually no grain structure of their own. Where no magnifying viewer at all is used, the transparency should be placed against a suitable diffusing material before being held up to the light. Some manufacturers of colour films return their transparencies after processing in plastic sleeves with one side clear and the other translucent to provide a certain degree of diffusion.

SLIDE DISPLAY CABINET. The slides are supported in grooves in front of a sheet of glass. A tubular filament or fluorescent lamp illuminates a white reflector facing the front panel. Careful choice of illuminant is desirable for colour slides.

Diffusing screens are also used in the less expensive viewers with incorporated light source. The screen should in this case be not too near the lamp (otherwise the illumination is again uneven) nor too near the transparency if the screen has a grain texture.

Condenser illumination in small viewers is comparatively rare. However it provides a much more brilliant light and better utilization of the output of the lamp. Condenser illumination is, however, also liable to lead to unevenness in lighting, unless the condenser system is of high optical quality and correctly adjusted.

Hand Viewers. These consist of a plastic or metal housing with a magnifying lens at one end and a slot to take the transparency behind it. A diffusion screen is fitted at the opposite end to the magnifier and the transparency is viewed

HAND VIEWER. Can be carried in the pocket. A, diffusing screen. B, slot to take slide. C, magnifier eyepiece. In use the viewer is held up against a lamp or window; the diffusing screen then provides an evenly bright background for the slide.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

by placing the lens to one eye and looking through the viewer at a suitable light source. The lens is usually a simple meniscus, and may be either in a fixed position or in a sliding tube to enable it to be focused on the transparency. The diffusion screen may be of etched or flashed opal glass or translucent plastic. The grain in the diffuser is rendered less noticeable by placing it some distance away from the transparency.

In folding viewers, the slot for the transparency and the diffuser are placed close together for compactness. They are made to fold down on to one end of a rectangular platform and the magnifiying lens folds down on the other. Sometimes the centre platform incorporates a slide which can be extended as required to enable the transparency to be brought into focus. When folded the viewer, which is often sold complete with a leather purse, can easily be slipped into a pocket. The transparency is not boxed in with this type of viewer, and the image may appear less brilliant than it would if it were entirely enclosed and all the light came directly through it.

It is obviously an advantage for the viewer to provide its own illumination, and some hand viewers are made to do this while retaining the attraction of portability.

The main part of the viewer is a battery case, holding two, or sometimes three, torch batteries, which light one or two torch bulbs. The bulbs are covered with a diffuser just large enough to cover the transparency. Viewers with a magnifying system of one lens will yield only limited magnification without aberration and distortion. To increase the image two or three lens units are employed. Certain models have a switch to turn on the light, but it is more common to make the necessary electrical contact simply by means of depressing the slide into the viewer. In some cases the slide can be locked into position, with the light remaining on, by pressing the slide both downwards and also backwards into a small recess.

Table Viewers. These are bigger and more rigid than the illuminated hand viewers and intended to rest on a table or desk when in use. The component parts are the same as in the illuminated hand viewers but are not designed to fold into a small space. In some cases the base is adjustable to allow the viewer to be tilted to a convenient angle for viewing. Their larger size permits the use of bigger lamps, which may be operated from the electric mains. Certain battery models are fitted with small transformers, which enable them also to be used off the mains. Some viewers are designed to hold a magazine, which does away with the need to load each individual slide separately for viewing.

The viewers mentioned so far give only a relatively low magnification, and can be used by one or two persons only at a time. A more elaborate kind of table viewer shows a bigger picture which can be seen by several people at once. This viewer uses a low power projector lamp and condenser system which project an image of the transparency via a system of surface-silvered mirrors on to a translucent screen measuring up to 7 × 7 ins. Since this type of viewer is really a self-contained projector and screen, it is much more expensive than the ordinary directly-viewed magnified image type.

TABLE VIEWER. Gives maximum enlargement of small transparencies, incorporates own lamp. A, reflector lamp. B, diffusing screen. C, heat filter. D, slide in chute. E, magnifying system deeply hooded from stray light.

Viewers for Exhibition Stands. For exhibition and advertising, sets of transparencies are often mounted in cabinets and illuminated from behind. The cabinets are placed in as dark a situation as possible, and the illuminated area is surrounded by the largest possible area of black. Display cabinets of this sort incorporate diffusing screens to spread the illumination evenly over the transparency, and filters both for correcting the colour values of the transparency and for filtering out the heat rays.

A better type of cabinet is being used nowa-

TABLE PROJECTOR. Although shaped like a large viewer, the instrument incorporates a projection system. This throws an enlarged image on to a screen by back projection.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

days by photographic societies for displaying transparencies. It is constructed in the form of a long box made to hold a fluorescent tube and the transparencies are arranged in horizontal rows on rails running the length of a suitable window in the side of the box. The tube is backed by a parabolic reflector which illuminates the transparencies evenly, and filters for colour or heat are unnecessary.

STEREO VIEWERS

Stereoslides of 6 × 13 cm. and 45 × 107 mm. formats were at one time popular, but today stereos are most commonly taken on 35 mm. film, the usual format being 24 × 23 mm., in mounts 45 × 100 mm.

The essential requirement of a stereo viewer is to present the two transparencies recorded by the camera so that the left eye sees only the image taken by the left camera lens, and the right eye the image taken by the right camera lens. This is achieved by using two viewing lenses placed approximately 2½ ins. apart, and by mounting the transparencies with a similar separation distance between them. As with monoscopic viewers, stereo viewers may be of the illuminated kind with a lamp or of the more simple type to be used with an external light or daylight.

The positives are mounted in positions where they give the correct convergence and where they can be fused with ease. This condition is met when lines joining corresponding points in the two prints are parallel to one another and to the lines joining the centres of the viewing lenses, and when the positives are spaced so that beams from these points diverge very slightly towards the magnifying lenses and the eyes.

It is impossible to fuse the positives if they are spaced wider than this and discomfort is soon felt when they are closer.

STEREO VIEWER. Incorporates its own light source powered by a torch battery. On the more versatile models the lenses can be focused individually, and the separation adjusted.

If the pictures themselves are narrower than the correct spacing, no difficulty arises, but if they are so wide that they would overlap, some prism or mirror system must be employed so that they can be mounted clear of each other, while at the same time appearing to have the normal separation. A number of stereoscopes have been designed for viewing large prints in this way, using a suitable beam splitter.

Non-illuminated stereo viewers bear a close resemblance to the hand viewers used for viewing flat or two dimensional transparencies, apart from the fact that there are two lenses instead of one and the viewer is correspondingly wider.

Inexpensive viewers in metal or plastic are obtainable with or without focusing adjustment and they may be of the enclosed box type or open folding type.

Illuminated stereo viewers are usually made of plastic and the illumination provided by two torch batteries operating a single bulb. The better models are fitted with achromatic lenses, and in addition to a focusing adjustment, there may also be some means of varying the interocular distance of the lenses.

Split Frame Viewer. Special viewers exist for slides taken with beam-splitting devices used with 35 mm. cameras. No additional cutting, transposing or mounting of the transparencies is required. The transparency is inserted in the viewer in its cardboard mount, just as it is returned from processing. Two pairs of surface silvered mirrors or prims present each image to the appropriate lens with the correct separation.

The simple viewers of this type have a plastic or pressed metal case, have no built-in illumination, the lenses are of fixed focus and the interocular distance cannot be varied.

Prismatic Film Viewers. Another better viewer for this type of beam-splitter stereo film employs a system of prisms in place of the mirrors. The prisms enable the film to be viewed without transposing. Each eyepiece focuses independently, and the interocular distance can be varied. This type of viewer is held in the hand and pointed at the light. Both split frame attachments for use on 35 mm. cameras and the necessary viewers have now gone off the market.

A similar type of viewer, which is no longer in production, makes it possible for films taken in twin-lens 35 mm. stereo cameras to be viewed without cutting. The viewer uses the same system of reversing prisms which makes it unnecessary to transpose frames. The film is transported by sprockets, the transport being similar to that of the camera so that the frames come into view by turning the knob as far as it will go. The lenses can be focused and the distance between them varied. This viewer can be fitted to a stand and can either be used in conjunction with external light or it can be fitted with a special lighting attachment working from the mains. C.W.L.

Stereo Print Viewers. Since stereo pictures in the

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

form of paper prints still require special viewing to see the depth effect, various stereo viewers for such prints also used to be produced. In their simplest form, such viewers consist of a holder for the stereo pair of prints, and a pair of eye-pieces (or simple magnifying lenses) set an inch or two in front of the stereo prints. Frequently such viewers are designed to fold for easy carrying around in the pocket.

Usually print viewers are intended to be used by daylight or other prevailing illumination, and only require holding in such a way that both stereo prints are equally strongly illuminated. More elaborate types may include their own light source, adjustable eye-pieces, etc. Stereo prints usually come in standard sizes mounted on 6 × 13 cm. or 45 × 107 mm. mounts for direct insertion in the viewer. Stereo positives in 35 mm. size are rarer.

Stereosopic Aerial Photographs. Photographs taken for aerial survey and reconnaissance work are frequently exposed at intervals—as the aircraft flies along—which make each picture overlap its neighbour by about 60 per cent. Such adjacent frames are usually viewed stereoscopically in print form with the aid of special viewers. This permits much more detailed examination and recognition of ground features in the photograph. Prints—or, more usually, transparencies—may also be viewed with the aid of stereographic plotting instruments for accurate evaluation and survey, for example for map making. In these instruments different points of the image, apparently seen in depth, are matched up with floating marks. These indicate by their movement not only the lateral disposition of picture details but also their apparent height above the ground. Such stereoscopic surveying requires elaborate viewing equipment which must not only be highly precise but may also be linked with stereoautographic plotting and mapping gear.

SPECIAL VIEWERS

Negative-positive Viewers. Sometimes it is useful to be able to see a negative image as a positive (or occasionally vice-versa). Several viewers exist for this purpose, and depend on one of two principles: (1) the quenching effect of infra-red radiation on the emission of fluorescent light by fluorescent screens excited by ultra violet rays; or (2) electronic image reversal in a television playback system.

The quenching type of viewer is the simpler of the two. It consists of a projection set-up, with a lamp, condenser and lens. The lamp is specially rich in infra-red radiation, and is usually filtered to eliminate most or all visible light. The projector projects the negative on to a fluorescent screen excited by ultra-violet rays.

Where the infra-red radiation reaches the screen, it quenches or subdues the fluorescence in proportion to the intensity of the infra-red rays falling on it. Thus where little light comes through a negative (the dense portions) the image on the fluorescent screen is brightest. Where a lot of light comes through the thin areas (shadow portions) the fluorescence is subdued more and the image appears darker. The result is a tonally reversed picture, in other words a positive from a negative.

The apparatus for this purpose is comparatively bulky and complex, since it must include both the projection system and infra-red source as well as an ultra-violet emitting lamp. The latter is also filtered to allow only ultra-violet rays to reach the fluorescent screen.

Usually such viewers yield a slightly enlarged image of the negative; they can also be designed for adjustable magnification. Their main use is in the quick evaluation of negatives in a number of industrial fields where a positive is not required at the time or where making a positive would be too lengthy. They are also of potential use to photo dealers, to show customers what their negatives look like as prints.

When an image is reproduced by a closed-circuit television chain (camera and receiver) it is a comparatively simple matter to adjust the circuit so that the reproduced image is negative with respect to the original. This is one of the aspects of the contrast control; hence a negative cannot only be shown as a positive, but also as one of any selected contrast.

NEGATIVE-POSITIVE VIEWER SYSTEM. An infra-red beam is projected through the negative on to a flourescent plate excited by an ultra-violet lamp. The infra-red radiation coming through the negative partially extinguishes the fluorescence, so showing a positive on the plate. A, mirror. B, condensers. C, slot for negative. D, projection lens. E, green screen for viewing the image on the fluorescent plate. F, infra-red projection lamp. G, ultra-violet light source. H, fluorescent plate.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Television systems for this purpose are far more expensive than their quality warrants, but they have some potential use for determining the paper grade required for printing a given negative.

Of more interest is the application of this idea to colour printing. With a three-colour television system it is not only possible to reverse a negative to a positive, but also to transform the negative colour effects to positive ones. Television systems for a negative-positive colour viewing have therefore been used for colour grading—i.e. determining the type of filtering necessary to produce a correct positive colour print from a negative.

Basically this involves setting up specific control positions corresponding to the filtering required for a perfect colour print (determined by independent tests) and adjusting the controls until the positive colour image on the television screen corresponds to that obtained in the print. For other colour negatives the required printing correction can then be obtained from the necessary readjustment of the controls on the television receiver to achieve a good colour reproduction in positive from the new negative. Systems of this kind are in use particularly for the colour printing of motion picture positives and provide a speedier method of negative grading than orthodox test procedures.

Microfilm Viewers. Usually microfilms are viewed and read with the aid of microfilm readers—table-top projectors which project the microfilm image on to either an easel or a back projection screen at a magnification of 10 to 15 times. Most of these readers will take 16 mm. or 35 mm. microfilm in continuous rolls, or will project individual unitized microfilms (film cards, aperture cards, etc.). Some microfilm readers also project positive prints (microcard images) since that is the only way of viewing these positives which require magnifications up to 25 times to restore them to original size.

Small microfilm hand viewers also exist, mainly for quick checking of microfilm frames rather than detailed reading. They are generally compact instruments, often with their own light source (battery powered) and yield a 5 to 10 times magnification of the microfilm frame.

Cine Viewers. 8 and 16 mm. cine film is almost invariably projected for observation, since the projector must also incorporate the means of moving the film at the required rate through the optical system. A few hand viewers also exist, however, and consist of a simple hand-driven transport system, a viewing magnifier and either a built-in battery-powered lamp or a diffusing screen for holding the viewer up to a suitable light source. For viewing, the film is cranked through the viewer while the eye looks through the eyepiece at the rear. The image is still very small, and mostly such hand viewers are to be regarded as toys. L.A.M.

VIEWFINDER

When taking a picture it is necessary to know not only in what direction to aim the camera but also how much of the subject will be included in the picture. For this reason practically every camera has a viewfinder of some kind.

The most straightforward way of checking the image recorded on the film or plate is to observe it on a screen placed in the back of the camera. The screen is then replaced by the sensitive material for the exposure. This is the oldest viewing system and is still used in technical and certain other cameras. The screen shows exactly how much of the subject the lens projects on to the film, and—if a ground glass screen is used—it also indicates the sharpness of the image.

The use of a rear screen is however practical only if the camera is mounted on a tripod, to photograph comparatively static subjects. When the camera is held in the hand or used to photograph moving objects, a back focusing screen is out of the question.

There are two ways of getting over this problem. One is to have a focusing screen not at the back where the film is positioned, but on top. A movable mirror inside the camera then directs the image on to the top screen for viewing and focusing, and moves out of the way for the exposure so that the lens can project the picture on the sensitive material. This arrangement is a single-lens reflex camera and permits viewing and focusing right up to the instant of exposure.

The other way is to build a separate sighting system on to or into the camera, and align it sufficiently accurately to indicate the field of view taken in by the camera lens (or lenses if interchangeable).

A hybrid solution is the twin lens reflex where the viewing device is almost a camera in its own right, with a mirror and a top focusing screen. Only in this case the mirror is not movable but the so-called viewing camera is attached to the camera that takes the picture.

INDEPENDENT FINDERS

Viewfinders which are built on to or into the camera may be simple framing devices, rather like the sights of a rifle or they may employ optical systems derived more or less indirectly from a Galilean telescope.

Frame Finder. The frame finder, which is one of the simplest and best of all viewfinders,

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

FRAME FINDER. The eye looks through a rear sight centred behind a front frame which indicates the limits of the field of view. Alternative or interchangeable front frames may be provided for lenses of various focal lengths. The surroundings of the subject are visible outside the frame.

OPTICAL FINDER. Uses the principle of an inverted Galilean telescope to present a reduced image of the subject. The separation between the lenses controls the angle of view (and hence the size of the subject field taken in) and scale of the finder image as visible to the eye.

consists of a metal—usually stiff wire—frame corresponding to the shape and size of the negative, and a small peep-sight. The frame is mounted above the lens and in the same plane, and the peep-sight is mounted on the camera body in the same plane as the sensitive material. The axis of the frame and peep-sight is parallel to the optical axis of the lens.

When the eye is brought close to the aperture of the peepsight, the view bounded by the wire frame is almost exactly the same as the view seen by the lens. The only error is that of parallax, which is more or less negligible for subjects beyond about six feet. Apart from this the frames of the two pictures are identical. More than this; they are the same for any lens of normal construction—wide angle or long focus—and all camera movements provided that the front section of the finder always moves with the lens as one unit.

The frame finder unfortunately makes an awkward projection that in effect almost doubles the bulk of the camera but it can also be designed to be collapsible.

It is possible to make a small frame finder by mounting a proportionately reduced frame closer to the peep-sight. But as the frame comes closer to the peep-sight it becomes more and more blurred until it gives only a hazy idea of the picture boundaries.

Direct Optical Viewfinders. Optical viewfinders, consisting of a negative lens with a small positive lens mounted behind it, are probably more used than any other type. They are also sometimes known as Newton finders. The limits of the field are masked on the negative lens, and the scene is looked at through it with the camera at eye level.

In older models the front and back components of this type of finder are simply mounted in frames which fold flat against the side of the camera; they are mounted in a fixed tube, or built into the camera body.

This type of finder is reasonably accurate, and it gives a bright picture that is neither inverted nor reversed. When it is mounted in a separate tubular mount, it may even carry some form of automatic or adjustable tilting device to compensate for parallax.

Albada Viewfinder. The Albada viewfinder (named after its inventor) is a special type of frame finder in which a white line, framing the negative area, is seen apparently suspended in the plane of the subject. This image is the reflection of a miniature frame painted on the inside of the rear plain glass window of the finder. The reflection is seen in a half-silvered mirror of curved glass which forms the front window of the finder.

This finder has a number of advantages: the image is undistorted; the frame is sharply focused by the eye; part of the subject is visible outside the frame—a great help when following moving subjects.

Magnification. The inverted Galilean telescope type of optical system generally shows the view on a greatly reduced scale. The optical components of such a finder can however be very small and so take up little space in the camera. By increasing the separation between the front and the rear lenses, suitably matching the power of the two lenses used and making the front lens large enough, it is possible to increase the image scale so that the finder shows the subject in nearly natural size. The current preference is for such full-size finders, which

ALBADA FINDER. This is an optical finder, with a partly reflecting rear surface to the front lens. This surface reflects a white frame which surrounds the inside of the rear lens. The frame thus appears suspended in mid-air visible at the same time as the subject, outlining the field area.

therefore take up rather more space on the camera.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

The magnification of the finder in every case is the ratio of the image scale seen through the finder to the image scale as seen by the unaided eye. One eyes looking through a full-size (1 : 1) finder would thus see the subject in the same size as the other eye looking directly at the scene. The big advantage of a full-size finder is that both eyes can be open for viewing, without discomfort.

Bright-line Viewfinder. Many modern cameras combine the optical viewfinder—often in an enlarged form to give nearly full visual image size—with the Albada principle to produce the bright-line finder. This again shows the subject area outlined by a brilliant reflected frame. It is also known as a brilliant-frame, reflected-frame, or crystal-frame viewfinder.

Modern brilliant frame finders frequently achieve the same effect by reflecting a white frame from a second finder window into the optical system. This second window is covered with a diffusing screen, and the brilliant frame is cut into a masking plate situated behind the screen. A prism or mirror behind this reflects the frame into a semi-reflecting mirror in the optical path of the finder, and from there into the eye. This arrangement permits a brighter frame to be combined with the finder image, and is also more suitable for full-size brilliant frame finders. In addition it provides a way of incorporating automatic parallax compensation, by linking the masking plate movably with the focusing adjustment of the lens (see below).

Another type of brilliant-frame finder uses only a diffusing window with a masking plate behind it. Here one eye looks through the system to see the bright frame, while the other eye observes the subject directly. By a process of visual fusion the frame then appears superimposed on the scene. Using this kind of finder needs a little practice, and it does not work with people whose binocular co-ordination is in any way restricted (such people would not be able to see a stereo pair of images as a three-dimensional picture).

Universal Viewfinder. Cameras with interchangeable lenses need a series of viewfinders to show the correct field of view for each focal length of lens. A more convenient system is to use an adjustable universal finder. There are several types of such finders.

The simplest kind is a frame finder with two or more alternative front frames which swing or clip into position as required. More elaborate and versatile types consist of an optical finder with a built-in masking device. Turning a knob or ring makes the mask frame larger or smaller. The control ring is generally calibrated with the various focal lengths of the lens.

In another type of universal finder, the frame remains the same size and the image increases or decreases according to the focal length of the lens. This type of finder incorporates a lens of variable focus, or a range of front components on a rotating turret, and thus it imitates what actually happens in the camera.

Finders such as these are sometimes even coupled to the lens flange. When the lens is changed for one of a different focal length, the finder is adjusted by the lens fitting.

All such universal finders are expensive and intricate pieces of optical equipment which may easily cost as much as a lens.

A simpler solution adopted for some cameras taking interchangeable lenses is the multiple frame finder. There a series of bright-line frames are marked in the standard camera finder, showing also the field of view with two or more alternative lenses. The frames may be reflected from a separate glass plate; by incorporating a movable mask it is possible to arrange for only one frame to be visible at a time. The frame changing control is then sometimes linked with a pin or other fitting on the lens for automatic changing over when fitting a different lens in the camera.

MULTIPLE FINDER WITH FRAME SELECTOR. The image frames for different focal lengths appear on fitting the appropriate lens into the camera, or on operating a separate finder frame selector (bottom). A, main finder window. B, illuminating window for finder frame. C, movable frame mask to uncover different image frames in the frame plate. D. This may be coupled with the focusing movement as well to provide automatic parallax compensation. E, beam splitter prism. F, eyepiece. G, rangefinder window. H, rangefinder wedge. J, reflecting prism.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

STRAIGHTFORWARD MULTIPLE FRAME OPTICAL FINDER. Several image frames are visible in the finder field, indicating the view taken in by different focal lengths—for example, 35, 50 and 100 mm. A, beam splitter prism (to combine the viewfinder with the rangefinder beam). B, field lens. C, graticule plates with finder frames.

Reflecting Viewfinder. The elementary reflecting type of finder has nothing but its cheapness to explain a long run of popularity in low and medium-priced cameras. It consists of a short-focus positive lens which forms the image, and a 45° mirror which reflects the image on to a horizontal ground glass or a second positive lens.

The image seen in the top of the finder was never very bright, it was reversed, and its boundaries were uncertain. Finally, because the finder had to be held below eye-level, it imposed an unnaturally low viewpoint.

In spite of all these shortcomings, however, makers continued to fit such finders to their cameras until the early 1940's. Since that date, the small reflecting finder has practically disappeared in favour of the optical direct vision finder, and the large brilliant finder.

Brilliant Viewfinder. The brilliant type of finder is simply an enlarged and improved reflecting finder. It has a positive image-forming lens, a 45° mirror or prism and a large, brilliant viewing lens which takes up practically the whole of the top of the camera. The size of the picture shown in the viewing lens is often as big as the actual negative frame.

Because this type of finder is always built into the camera body and is too large to leave room for a second similar finder, the camera can only be used in one position. This rules out the rectangular formats which demand two positions—"portrait" and "landscape"—so the large brilliant viewfinder is generally fitted only to cameras that take a square picture.

Special reflecting finders are generally included in the accessories available for expensive miniature cameras. One of the main reasons for wanting to use such a finder is that the camera attracts less attention when it is held at waist level than at eye-level. It can also be used with the camera pointing at subjects to the right or left of the photographer. So it is often a help for taking candid pictures. It can also be used for taking photographs over the heads of the people in a crowd if the camera is held upside down.

Accessory Finders. In addition to the finder built into the camera, additional viewfinders are frequently available for precision 35 mm. cameras. These usually cover the fields of view taken in by the various interchangeable lenses, and follow one of the designs described above.

Accessory finders are also produced for certain special purposes: right-angle optical finders for viewing in one direction while the camera points in another; close-up finders which are specially corrected for the field of view at specific close ranges and may incorporate a rangefinder; and various finder attachments to adapt the field of view to lenses of alternative focal length or to specially close subject distances.

Mostly such supplementary finders fit into the accessory shoe on top of the camera.

Finder accuracy. The value of a viewfinder depends largely on how accurate it is. It can be subject to three main errors: directional, framing and field size.

If the finder does not point in the right direction, it will not take in the view that the lens projects on the sensitive material. Ideally the finder axis should be parallel with the lens axis, though for near subjects it may swing in towards the axis. Directional errors are mostly found on inexpensive cameras, and may arise if for instance a reflecting viewfinder is attached to the camera by a thin and easily bendable bracket.

BRILLIANT FINDER. The front lens projects an image in the plane of the plano-convex lens on top of the finder, the light rays being reflected by the mirror. This type of finder can be quite large—sometimes the same size as the negative.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

VIEWFINDERS ERRORS. Top: *Sighting error. The viewfinder does not point in the same direction as the camera lens.* Upper centre: *Error of covering angle. The finder field takes in more than the lens, so parts of the picture visible in the finder may not appear on the film.* Lower centre: *Close-up loss of field angle. The increased lens extension at close distances reduces the angle of view of the lens so that the film then takes in less.* Bottom: *Genuine parallax error. Even with full correction for the different fields taken in by the viewfinder and the camera lens, there remains the perspective difference between the view of the finder and the camera lens. This becomes particularly noticeable at close distances.*

When the viewfinder, even though pointing in the same direction as the lens, takes in a field of view that is displaced relative to the view projected on the sensitive material, it suffers from a framing error. This is commonly referred to as the parallax error. It arises from the difference in viewpoint between the finder and the camera lens—which may be one to two inches apart. The finder, then includes an inch or two more at the top and perhaps also at the side of the view, with a corresponding reduction at the bottom and at the other side.

With a distant subject which may cover a field of many yards or even miles an inch or two is obviously negligible. At close range, for instance with the camera focused on 3 feet, the subject field may only be 2 to 3 feet wide and there a couple of inches lost at the top of the image frame may result in the cutting off of important subject matter. The error will be even more with a long focus lens (if the camera is interchangeable) since this covers a smaller subject field while the separation of the viewpoints between finder and lens remain the same.

For this reason most cameras incorporate some form of parallax compensation.

There are two kinds of field size error. The first is a constant one; it simply means that the finder takes in either more or less than the image field recorded on the film. Often the field is deliberately reduced to cover other finder errors, so that the view through the finder always shows less than will be recorded on the film. If the field size error is too great the discrepancy between the finder and the film images may be disturbing—especially in colour transparencies where it is not easy to cut down the picture when the transparency is mounted in a slide frame.

A small field size reduction is nearly always deliberate, since standard slide mounts for 35 mm. colour transparencies slightly cut down the picture area by making off the extreme edges of the image. So not everything that is recorded on the film in the camera is necessarily projected.

The second type of field size error is variable and arises with cameras where the lens is racked forward to focus on near distances. As the lens-to-film distance increases, the angle of view of the lens decreases. The viewing angle of the finder however remains constant. At close range the finder may therefore include a greater subject field—quite apart from any parallax error—than the film. Some cameras also incorporate a compensation for this field size error.

Parallax Correction. There are various ways of compensating for the framing error due to the finder parallax (the difference in viewpoint between the viewfinder and the camera lens). The simplest is to cut down the finder field so that it always takes in less than the film. With distant subjects the image will then include more at the top than the finder, while at near distances there will be more recorded at the bottom of the picture.

Some cameras have a viewfinder which tilts to point at the centre of the subject field at different distances. This tilt may be mechanically linked with the focusing movement for automatic parallax compensation. Or it may have a manual adjustment which is set to the distance at which the lens is focused.

Bright-line finders usually have one of two types of correction. The simplest is an outline of a second frame superimposed on the picture, and used to frame subjects nearer than say 6 feet. Frequently the normal bright-line frame carries two small marks near the top. The upper limit of the picture are at close distances is an imaginary line connecting these two marks. Similar correction marks may also be incorporated in a normal optical finder.

On other cameras the view is framed by a

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

sliding mask which is moved by a cam coupled to the focusing mechanism. As the lens focuses on nearer objects the mask slides down to take in more of the bottom and less of the top of the picture. (Where the finder is off-set to one side of the lens as well, the mask similarly moves both downwards and sideways.) Bright-line finders, where the brilliant frame is provided by the light coming through a masking plate reflected into the finder system, may have this plate movable and coupled with the focusing mechanism in the same way.

The field size error may be compensated by designing a sliding mask which reduces the picture field as it moves downwards (and sideways, where applicable). Usually the fact that the parallax correction marks in a brilliant frame include a smaller picture area than a full frame approximately compensates for the field size error as well.

On some cameras the finder is permanently set to take in the field corresponding to a subject distance of 6 feet. In that case only the field size error at still closer distances has to be taken into account, but for distant subjects the film again includes more than the finder shows.

None of these devices for dealing with parallax error can compensate for the perspective error also associated with parallax. The closer the subject comes to the camera, even with all framing errors fully corrected, the more the viewfinder tends to look down on what the camera sees straight in front. For this reason only a single-lens reflex camera system, which uses the camera lens to produce the finder image, is really reliable at very close distances. For most subjects however the compromise of normal parallax compensation methods is good enough.

Viewfinders that Include Other Information. A number of manufacturers use the viewfinder to display other essential information to simplify the operation of the camera. On rangefinder cameras the viewfinder and rangefinder windows are frequently combined so that a small central area of the viewfinder frame carries the double image formed by the rangefinder. This system allows the photographer to focus on any subject while arranging it in the finder, and to keep it in focus even if it is moving about.

Viewfinder windows are also used to display exposure data. Sometimes the needle and scale of the meter appear superimposed on the scene. Sometimes there is a second pointer which is coupled to the exposure setting ring. The correct exposure can then be set for any subject by pointing the camera at the scene and turning the exposure setting ring until the adjustable pointer coincides with the exposure meter needle.

Cameras with automatic exposure control frequently incorporate a colour signal, e.g. red and green in the viewfinder. This warns the user when the prevailing light is inadequate for a correct exposure with the automatic control

SYSTEMS OF PARALLAX CORRECTION. Top: *Brilliant frame finders on simple cameras often carry correction marks which indicate the limits of the field of view at closer distances.* Upper centre: *More advanced cameras may have the brilliant frame linked with the focusing movement, to shift in the finder field.* Centre: *On some cameras a mask in the finder moves to cover up the portions of the finder field not taken in by the film at closer distances.* Lower centre: *Sometimes the finder axis swings towards the lens axis at nearer distances.* Bottom: *The only absolute method of parallax correction with twin lens reflex cameras is to raise the camera between viewing and exposure so that the camera lens is in the position previously occupied by the finder lens.*

CC-0. Agamnigam Digital Presevation Foundation Chandigarh

system. On some automatic cameras both the stop and the shutter speed selected by the automatic mechanism appear in the finder so that the photographer has a running check right up to the instant of exposure.

The viewfinder may show in other ways the focusing zone to which the lens has been set.

REFLEX FINDER SYSTEMS

The viewfinder of a single-lens reflex camera is a full-size focusing screen on which the image is projected by the camera lens via a movable mirror. Full size in this case implies a screen area which is as big as the image area on the film.

This type of viewfinder shows the same image as the camera records on the film. As the distance from the lens to the screen is the same as the distance from the lens to the surface of the film, the image is sharp on the film during exposure when it is focused sharply on the screen. The image appears the right way up but it is reversed left to right. Moreover, this kind of finder is free from any parallax error and it shows the correct field with any lens and at any subject distance.

It can still be subject to a framing error if the viewing screen is smaller than the image recorded on the film. Usually there is a slight deliberate framing error of this kind, to allow for the image area lost in a mounted colour transparency. Framing errors can also arise if the screen is inaccurately mounted (for example if the image frame on the screen is not correctly centered or is tilted), but are constant with all lenses and at all focusing distances. With a plain ground glass screen, image brightness falls off rapidly away from the centre of the field. Modern reflex cameras overcome this by making the screen the underside of a plano-convex lens. This reflects oblique centre rays back towards the centre to make the screen appear uniformly bright all over. Instead of using a comparatively bulky field lens, the top of the screen may be shaped with concentric rings on the principle of a Fresnel lens. This achieves the same effect with a comparatively thin screen.

There are two ways of observing the screen image: at waist level looking down on it, or at eye-level through a suitable reflecting prism or mirror system.

Waist Level Finder. Here the image is observed by looking down on the screen in the camera top. The viewing screen is surrounded by a fairly deep hood to keep side light and reflections off the screen. The hood nearly always folds up when not in use. It incorporates a magnifier since the image is usually too small for really precise estimation of sharpness. Frequently the hood also has a built-in frame finder or Albada type of optical finder for eye-level viewing (though not focusing).

Waist level reflex finders of this kind are found on single-lens roll film reflex cameras and sometimes on 35 mm. models.

Eye-level Reflex Finder. The viewing and focusing screen itself can be observed at eye-level by placing a pentaprism on top of it. This reflects the screen image into an eyepiece where it appears upright and the right way round. This is the arrangement employed in the majority of modern 35 mm. single-lens reflexes. The image is viewed with the camera held at eye level, looking straight ahead. On a few models the viewing system is so designed that the photographer looks into the eyepiece at an angle of 45°.

Some eye-level reflex cameras use two mirrors instead of a pentaprism. This is a cheaper system but the image is either right way up and reversed laterally (when the camera is held horizontally) or upside down and the right way round (when the camera is held vertical). A more complex mirror system (Porro mirrors) is sometimes used and has the advantage of being lighter in weight than a pentaprism (especially in the case of larger roll film reflexes); on the other hand the Porro mirror is often more bulky.

On a number of precision single-lens reflexes (both roll film and 35 mm. film types) the finder system is interchangeable. Either a waist-level hood with magnifier can be fitted or an eye-level pentaprism unit.

In some cases the screen itself can also be changed to provide a variety of alternative screen types (plain ground glass, ground glass with central split-image rangefinder, clear screen for aerial focusing, etc.).

Image Magnification. When a focusing screen image is observed at waist level with the unaided eye, the visual scale is not constant; the image appears larger the closer the eye is to it, just as any normal object looks bigger from a closer distance. The term "full-size" is frequently applied to the focusing screen image, to imply that the image scale is the same, and the image size approximately the same, as the picture recorded on the film. This is somewhat confusing when a screen image is compared with the visual image of other kinds of viewfinder.

When the screen is observed through an eyepiece magnifier, as it is with all eye-level

REFLEX FINDER. A mirror reflects the rays from the lens on to the ground glass screen on top of the finder. Large precision reflex finders, as used on the twin-lens reflex camera, also show the image sharpness.

reflexes, the visual image scale can again be compared with the scene as observed directly in front of the camera. The scale of the finder image then depends on the focal length of the camera lens used and on the power of the eye-piece magnifier. Normally the system is arranged to yield a 1 : 1 visual image (in the same sense as with an optical finder, as described above) with a lens of standard focal length (50 to 55 mm. on a 35 mm. camera). The image scale changes slightly as the camera is focused on different distances, but this is unimportant.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The eye-level reflex image as observed through the eyepiece appears on a smaller scale when a wide angle lens is fitted to the camera; it appears enlarged with a long focus or telephoto lens.

Twin-lens reflex. A twin lens reflex camera has a viewfinder constructed on the principle of a single-lens reflex, but mounted independently on top of an ordinary box camera. The viewing and taking lenses have the same focal length and are mounted on the same panel. This ensures that when a viewing lens is focused on the viewfinder screen, the taking lens will be focused on the exact plane of the film. On a few of the cheaper cameras of this kind the viewing lens is fixed and the taking lens focused by scale. This reflex system is just a viewfinder.

Twin-lens reflexes are usually roll film cameras with a picture format of $2\frac{1}{4} \times 2\frac{1}{4}$ ins. (6×6 cm.), but may be convertible to take smaller pictures. A few 35 mm. twin-lens cameras have also appeared from time to time. However with such a small format it is not easy to see when the image is sharply focused and some magnifying viewer is essential.

Twin-lens reflex systems are usually limited to one focal length. Where the lens is interchangeable, both the finder and the taking lens must be changed together and are mounted in pairs on a common interchangeable panel.

Usually the finder of a twin lens camera is of the waist level type with a folding hood; sometimes this is interchangeable against an eye-level pentaprism.

Since the viewing lens is some distance above the taking lens, the twin lens reflex is again subject to parallax error. This may be corrected in several ways. The simplest is a permanent masking down of the screen area so that it never takes in more than the taking lens records on the film. On better twin-lens reflexes the finder system incorporates a moving mask coupled to the focusing mechanism. The mask then uncovers the correct field of view corresponding to the picture on the film. On a few cameras the finder lens tilts downwards during focusing to point at the centre of the subject area at all distances. For extreme close-ups with supplementary lenses—which require matched lenses fitted in front of both the finder and the taking lens—the finder attachment may incorporate an optical wedge which deflects the finder beam downwards.

Since the camera and finder lenses move forward together during focusing, the twin lens reflex system is free from any variable field size error. As the angle of view taken in on the film decreases, so does the same angle of view on the finder screen.

The methods of paraliax compensation with a twin lens reflex again cannot correct the perspective or viewpoint error associated with the different positions of the finder and taking lens. For really accurate viewing at very close distances the only reliable method is to mount the camera on a tripod, determine the view through the viewing lens, and then raise the whole camera through a distance corresponding to the separation of the two lenses, to record exactly the same view on the film.

Reflex Attachment. The optical viewfinder built into normal cameras is unable to provide accurate viewing and focusing at very close subject distances (macrophotography, etc.). Reflex attachments or housings are frequently available for 35 mm. precision miniatures with interchangeable lenses. There the lens extension tube, necessary for close work, is replaced by a tube of the same length equipped with a reflex attachment. This is simply a hinged 45° mirror and viewing screen mounted inside an accurately made housing designed for the camera, and transforms it into a single-lens reflex.

The mirror-raising lever is coupled to the shutter and the whole set-up works exactly like a reflex camera. The axial distance from the focusing screen to the lens is the same as the distance from the lens to the film surface.

The same type of attachment is necessary for use with very powerful telephoto lenses. In this case the angle of the lens is so narrow that the camera must be sighted very accurately to frame any particular area of the subject. It would be difficult to make a separate viewfinder to cover exactly the same view as the lens, and it would be impossible to check the accuracy of the set-up just before exposure. So a reflex attachment is built into the lens mount behind the rear component of the lens. F.P. & L.A.M.

Book: *Photographic Optics*, by A. Cox (London).

VIEWING FILTER. Another name for a panchromatic vision (P.V.) filter which shows the subject in its approximate brightness values, as it would be recorded in monochrome by a panchromatic emulsion.

VIEWPOINT. Position of the camera in relation to the subject at the time of exposure. Viewpoint has a considerable influence on both the practical and aesthetic value of the photograph.

There are two ways in which the viewpoint may vary: in distance and in height. Both factors may be varied independently and together they form one of the most important methods of control available to the photographer.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Distance. The closer the camera comes to the subject, the bigger the image. A telegraph pole 50 yards away produces an image twice as big as one 100 yards away; at 25 yards the image is four times as high, and so on.

But bringing the camera close does more than this; it increases the size of the subject in relation to whatever is behind it. Suppose the camera is looking straight down a road lined by telegraph poles 50 yards apart. Then, a pole 50 yards away will give an image twice the height of the pole behind it (100 yards away). But a pole 500 yards away will give an image almost the same height as the pole behind it.

This means that a particular subject appears bigger in proportion to its background as the viewpoint comes closer. So the apparent size of an object in relation to things farther away from the camera can be increased by bringing the camera closer to it.

Height. The normal viewpoint is at eye-level—i.e., between 5 and 6 feet from the ground. Most photographs are taken from this level when the intention is simply to produce a straightforward reproduction of the subject. Viewpoints above and below this level are used either to show details not visible from eye-level, or to present the subject in an unaccustomed aspect for special interest.

A high viewpoint shows more of the tops of objects than is usually seen. It also places the subject against a background of the ground and includes the other objects around it. So a high viewpoint tends to produce a "busy" photograph in which the subject has to compete with a mass of surrounding detail, most of it equally sharp since it is about the same distance from the camera.

There is very little novelty or shock value in a viewpoint above eye-level because it is fairly common for people to look at things this way—e.g., from upper windows.

A low viewpoint shows the unfamiliar underside of things but, what is more important, it tends to isolate the particular thing looked at from the surrounding objects. The background in this case becomes a plain wall, or the sky, or distant hills. To the photographer seeking to simplify his picture by eliminating all but his subject, this is the great advantage of the low viewpoint.

It explains the familiar kneeling stance of the press photographer.

Distortion. Whether the camera looks down or up, it exaggerates the proportions of the things nearest to it. So a high viewpoint makes the tops of things look big in proportion to the lower parts, giving an unpleasing top-heavy appearance to the subject. This effect, however, is often exploited in portraiture to increase the apparent size of a small forehead.

A low viewpoint has the opposite effect; it exaggerates the base of the subject, so giving it an air of strength and stability which is most appropriate with certain subjects—e.g., "strong man" studies.

For the same reasons lines which are parallel when viewed from eye-level converge towards the base when seen from a high viewpoint and towards the top when viewed from below. The most familiar example of this is the result of tilting the camera up so as to include the top of a building.

Sometimes this type of viewpoint distortion is used deliberately for effect, but generally it is undesirable and must be corrected either by the use of camera movements at the time of exposure, or by manipulation in the enlarging process.

The most familiar type of distortion is that caused by a too close viewpoint. As mentioned above, the closer the viewpoint to the subject, the bigger the near parts of it appear in relation to the more distant. So in pictures of people sitting with their legs stretched out towards the camera, their feet appear unnaturally large and in portraits a prominent nose or chin pointed towards the camera appears larger than in real life. For this reason a close viewpoint should be avoided—even 12 feet is not too far away for a natural portrait—and the limbs and attitude of the sitter should be disposed across rather than stretched towards the camera. The same procedure should be adopted in photographing any other subject if the proportions are not to appear exaggerated.

Perspective. The perspective of the picture—i.e., the relationship between the apparent sizes of near and far objects—is controlled by varying the distance of the viewpoint from the subject.

This is clear from the example of the telegraph poles discussed above. It does not depend on whether the subject is photographed with a telephoto, normal or wide angle lens. From the same viewpoint, the relative sizes of near and far objects will always be the same.

Scale. The scale of the subject—i.e , the relationship between the size of the subject and the size of the image formed in the camera—is decided by both the distance of the subject and the focal length of the lens. A closer viewpoint increases the size of near objects more than that of objects farther away; the scale of the image of an object can, however, be kept the same by simultaneous change of viewpoint and focal length. A lens of longer focal length increases the size of all objects in the picture area in the same proportion, whether they are near or far away, so it increases the scale of the picture. But it does not affect the perspective of the image.

So if the aim is to make the subject look larger in relation to the background, the view-

point must be moved closer. But if the aim is to get a bigger picture of the subject without moving closer to it, the answer is to use a lens of longer focal length. F.P.

VIGNETTING. Technique, in exposing prints, in which the picture is faded away more or less gradually towards the edges of the paper leaving a soft-edged, white border.

Vignetting is often used to eliminate unwanted background or other secondary matter —e.g., in portraits.

A card with a shaped hole slightly smaller than the area to be vignetted is held or supported a little above the surface of the paper.

MAKING VIGNETTES. The area to be vignetted is cut out of a stiff card, and supported above the enlarger baseboard. The printing paper is placed underneath the cut-out, so that the image is projected on to the paper through the vignette mask.

The negative and paper are arranged (with the orange cap over the lens) so that the image occupies the desired position inside the masked area. The print is then exposed normally.

The photograph can be vignetted into a dark surround by "flashing" the edges of the paper.

The term is also used to describe a similar effect resulting from the inability of a lens to cover the negative so that the outer edges are under-exposed and print out darker than the rest of the picture.

VINCI, LEONARDO DA, 1452–1519. Italian painter, sculptor, maker of letters, engineer, optician, scientist, anatomist and architect. Described the camera obscura in his secret notebooks, made numerous discoveries in optics and developed a theory of vision, including binocular vision. Also described "nature printing".

VINYL FILM. Sensitive emulsions coated on a plastic base consisting mainly of polyvinyl chloride acetate. Its advantage is low shrinkage as compared with cellulose nitrate or acetate, but it is not dimensionally stable above 40° C. It has been used for certain process materials and cartographic materials where accuracy of image size and scale are essential and no distortion must take place during processing.

Processing must take place at sufficiently low temperatures to avoid softening the film.

See also: *Supports for emulsions.*

VISCOSE SPONGE. Synthetic type of sponge used to wipe surplus water off roll films or miniature films before they are hung up to dry after processing. Films wiped in this way will dry more quickly.

Viscose sponges used for this purpose must be kept absolutely clean, as the slightest particle of grit in the sponge may scratch the film from end to end. Many photographers prefer not to wipe their films at all.

Some viscose film wipers consist of two viscose sponge pads mounted on the inside of a U-shaped plastic or metal strip. The film is drawn through between the two pads, which thus wipe both sides at the same time.

VISCOUS PROCESSING. Method of processing films—especially cine film—by spreading the developer, etc. on to the film surface in the form of a viscous paste or jelly. Used also in in-flight processing of aerial films, since the viscous solution is not as liable to flow under conditions of low atmospheric pressure and with the movement of the aircraft.

See also: *Rapid access.*

VISION

Vision is more than just sensitivity to light. Many of the lower animals and most plants respond to light but cannot "see" in the normal sense of the word. Only when the light sensitive organ can offer considerable information about the quality, dimensions and especially the movement of the outside world can the term "vision" be used.

The process of vision involves both the registering of light impressions and their interpretation. The first function is largely physiological, the second partly physiological and partly psychological.

PHYSIOLOGY

The process of seeing involves the reception of light impressions by the sensitive cells of the eye (the rods—highly sensitive but without colour discrimination—and cones—less sensitive but able to react to colour differences) and the transmission of signals corresponding to those impressions to the brain via the optic nerve.

The signals contain information about the intensity of the visual stimuli, their colour, and disposition. The brain interprets these signals as a picture of the scene perceived. In doing

so it relies in part on comparison with previously stored sense impressions (in the memory—not necessarily derived only from visual stimuli). The interpretation is affected by a variety of physiological factors as well as by the physical signal itself. The latter can, however, be modified by the circumstances of observation as distinct from the observed object itself.

Apart from straightforward deception the eye is therefore subject to various phenomena of adaptation which affect our perception of detail, brightness, contrast, and colour. Further, our sense of vision is also able to extract information from simultaneous signals presented to the two eyes, and derive from that an impression of depth and distance.

Discrimination of Detail. Apart from colour effects which will be dealt with later, detail is produced by a variation in luminance from one point to another in a scene, and results in a corresponding variation of illumination across the retina. The ability to detect such detail is a basic property of vision. It has often been described in two parts: the detectability of small luminance differences and the visibility of different sizes of pattern. The first part has been used to describe the tone-scale requirements in photographic materials, the second to investigate sharpness and graininess requirements. More recent treatments have emphasized the inter-dependence of the two parts of the description. Thus visual threshold contrast (i.e. minimum detectable luminance difference) is found to vary with the size of the detail and the luminance level.

Flicker and Fusion Phenomena. If the luminance of a luminous area varies rhythmically, the sensation of flicker is often experienced. Whether or not flicker is seen depends on three main factors: the rate at which the luminance oscillates (cycles/sec), the average luminance level, and the degree of variation of the luminance.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

This is an extremely important aspect of ciné projection. The data may be reduced to a convenient form which for average cine scenes, expresses the critical flicker frequency for different average luminances on the screen. Below the critical flicker frequency the scene appears to flicker while above that frequency it appears steady. In this steady state fusion of the successive flashes of light occurs due to the property of persistence of vision. Above the fusion frequency it has been shown that the apparent luminance is given by the value of the time average of the actual luminances. This relation is accurate for a large range of frequencies above the fusion value and for a wide range of flash durations, certainly down to 10^{-8} second.

Colour Vision. The fact that the eye is sensitive to a wide range of wavelengths of light does not of itself imply the existence of colour vision. The sensitivity curves of the rods and cones are similar, yet only the cones have colour discrimination. This then is the important aspect of colour vision: that certain wavelengths of light give totally different and distinguishable sensations from others.

About a century ago the first efforts were made to measure colour objectively, and it was found that mixtures of blue, green and red light (called primary lights) could match nearly all known colours, including "white". Over the years these experiments have been embellished but they still form the basis of our ideas about colour vision.

Grassmann in 1853 propounded these basic ideas in the form of laws. In these he stated that the eye appreciates only three variables in the sensation of colour. How these variables are chosen depends on the context in which they are to be used, but there is never more nor less than three needed. In dealing with colour mixture he stated that once a colour match has been established between two lights, they can be treated as identical in any further colour mixture or colour matching measurements. The surprising thing here is that the statement is still true even if the two matching lights have quite different spectral compositions. Such a match is called metameric.

Mechanisms of Colour Vision. The association of colour vision with the cones in the retina is well established. Colour discrimination is at its best in the luminance range 1 to 10^4 ft.-lamberts where rod response is negligible and yet the cones are not over-loaded by the retinal illumination level.

Although a large number of theories have been propounded and examined, no completely satisfactory explanation of all the facts of colour vision is yet available. Nevertheless, several of the proposed theories fit the facts of colour mixture sufficiently well to form good working hypotheses.

VISUAL SENSITIVITY TO DETAIL. To distinguish fine detail to be distinguished. The detail here is assumed to be viewed at 10 ins. from the eye, with an illumination level greater than 10 foot-lamberts.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The trivariant nature of colour vision implies that at least three different cone responses are possible either by each cone having three modes of response or by there being three types of cone. Histological examination of the cones has shown no differences between them. The presence of a pigment in the rods which appears to take part in the visual processes of those cells suggests a similar mechanism might produce different cone responses. Three differently coloured pigments either present together in each cone, or distributed separately throughout the cones, could result in the three required spectral responses, somewhat in the same way that colour filters may be used to produce colour separation negatives. Unfortunately, no sign of any pigments has yet been found in the cones. This may be simply an indication of the difficulty of detecting pigments which if they were like the rod pigment, would bleach when exposed to light. Nevertheless, many authorities still consider that the trichromatic theory assuming three pigments in the cones is the most reasonable explanation of colour vision.

The other, usually more complex, theories of colour vision have been devised mainly to explain more correctly the facts of defective colour vision. Hering's theory is perhaps remarkable in stressing the psychological aspects of colour, in particular the presence of pairs of opposite sensations—white-black, yellow-blue, red-green.

The relation of light to colour still remains very complex; for instance, many different spectral compositions of light are incapable of evoking different colours. On the other hand, with an identical light stimulating the eyes in different circumstances, very different colours may be produced. Indeed, there are many circumstances, apart from the colour stimulus itself, which are capable of affecting markedly the perceived colour; these include the state of adaptation of the observer's eyes, the focus of his attention, the retinal location where the stimulus impinges, size of stimulated area, duration of stimulation, and contrast of the immediate surroundings with the colour stimulus.

DARK ADAPTATION OF THE EYE. After about 8 minutes the cones in the eye have reached their lower limit of response (photoptic phase—I) and thereafter the rods take over the adaptation process (scotoptic phase—II).

Adaptation. If there is a change in luminance, the retina changes its response characteristics to give the best performance possible at the new luminance level. This process is luminance adaptation, and allows us to maintain much the same picture of the outside world under a wide range of luminance levels.

For sudden rises in luminance adaptation is rapid but it is generally much slower for sudden falls in luminance. In particular, adaptation from day-vision (photopic) to night-vision (scotopic) may take as long as 30 minutes.

This type of adaptation is obvious to any user of photographic darkrooms as well as to any traveller on a dark winter's night. It is probably less obvious that it plays a part in the correct appreciation of projected pictures.

Perhaps of even more importance in the viewing of colour pictures (especially projected transparencies) is the related phenomenon of chromatic adaptation. When we move from daylight to an indoor room lighted with incandescent lamps, we are at first aware of a big change in the quality of the colours around us—everything looks more yellow. Very rapidly, however, this sensation disappears as under chromatic adaptation the colours revert to their "normal" appearance. There is often a residual change in certain colours even after adaptation. This is due to true colorimetric changes in the relationship of different colours when we change the quality of the light—one of the reasons why we insist on daylight for critical matching when buying dress and furnishing fabrics.

This overall chromatic adaptation can also occur for much more pronounced changes, although there comes a stage at which the eye can no longer compensate for the changes. In the projection of colour transparencies chromatic adaptation can make us much less critical of a slight defect in colour balance if it is consistent through a series of slides. When we insert a slide of slightly different balance, however, the difference is easily apparent, and in a magnified form, until the eye is adapted to the new conditions.

Colour contrast is a related effect of considerable importance. If two different colours are viewed side by side, each tends to enhance the colour of the other. In other words, the difference between the colours is magnified by viewing them together. A different effect occurs if the two coloured areas are quite small and especially if they form a repeating pattern. The two colours then tend to blend and the difference between them is reduced. If the individual coloured areas are smaller still the pattern will look of one uniform colour derived from a mixture like the two actual colours. This effect is found frequently in fabrics.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

After-Images. A further effect related to adaptation is that of after-images. These occur if we stare hard at a small brightly coloured object, let us say a red box, and after 20 or 30 seconds we suddenly look away at a piece of grey card. The after-image of the red box is a blue-green colour rather than red. The red receptors of the area of the retina where the image of the red box fell were fatigued (adapted). On looking at the grey surface the red receptors therefore responded much less than the blue and green. Thus a blue-green colour was seen. The red receptors soon recover so that the after-image is seen only for a second or so. Similar effects occur with other combinations of colours.

Defective Colour Vision. As with other physiological properties there are small differences between the colour vision of one person and another even when they are normal. Some people however (about 8 per cent of men and about ½ per cent of women) have defective colour vision, which in most cases is of an hereditary nature. In such cases the discrimination between one colour and another is reduced.

The most common form of colour vision defect results in a confusion of reddish and greenish colours. There are two forms of this defect: one in which the relative luminous efficiency curve is much the same as in normal vision, the other in which this curve shows much lower values in the yellow and red regions of the spectrum. When the defects are present in their full form these are termed deuteranopia and protanopia respectively. In a less pronounced form they are called deuteranomaly and protanomaly.

We know from rare cases where only one eye is defective that in these types of defect all colours look like mixtures of yellow, blue and grey.

Much more rare forms of defect involve an absence of blue from the perceived colours (tritanopia) and a complete absence of colour perception of any sort (monochromatism).

These defects tell us a great deal about the mechanisms of normal colour vision, and at the same time constitute the major difficulties in the theories of colour vision.

Methods of detecting colour vision defects fall into two classes. The first is the use of coloured patterns in which the subject is asked to distinguish figures or shapes (e.g. the Ishihara Tests). The second is the use of simple colour matching instruments (anomaloscopes) where the subject has to adjust a mixture of lights to match a standard colour. F.J.B.W.

Colour Association. Despite all the factors affecting the colour appearance, colours are normally perceived as belonging permanently to physical objects or situations out in the external environment. By a casual look round, one may perceive multitudes of colours as belonging to sky, clouds, soil, grass, trees, flowers, animals, people, clothing, conveyances, signs, lamps, decorations, buildings, and photographs. This effect of "belonging" is a consequence of perceptual development.

Colours seem to belong to objects partly because objects tend to continue to look the same even when the light illuminating them is changed and partly because they regularly reflect, transmit and emit light in ways which are characteristic of them. Another reason why colours seem to belong to objects is that the orientation, size, shape, and distance away of an object determine the size, shape, and orientation of the colour stimulus pattern from the object to the eyes; therefore, the colour may seem to coincide with the object whether it is moving or motionless. Such realationships assure close association of particular colours with particular objects as a phase of the general perceptual development of any infant. The colours of many familiar objects come to be well-remembered along with other characteristics of the objects. Thus, with a rose regularly looking red, and even so recalled, while other flowers regularly look other colours, it seems inevitable that red should be perceived as belonging to the rose. S.M.N.

Monocular Vision. An observer looking at a scene with one eye sees it as a picture in two dimensions in the same way as the single lens of the camera sees it. That being so, he should receive the same impression as he would from a photograph in true natural colours seen from the same viewpoint. Such a picture would convey the outlines and colours of objects, but it would give no idea of how far one object lay behind another. There would be no real depth in the scene although all the objects would appear in perspective.

In fact the impression on the observer's brain would be better than this. The brain adds something of its own knowledge and experience to the purely geometrical reproduction of the scene on the retina of the eye. It continues to create an impression of depth from the presence of other factors that normally supplement the stereoscopic impression produced by binocular vision: memory of the true relative sizes of objects in the scene helps the observer to estimate their distance; because of parallax, any slight movement of the viewpoint makes objects move in relation to each other in a way that indicates their relative positions; distant objects are generally lighter in tone than nearer ones; and the eye of the observer is constantly refocusing as it shifts between near and far objects.

So that, while the optics of monocular vision suggest that a scene viewed with one eye should appear flat, in practice this is not so. People who have lost one eye can continue to drive motor cars and work machines without any difficulty. At the same time, the impression of depth is by no means as complete as that given by two eyes.

CC-0. Agamnigam Digital Preservation Foundation Chennai

Binocular Vision. When two eyes look at an object, they converge more or less—according to the distance from the object—so as to form the separate images on corresponding parts of the retina. This automatic act of converging is coupled to the focusing mechanism of the lenses of the eyes. The effort of making the two images coincide focuses the lenses for the particular distance which corresponds to the angle at which the eyes converge (the principle is the same as that of the optical rangefinder). This ability to converge and focus the eyes at the same time is acquired during the first few months of life.

At the same time, because two eyes view the object from two separate points of view, each sees a slightly different picture. The brain fuses these two pictures and thus helps to convey the solidity of the object and indicate its place in the depth of the scene. When the eyes look at an object more than about 200 feet away, the two lines of sight are practically parallel, and the two pictures are substantially the same. So that beyond 200 feet away binocular vision no longer helps to give the impression of depth, though special techniques in stereophotography can bring out depth.

Seeing in Perspective. The scene in front of the eye is reproduced as an image in perspective on the retina. A camera, built to the same specification, would produce the same image. But the human eye is more than a camera, it is part of a brain, and the brain interprets the picture in its own way, which is not always the camera's way.

The eye accepts a photograph which shows horizontal railway lines converging as they recede. But it quarrels with a photograph which shows the same effect taking place with the walls of a vertical tower. In fact, both pictures are right according to the laws of perspective, but while the eye is familiar with the horizontal picture, it finds the vertical picture strange.

The eye sees the picture of converging railway lines in one piece, as the camera takes it. But when the eye looks up at a tall tower, it scans it from bottom to top and, in fact, looks at it in sections. The broad base is never consciously compared with the apparently narrow top until the two are seen in a photograph taken by pointing the camera upwards. Seen in the same picture, the proportions appear completely false.

Sometimes the apparent falsity is worth seeking deliberately for its novelty or shock value. Many photographers make use of it for such reasons. But it is generally objectionable in normal photography where it is wiser to satisfy the eye by showing all vertical lines as parallel to each other and to the sides of the picture. This can be done on the negative or, where the lines converge on the negative, on the print.

Animal Vision. The eyes of animals are similar in most respects to those of human beings, but there are probably differences in the way they see things and in the colour sensitivity of the retina. Experiments to find out more about the physiology of animal vision have been carried out, using the actual lenses from the eyes of dead animals.

Successful photographs have been taken with sheeps' eyes in the course of these experiments. The eye of a slaughtered sheep has a window cut in the back of it and a ¼ in. disc of sensitized material is inserted. The tiny negative is exposed by flash lighting; developed and enlarged it yields a recognizable picture.

This method could bring useful information about the physiology of human vision. R.B.M.

PSYCHOLOGY

Vision is one of the tools the mind uses to find out something about the world around it. The carpenter uses it to make sure that two screws are the same size; the toddler uses it to watch his step; the photographer needs it to find out what kind of picture he can make from a scene of cows and trees. In each case, light rays are being focused on the sensitive surfaces of the retinae, and the images thus produced in the eyes are transmitted to the appropriate parts of the brain by means of the fibres of the optic nerves.

Physiologists have some information on what happens to the optical stimuli in the brain. But the facts they know will help us little when we wish to find out why and according to what rules the carpenter, the toddler, the photographer see what they see. At the present time the best answers to these questions are not found by studying the nervous system but by looking at what is accessible to all of us, namely experience.

Here, then, the psychologist takes over. His task is complicated by the fact that vision is not an isolated operation. It is constantly influenced by other activities of the mind, which looks at things for a purpose, reacts to them with desire or refusal, remembers things observed and learned in the past, thinks about them, and applies standards as to what they should or should not be like. The strivings, past experiences, thoughts, and judgements of values that are particular to the photographer make his visual experiences different from those of the carpenter or the toddler.

Even so, there are certain basic rules that seem to hold for all seeing. Some of them will be taken up first.

Organization. The visual field presents well segregated units, such as buildings, trees, human figures. This is surprising if we remember that the retina of the eye consists of millions of relatively self-contained receptors or groups of receptors, each of which transmits but one point of the image.

How are the point-sized stimulations grouped

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

ORGANIZATION. Visual elements tend to combine spontaneously into groups which share common perceptual properties, such as shape, size, colour, brightness, spatial orientation, etc. Here the black, short, vertical bars form one group, whereas the white, long, obliquely oriented ones form another. If the elements of a group show repetitive characteristics of orientation, a certain rhythm presents itself.

together in such a way as to form images of objects?

The rule which controls visual organization can be stated in two ways: "from above", that is, with regard to the whole, and "from below", that is, with regard to the parts.

From above: "The elements of a visual field will spontaneously group themselves in such a way that the simplest possible organization of the whole results." Example: if the colour, shape, texture, and position of an insect are adapted by nature to those of a twig, the insect will be seen as a part of the twig, our better knowledge notwithstanding. By unifying twig and insect a simpler over-all pattern is obtained than by separating them.

From below: "The elements of a visual field will combine spontaneously to the extent to which they share perceptual properties." That is, objects that resemble each other in shape, size, colour, brightness, spatial orientation, etc., are related to each other visually.

The photographer does not often concern himself with mere geometrical patterns; however, it is essential that he learn to look at the more complex things of nature as though they were meaningless forms. Only in that way will he observe the purely visual properties that determine what is seen. Our eyes profit surprisingly little from what we know intellectually about the objects represented in a picture. What is only known but not seen makes a poor effect photographically. We may understand very well that a certain area in the picture represents a tree and another a house; but if the two areas have visual properties that make them fuse rather than separate, knowledge will not remedy the defect. In the same way, if a duck looks like a patch of mud, it will not be transformed into a duck by the camera.

The photographer should look at things as though he had never seen them or heard about them. For what he photographs is, strictly speaking, never the object "itself" but certain visual properties of the object. If you set out to photograph your wife you are likely to produce a non-committal, uncharacteristic, vaguely female effigy unless you ask yourself, consciously or unconsciously: what particular properties of this person do I want to bring out? What visual factors express these properties? The erectness of the body, the curve of the jaw line, the light reflections on her hair? If so, it is these features you must strengthen and sharpen by the choice of the right moment, the control of camera angle, distance, lighting, etc. Nothing in this world is anything but the totality of its properties.

Identification. To identify objects effectively in a photograph requires more than enabling the beholder to guess what is in the picture. In practical life, all the cognitive capacities of the mind, namely, sensory perception, memory, and reasoning, co-operate in steering the person through the business of the day, and in Western culture the share of vision in the work of this team has been severely reduced. The average person has become accustomed to relying on his or her eyes for little more than a minimum of cues, sufficient to distinguish red light from green light, avoid running into lamp posts and passers-by, tell a customer from a salesman, and so on. Therefore, such a person seems half-blind when called upon to look at a painting or to take a photograph; because these activities require the observation of a maximum rather than a minimum of visual features and make it necessary to understand by means of the eyes what otherwise is taken care of by routine identification based on learning in the past.

Photographic identification requires that the pattern in the picture be relatable visually to the image the observer has formed of it, or is expected to form of it, in his mind. This does not necessarily mean that a great deal of detail has to be reproduced. In fact, the visual identity of an object is most effectively conveyed by the "structural skeleton" of its main axes and proportions, easily rendered by a simple line drawing, but often hidden by a photograph, so that animals, young children, primitives, who immediately understand an elementary drawing, may see nothing but a jumble of spots in a snapshot.

It is relatively simple to recognize the picture of a woman executed in the most extravagant modern style so long as it respects the basic structural skeleton of the object. It is more difficult to recognize a natural form when viewed from an unusual angle, which foreshortens and all but destroys the familiar structural skeleton. No matter what angle or lighting the photographer may choose, he must see to it that in his picture the main visual characteristics of the object clearly dominate all the detail of shape, colour, and texture.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

IDENTIFICATION. Left: *It is comparatively easy to recognize an unusual stylization of a familiar object—e.g., a Picasso-like figure of a woman—as long as it respects the basic structural skeleton. In other words, the layout of the figure must correspond in its sense—even if not in its proportions—to a natural object.* Right: *It is more difficult to recognize a natural figure when it is presented from an unusual angle that does not immediately reveal the familiar structural shape.*

Emphasis. What main characteristics of the object should we emphasize? This depends on the purpose of the photograph. A documentary picture taken to serve technological or scientific ends must bring out the particular features which are relevant for the competent handling of the physical object. It must visually define the local colours and textures, the typical shapes and proportions, the decisive spatial relationships. The artistic photograph, on the other hand, is meant to convey the expression rather than the physical properties of the object, that is, it must stress the features that carry the feeling to be transmitted by means of the object, the ruggedness of a mountain, the sensitivity of a hand, the gracefulness of a vine.

Expression. Expression results from the "forces" transmitted by visual qualities. No knowledge of the mood inherent in the subject matter of the picture will replace appropriate photographic expression. A beach scene rendered by sagging contours, heavy masses, and gloomy contrasts is no beach scene but a funeral.

What makes for expression? The main rule indicates that nothing is expressive unless it fulfils two conditions: it must be visually clear-cut, and it must be dynamic.

First, an unsure contour, an undefinable colour, a disorganized arrangement are incomprehensible to the eye and therefore lost for the message the picture is supposed to transmit. Secondly, a visual pattern which does not unmistakably produce the fitting measure of tension and relaxation, stability and instability, crescendo and diminuendo, is not expressive. Oblique position, overlapping, distortion, asymmetry, wedge shape, make for tension and instability. Vertical and horizontal orien-

EXPRESSION OF TENSION. Oblique positioning, overlapping of lines, distortion of shapes, asymmetry, wedge forms, and pointed shapes make for tension and convey instability.

EXPRESSION OF RELAXATION. Vertical and horizontal orientation, completeness, normal aspect, symmetry of shapes, and regular outlines give a relaxed impression and convey stability.

tation, completeness, normal aspect, symmetry, make for relaxed stability.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Knowledge. We have said that knowledge must not be relied upon to replace interpretation by visual means. Nevertheless, it is highly desirable that the photographer should have some information about the things he is portraying and that he should have done his own thinking on them. Nobody can be expected to make a scientifically useful photograph of a medical preparation, a machine, or the behaviour of a group of animals unless he is familiar with the meaning of what he sees and unless he knows what the essentials of the object or happening are. Many of the best artistic photographs show that their makers have not only been intrigued by the play of pattern and texture, but have understood through their eyes what lies beyond the reach of vision and, in turn, have succeeded in expressing by the visual surface some of the things they have learned and thought about their subjects.

Translation. A photographic picture differs in many respects from what we see in the world around us. Also our attitude toward what we see is not the same in the two cases. Therefore if you want something in the picture to look as it does in everyday life, you cannot simply make a mechanical copy of it. You must translate it into a new medium, that is, adapt the object of the "real" world to the conditions of the picture world.

Selection *v.* Contemplation. In everyday life we use our eyes mainly for the purpose of practical orientation: we pick out the things we need to know about and ignore the rest. This attitude is enhanced by the fact that the visual field is largely accidental, crowded with irrelevant things, and lacking in any definite pattern and colour scheme. Under these conditions, the best we can do is to assume the "selective attitude". When people look at pictures, a different attitude is appropriate. It may be called "contemplative". Contemplation means receiving what is offered rather than searching for what is desired. It means dealing with the visual matter as an organized whole, in which every element is a necessary and significant part. An accidental "slice of reality" will leave the contemplative eye confused. The main reason why the amateur so often produces poor results is that he persists in the selective attitude while handling his camera. Later, when he looks at his prints, he finds himself partially transformed from a practical into a contemplative man, and discovers to his bewilderment that his picture is populated with chopped-off feet, stray boxes, and alien background figures, which "did not count" when he looked at his subject.

Space. The world we see around us is practically boundless. The picture cuts a piece out of this continuum. The frame changes almost all visual qualities because they depend on relations within a larger context. A kitten may cease to be small when the large things around it are not shown. The striking quietness of a tree may have come about by contrast with its restless environment, and the active gesture of a mother may be incomprehensible without the child to which it refers. On the other hand, objects reveal hidden virtues when relieved from an overwhelming context. The selected portion of the visual field must be self-contained and self-explanatory. Furthermore, the frame does not only remove an environment but also adds one. It provides a severe rectangle, to whose verticals and horizontals all shapes in the picture must clearly relate themselves.

In everyday life, any object we look at has a well defined place in the total space which contains all other objects, notably the observer himself. The framed space of the picture has no such connexion with its surroundings. Distant mountains may cease to look distant

FRAME AND CONTENT. The frame of the picture can alter the visual qualities and apparent content of the subject. **Left:** *The active gesture of the subject is incomprehensible by itself.* **Right:** *It makes sense when the child is included in the frame to complete the picture. Such a change of framing also alters the dynamic equilibrium of the picture from an unstable to a stable one.*

because distance is a relation between near and far. The surface of a lake, taken from a bridge, may look upright in the picture, and a tilted camera will produce a tilted building. Which may or may not be what the photographer wished to obtain.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Time. The camera frames the subject in time as well as in space. It picks a momentary phase from a time continuum. Psychologically, however, a snapshot is not experienced as a part of a time context but as a translation of action into a timeless picture, in which movement can be expressed only by the pictorial means of oblique orientation, outspread legs, blurred shape, etc. The photographer is always in search of the "pregnant moment", which epitomizes the features of a given situation.

Depth. The ability of a photograph to convey depth and volume is limited. Unless the stereoscopic technique is used, both eyes of the beholder receive the same image and thereby reveal the flatness of the picture. This does not rule out depth entirely since effective means of creating the third dimension are available within the visual pattern itself. Perspective, overlapping, shading, light contrasts, etc., must be stressed by the photographer if he wishes to compensate for the lack of "binocular parallax".

However, even at best the range of depth is limited in a picture. The weaker the depth effect, the less there is of what psychologists call the constancy of size and shape, that is, the tendency of everyday vision to eliminate perspective distortions and to see objects, and parts of objects, in their physically correct size relationships. Hence the gigantic hands of portrait sitters and the desperately small background landscapes.

This effect is reinforced when a photograph is viewed from too far away, that is, when the angle at which it is seen is smaller than the one at which it was taken.

Colour. Black-and-white photography reduces the colours of everyday vision to a brightness scale, whose particular nature depends on the sensitivity of the film to the various wavelengths of light. It reduces the three-dimensional world of hue, brightness, and saturation to the one-dimensional world of the grey scale. Thereby it simplifies the relations between the elements of the picture.

This is like translating a symphony into a tune that is played on a flute. Things that looked different in reality may look alike in the picture. This may make them harder to identify, but at the same time the smaller number of visual values can enhance the order and clarity of the composition. Also by controlling the lighting the photographer is free to assign to any particular object almost any value of the brightness scale from black to white.

In colour photography this freedom is severely curtailed, and the bewildering variety of visual values makes it difficult to unify the composition. Here the photographer can help himself best by choosing subjects which contain a relatively small number of hues. The complexity of the richer medium will reward the colour photographer for his greater effort. It offers him a life-likeness and an emotional appeal in comparison with which a black-and-white picture looks cold and abstract.

Photography *v.* Painting. While it is true that photography draws well shaped visual patterns from the largely accidental raw material of reality, the very nature of the photographic medium indicates that it offers its best in a realm somewhere in between everyday vision and the highly controlled creations of the painter.

Not by accident was photography discovered in a century which had found in the momentary aspects of surface, shape and action a new instrument for the interpretation of life. The human mind always roams between the poles of abstracted order and the bewildering freshness of direct experience. Vision reflects both order and complexity and is constantly in need of either one. At a time when painters are taking full advantage of a medium that permits them to render the basic melodies of human existence by means of remote patterns, it is the function of the mechanical technique of picture making to remind us that reality remains an inexhaustible source of challenging disorder. R.A.

VISUAL AIDS

On a wide definition visual aids would include anything that helps a teacher to teach, or a learner to learn, by means of an appeal through the eye—e.g. the blackboard, charts, models, etc.

More specifically the term, however, denotes visual material developed or made available for schools in the form of projection images such as cine film, film strips or slides. Such material is comparatively inexpensive, since it is produced by mass copying, and is easy to store.

Cine Films. Educational films are supplied to schools in 16 mm. size on safety film; they may be in colour or black-and-white, in sound, silent or mute versions. In content and style of production they are distinct both from entertainment films and from general documentary films.

Each educational film is planned to serve a

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

definite purpose in the teaching of a specific subject to a given age-range of pupils. As the film is an aid to the teacher and not a lesson in itself, it can deal with the part or aspect of the subject which is most suitable for visual presentation. For satisfactory incorporation in a lesson the film is kept short; 10–12 minutes is the common length, though some classroom films run for 20 or 25 minutes. A wide variety of photographic techniques is employed: direct photography, animated diagrams, photomicrography, speeded-up and time lapse photography, and other devices; these techniques are not used for their stunt or surprise value, but for clarifying and instructing.

In sound films the sound track consists usually of a commentary, which is carefully planned to suit the subject and the age-range of the children, and is exactly synchronized with the visuals. Sound tracks also include natural sounds, for example in films of animals; or natural dialogue, for example in French teaching films. Music is used only when it is relevant to the subject, for example in a film on ballet or on the symphony orchestra; the inclusion of background music, as so commonly used in feature and documentary films, is generally condemned by teachers as distracting and unsuitable. It is usual to supply with an educational film a brief booklet of notes for the teacher, explaining the aim of the film and describing its contents.

Usually the sound track on such films is an optical one, which is cheaper to produce on a mass basis and incapable of being erased or otherwise interfered with. Magnetic sound tracks are easier to produce for films in small numbers, and also offer the facility of providing single copies of the film with sound tracks in different languages.

Narrow-gauge 8 mm. film is to some extent replacing 16 mm., mainly because it is cheaper. Magnetic 8 mm. sound films have the same applications as similar films in the 16 mm. gauge. Optical 8 mm. sound offers the advantage of still less expensive mass production of the films and protection against accidental erasing of the sound track. The quality of magnetic sound on 8 mm. is however, still superior to that of optical sound. The latter is adequate for speech and commentary.

Another application of 8 mm. film developed only in this gauge is the concept film. This is a short film length, running for about one to two minutes, illustrating a single idea or concept in dynamic terms. This may be a simple movement cycle, for example the action of the heart for a biology class, filmed either from a live subject or in the form of an animated diagram film. Such concept films are interpolated in the normal lecture or class whenever required, and do not take up an appreciable time proportion of a lesson. For easy presentation such concept films may be shown on special daylight projectors taking cassettes of the film in a continuous loop. The movement cycle can thus be shown without virtually any preparation.

Film Strips and Slides. The 35 mm. film strip is very widely used in schools. Single frame size (18 × 24 mm.) is generally adopted as the standard. Most teaching film strips are in black-and-white form, though colour is considered desirable in subjects such as nature study and art, and also for all material planned to be shown to young children. The number of frames varies; but the commonest practice is to supply about thirty frames, often divided into sub-sections according to subject matter. As with cine films, the visual material is carefully planned for a specific purpose, and is accompanied by a booklet of teachers' notes. Film strips are generally prepared from master-cards, which may be photographs, diagrams, or drawings in a wide variety of styles; elaborate montages are not often successful.

The double frame (24 × 36 mm.) finds favour with some users.

Film slides 2 × 2 ins., which some teachers prefer, are an alternative to the film strip. A few such slides are sold in commercially prepared sets; but it is more common for teachers to make their own slides by cutting up film strips and inserting individual frames in special glass or paper mounts which are marketed for this purpose. The old-fashioned glass lantern slide $3\frac{1}{4} \times 3\frac{1}{4}$ ins. is no longer widely used, but $2\frac{3}{4} \times 2\frac{3}{4}$ ins. slides are.

Sound and Slides. Current systems of coupling between automatic slide projectors and tape recorders permit complete lessons to be assembled in slide form, with the teacher's explanations recorded on tape. The tape can moreover carry cueing signals to actuate the slide change by remote control at the appropriate points of the lecture. This system is flexible as the teacher can prepare his lesson whichever way he wants to. He can include as many or as few slides as he wants, subject to the capacity of the projector. In the last resort the presence of the lecturer or teacher is only necessary for direct contact with the pupils, such as answering questions. This is indeed the way in which audio-visual systems are frequently used for briefing and instruction in industry, the military forces, etc.

To some extent the same considerations apply to sound in the form of recorded lectures in conjunction with film strips. As, however, the sequence of images on the strip is unchangeable, film strips with sound accompaniment are more set in the character of their lesson. The visual and sound records have to be specially planned and prepared with a view to production in larger numbers.

With film strip there is also the possibility of recording the sound on gramophone discs. The fact that such a sound record does not permit changing or adaptation is in this case no handicap. The combination also has the advantage that it is easier to prepare for pro-

jection. A number of film strip projectors combined with gramophone record players exist for this purpose.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Sound On Its Own. Sound recordings by themselves, without picture, are also a fairly widespread teaching aid, especially for learning foreign languages. The oldest and best known system is the gramophone record, and language lessons on records have been issued by certain firms for several decades. The tape recorder is a more modern and much more flexible means for this purpose, since it enables the student to record his own voice alongside a teaching track (with a twin track recorder) for comparison of pronunciation, etc.

An elaboration of this idea is the language laboratory where a number of pupils are gathered in one class, each equipped with a tape recorder inside a more or less sound-proof booth. The tape machines are connected to a master machine for the instructor who can communicate with all pupils simultaneously or with any selected one individually. Pupils record their exercises on their own tapes, can play them back and have them corrected by the teacher.

Language laboratory instruction is of course combined with visual work to cover the written aspect of a language. This may be achieved with a remote-controlled projector which projects sentences and other written material on to a screen in front of the whole class. Or the teacher may fall back on the blackboard or an overhead projector.

Overhead Projection. Cine, film strip and slide projectors can show material reduced photographically to the image size which such a projector can handle. This therefore implies preparation.

The overhead projector is suitable for impromptu visual demonstration, and is the optical equivalent of the blackboard. The teacher there can write or draw material on a transparent foil over an illuminated light box, and the image is simultaneously projected on to a screen behind the instructor via a mirror system. The writing surface is large enough for convenient operation, usually about 10 × 10 ins. The overhead projector can also be used to project large transparencies on the screen. It usually needs at least partial darkening of the room. Though this reduces the degree of teacher control over the class in the case of younger children, it increases the concentration of the students on the material presented.

Other Aids. Other items of teaching equipment generally included as school visual aids are: wall charts presenting information by means of selected photographs or pictures with some verbal explanation; microslides; geographical maps; displays of samples and specimens arranged to convey information; and models of various types.

Uses. The basic principle in the use of such visual aids in the classroom is that they in no way supersede the teacher, but help teacher and learner by giving a vivid impression through the eye. Visual aids are used as part of a lesson; they are often preceded or accompanied by explanations from the teacher and followed by questions, discussion and other classroom activities by the pupils.

The particular value of the visual medium in school teaching lies in the appeal which pictures have to all children; the emotional response of pleasure and interest is exploited by the teacher and linked with the intellectual effort of learning facts and understanding cause and effect. There are obviously many classroom topics that can be understood better when the teachers' words or the textbook explanation can be illuminated by pictorial illustration. Some children who have difficulty in following a verbal presentation can understand a well-planned pictorial explanation.

Visual aids (in particular films, film strips and wall charts) are used also in different teaching situations outside the ordinary school: for apprentice training in factories; for religious teaching in Sunday schools and churches; for mass-education; for adult education and technical instruction; and for advertising. Content and production vary according to the special circumstances for which the material is required.

Equipment. The use of films and film strips in schools involves the provision of a certain amount of apparatus. Many firms specialize in the production of school 16 mm. cine projectors and classroom film strip projectors; the emphasis is on robust construction, portability, easy maintenance and low price.

Equally, the machine should be easy to set up ready for projection and not require too much expert handling by the teacher who also acts as the projectionist. Hence some modern projectors incorporate automatic film threading and certain other refinements. For school room use a projector with the loudspeaker built into the same case is preferable to one with a separate speaker—which needs extra wiring up, the running of cables, etc.

Since 16 mm. films come with optical or magnetic sound tracks, a combined optical and magnetic projector is preferable to one suitable for optical tracks only. Where a school has several projectors, only one need have provision for recording magnetic tracks; the rest can be (and usually should be) pure playback projectors. The one projector with recording facilities can be used for adding sound tracks to films produced specially for the school.

A zoom projection lens is a help, especially if one machine has to be used in several classrooms of different size, but not essential.

An 8 mm. projector for school use must again be robust, easy to handle (with automatic threading) and capable of projecting striped 8 mm. sound films.

Projectors with an integral back projection screen have certain important advantages. One is that a film can be presented without darkening the room. Further, the projector is set up in front of the class instead of at a point behind it, so that the teacher retains direct contact with his audience. Special projectors of this kind are also available for the screening of concept films in the form of pre-loaded film cassettes. These are simply clipped into the projector to set the machine going immediately, and require no threading whatever. With sound film projectors for cassette loaded films some threading through the sound head is usually necessary, but even this is minimal. As the film is arranged as a continuous loop in the cassette, the same movement cycle can be shown repeatedly to facilitate understanding by the class.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Back projection screens are also useful with film strip and even slide projectors. For projection on a large screen it is generally best to have the screen itself permanently in front of the class, either behind the blackboard (many modern classrooms are designed to make this possible) or in the form of a roller type screen suspended above the blackboard and pulled down when necessary.

If the projector is set up behind the class, some form of remote control is desirable, so that the teacher can remain in front. The remote control units normally supplied for still projectors come with rather short leads (intended mainly for home projection). Alternative remote control systems, suitable for classroom use, employ either ultrasonic sound signals or wireless signals—in either case eliminating the need for a cable connection between the projectionist and the projector altogether.

Like a complete 16 mm. or 8 mm. sound film, a slide or film strip series with a sound commentary on a pre-recorded tape is more or less a self-contained lesson or part lesson. The teacher then has no other function during the show than to supervise the class watching the film or slides. Any questions and answers must come afterwards.

There are two other systems for providing a more flexible method of instruction, still using pre-recorded sound accompaniment. The first is the sound slide, consisting of miniature slides mounted in special large frames carrying a magnetic track surrounding the slide itself. A brief explanation or commentary can be recorded on that track (usually lasting about 20 seconds per slide) and the slides changed by the teacher by remote control. The teacher thus determines the rate at which the pictures are shown, and can interrupt the presentation at any point for questions and answers. A similar system also exists for film strips, with an optical or a magnetic sound track recorded on every alternate frame next to an image frame.

The other type of projector is much more a teaching machine, consisting of a slide or film strip projector with built-in tape recorder. The complete lesson is pre-recorded in image and sound, but the pupil controls the rate at which the pictures (and their corresponding sound commentary) are shown. He advances the image once he has taken in the information presented, and can also back track to the previous illustration and sound when required. Such machines require no teacher at all (except for the preparation of the material), and have been used also for instruction of apprentices, mechanics on a factory bench, maintenance engineers following a complicated repair or maintenance routine, and so on.

All these adaptations require special equipment. They have therefore not yet spread very far into general student instruction.

Other projection aids for educational use include episcope and overhead projectors. Episcopes are used for the showing of opaque pictures, but are largely falling into disuse owing to the comparative dimness of the projected images. Usually it is more practical to copy an illustration required from a book on to a reversal film and use the transparency for projection in a normal slide projector.

Micro projectors are sometimes supplied to school science departments. These enable microscope slides to be shown to a whole class simultaneously, where it would be impractical to let every student look in turn through a microscope with the specimen set up.

There are numerous commercial firms producing classroom film strips and wall charts; school film production is severely restricted by economic difficulties. There is also a certain amount of amateur production of school visual aids, particularly of film strips; this material is often of limited or localized use, but some of it is used on a national scale.

Schools obtain wall charts and other pictures in much the same way as they obtain text-books. Films and film strips are obtained from various sources. Film strips are generally purchased and kept in the schools. Films are usually hired, either from a library organized by the local education authority, or from a commercial library, or from the library of the Educational Foundation. There are some free sources of films and film strips, but the material they supply is not always appropriate for classroom use.

Concept films are also available through the library of the Educational Foundation. These are mostly sold outright, since they are required repeatedly in basic lessons. It is therefore more worthwhile for a school to build up its own library of such concept films. In Britain these titles are sponsored by the makers one of the 8 mm. cassette projectors. Short films of other single concepts are also available for educational use as part of the Scientific Film Encyclopaedia. This is a collection of basic movement records produced by a scientific film institute in Germany, but available inter-

nationally under the auspices of the International Scientific Film Association.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Television. Unlike the other visual aids which are directly under the control of the teacher for any one class, television is a more centralized affair. Educational programmes are available over the national broadcast television networks. But they are tied to specific broadcast times, and thus oblige the teacher to organize his schedule to fit in with such times. Experiments have been carried out in Britain and elsewhere to produce special programmes for a school or group of schools, relayed by a closed circuit system from a central point. This, however, still ties a class to a fixed time for the transmission, especially where the latter is largely made up of live material.

There are two possible developments in the use of television, especially in closed-circuit systems.

The first is the use of tele-cine transmissions, playing a film through a closed-circuit system to a class or a number of classes. Where several classes are involved, this requires co-ordination. But once a school is equipped with closed-circuit television, this is permanently installed in all classrooms, requires no preparation or setting up, and is available for daylight observation. Also a single film—usually obtained from a library—can be shown to a larger number of pupils.

The other possible development is video tape. Here the film is entirely replaced by a tape recording which may be played back either on a central video tape machine or even on individual tape playback units in specific classrooms. Such a set-up, however, requires expensive equipment.

National Organization. Many difficulties have been encountered and overcome by educationists during the recent development of visual education in this country. To promote and assist the wider use of visual methods in the classroom is the function of the National Committee for Audio-Visual Aids in Education, set up in 1946. Composed partly of representatives of teachers' organizations and partly of representatives of local education authorities, it is responsible for evolving general policy and watching the interests of teachers. Its parallel organization, the Educational Foundation for Visual Aids, was set up in 1948 as a non-profit-making educational trust to arrange for the production of new visual aids, for the supply of equipment to schools, and for the distribution of visual material for hire and for sale. These two national bodies work in close association to solve the many problems involved. They have a free advisory service on technical matters and on visual material; organize courses and conferences on visual education; and run a film library with a sales service of films and film strips with free preview facilities. Their information service, called VENISS (Visual Education National Information Service for Schools) provides combined national catalogues of available films and film strips, a monthly magazine called *Visual Education*, a year-book of visual aids, and occasional pamphlets and information lists.

Teachers are directly represented on the National Committee by means of a special sub-committee called the Central Committee of Teachers' Visual Aids Groups. Throughout the country groups of teachers who are specially interested in visual education combine in visual aids groups, for the discussion of visual aids topics, the review of new visual material, the production of their own films and film strips, or for training in the use of equipment, and other activities. These groups elect representatives to the Central Committee and hence are constantly in touch with national developments.

The production of new visual material is an especial concern of the national bodies. Contact with teachers through the groups supplies information on what material is required. Efforts are made to secure production of selected topics through negotiations with industrial and other sponsors; the Educational Foundation itself sponsors production as far as possible out of its trading profits. In every case a practising teacher is appointed as educational adviser to co-operate in the production of each visual aid so that the producer may know what is acceptable to teachers. The national bodies are always prepared to co-operate with commercial producers, to give free advice to amateur producers, or to provide information for sponsors on the production and distribution of visual aids.

Standards. Most of the dimensions and other specifications of audio visual materials are subject to national and international standards. These define slide and film strip sizes, 8 mm. and 16 mm. film, screen brightnesses, image definition, and sound tracks and sound systems. J.A.H. & L.A.M.

VISUAL APPEAL. Visual appeal denotes the ability to catch the eye and hold the attention. It transcends the subject matter and artistic merits of a picture and includes the potential response to their combined attraction. That is to say that visual appeal depends on both what is shown and who is looking at it.

Any snapshot of a baby would provide ample visual appeal for its family. Comparatively dull photographs of a new piece of machinery

are still very likely to interest its potential users. But to produce or find pictures of sufficiently wide appeal that will draw the eyes of hundreds of thousands to some magazine cover or advertising display is not quite so simple.

CC-0. Wellcome Library. Digitized by Sevaa Foundation (Chennai)

Pictures that meet such conditions are sometimes caught by photographers who either just follow their instincts or are lucky enough to stumble on the right opportunities. More often, however, they are supplied by skilled professionals who repeat and vary effects based on certain fixed formulae—even when they are not conscious of doing so.

Methodical analyses of visual appeal are largely speculative. Although controlled investigations of the subject in terms of experimental psychology are conceivable, the data we possess are neither complete enough nor sufficiently documented. It is generally agreed, however, that visual appeal is a complex phenomenon and whilst the terms applied to its components vary a great deal and may be grouped in many ways they usually cover three categories: novelty impact, emotional response and signalling force.

Novelty Impact. Novelty impact is governed by news value, personality content and action.

(1) The value of any news clearly depends on just how new, how big and how close it is to the man whom it seeks to inform.

(2) The more a personality is known the greater his or her pictorial impact. Yet the face of any person still has a stronger impact than a scene lacking human content.

(3) Anything dynamic will attract attention. Action, movement, expression, visually score over repose.

Emotional Response. Emotional response is evoked primarily by the human element in the picture. This can be broken down under the more specific facets of survival, sex, success, experience and escape. Most of these appeals are elementary and people are hardly ever indifferent to them. They remain effective irrespective of whether the reaction to them is positive or negative: approving or disapproving and whether it involves pleasure or revulsion, temptation or fear.

(1) Death being the ultimate problem of everybody alive, any pictorial demonstration of survival is universally fascinating. This explains the unfailing attraction of all young creatures—but also of catastrophe, murder and any form of violent fate from which the reader may feel reasonably sheltered.

(2) There is an effective appeal of sex, not only in the obvious display of it but also in the associations that the subject may evoke. The world of entertainment, for example, is an inexhaustible source of such associations as it draws mass attention to its stars and blends their personalities with the parts they play.

(3) Other people's success stimulates curiosity, challenges ambition and evokes envy. All these varying responses look for the identical reassurance that the person behind some achievement is as human as ourselves.

(4) It is human to cherish any confirmation of one's own experiences. Familiar faces, places and situations are likely to meet with warm response. Everyday aspects of everyday subjects may have little appeal, but there is a great deal of it in unusual aspects.

(5) There is a promise of thrill in change, distance and adventure; pictures that feed people's dreams are popular.

Signalling Force. Signalling force is the power in a picture to make itself noticed by its sheer formal qualities; these are clarity, pattern and emphasis.

(1) The primary task of any picture is to concentrate on its subject, lift it from its surroundings and show off exactly as much detail as its story needs.

(2) A picture should be obviously self-contained; its unity may be visibly reinforced by distinctive framework, balancing elements or graphic space management.

(3) Emphatic angles of view and perspectives, a strong suggestion of direction, speed and tension as well as contrasts of size, tone, light or colour possess strong pictorial momentum.

Application. Any successful picture will have something of all the three basic categories that add up to visual appeal. But only a few of the many elements on which any of these categories rest are likely to be present at any one time.

It is useful training discipline for photographers, designers and art editors to apply some such method of classification as this to analysing existing publications and photographs.

This is done, as a rule, by using a points system based on credits that represent these several appeals.

Although both the classification used and the evaluations gained in an exercise of this type are bound to be arbitrary they help to standardize habits of pictorial judgement provided the experimenter will force himself clearly to account for his motives in crediting points rather than worry too much about exactly how much credit this or that subordinate element would deserve. At any rate such an approach is a great deal more effective than just following the time honoured but vague advice to visit art galleries and look at the work of the masters. A.K.-K.

VOGEL, HERMANN WILHELM, 1834–98. German chemist. Became the first professor of photography at the forerunner of the Technische Hochschule (Institute of Technology), Berlin (1864). Founded several photographic societies and an important periodical, *Photographische Mitteilungen* (1864). In 1873 discovered the dye-sensitization of collodion plates and laid the basis for ortho and panchromatism and for three-colour photography. In 1884 used

Azaline for sensitizing in green, yellow and orange; this was a mixture of quinoline red and cyanine, but was later superseded by the isocyanine dyestuffs. In 1884 developed with Obernetter and Perutz the Vogel-Obernetter eosin silver plate which was the first orthochromatic dry plate. Also worked on sensitometry and described widely used printing paper photometers and tube photometers. His *Handbuch der Photographie* (from 1867 onwards) was one of the most important textbooks of the late nineteenth century.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

VOIGTLÄNDER, PETER WILHELM FRIEDRICH, 1812–78. Austrian optical manufacturer. Established in 1849 a new branch of the family firm (founded 1756 in Vienna) at Brunswick. Manufactured from 1841 the famous portrait and landscape lens calculated by Petzval in 1840. Produced in 1841 the first metal daguerreotype camera. Biography by H. Harting (Brunswick 1925).

VOLT. Unit of pressure or potential in electricity. When using photographic equipment that requires an electrical supply, it is important to ensure the supply voltage is the same as that specified on the equipment. This can be particularly important in colour photography with electric lighting, as variations in supply voltage affect the colour temperature, as well as the intensity, of the light. Voltages above those recommended for a lamp also radically shorten lamp life.

VOLTAGE STABILIZER. Electric circuit, usually a variable transformer, designed to deliver a constant output voltage despite fluctuations of input voltage. The main use of voltage stabilizers is in colour photography and colour printing, where voltage fluctuations in the mains supply would affect the colour temperature of the exposing or printing lights, and thus might upset the colour balance. Voltage stabilizers are also essential in sensitometry to keep the light of lamps constant.

See also: *Transformer.*

VORTOGRAPH. Name given to any abstract picture made with the kaleidoscopic apparatus first used by Alvin Langdon Coburn in 1917. Three mirrors were fixed together, as in a kaleidoscope, so that the subject could be photographed through the middle of them to produce repeating patterns.

See also: *Abstract photography.*

VULCANITE. Black plastic material made from indiarubber and used for a number of camera parts (including the outer body covering in place of leather) and darkroom utensils (e.g., print paddles, forceps, etc.)

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

W

WALL, EDWARD JOHN, 1860–1928. English chemist, photographer, editor and instructor. Worked first as chemist for B. J Edwards & Co., London, who introduced the first orthochromatic plates in England; later with European Blair Camera Co. and several American motion picture film companies. Wrote a widely used *Dictionary of Photography* (from 1889 onwards in many editions), the *History of Three-colour Photography* (1925), and other books. In 1907 he described the principle of bromoil printing.

WARM TONE DEVELOPER. Certain positive developers which can produce image colours ranging from warm black to reddish-brown—depending on the developer or development time. Warm tones are often more effective than the normal blue-black, particularly for sunny subjects and portraits printed on a cream-tinted paper.

WARNERKE, LEON, (Vladislav Malakhovskii) 1837–1900. Russian civil engineer. Established in London (1870) a private photographic laboratory. Lived from 1880 partly in London and partly in St. Petersburg and established a photographic factory in Russia. Invented the Warnerke sensitometer which was the first practically serviceable device for measuring speed (1880); this he used in his investigations on the silver bromide collodion and gelatin dry plates. Also discovered the tanning action of pyrogallic acid and invented (1875) a roll-holder for silver bromide collodion stripping paper. Manufactured silver chloride gelatin papers from 1889. Received the Progress Medal of the Royal Photographic Society in 1882.

WASHERS. Both negative and positive materials must be thoroughly washed after processing to remove any remaining chemicals which might attack the silver image—or destroy or stain the base.

In each case the efficiency and speed of washing are governed by the rate with which the fresh water can replace the contaminated water in contact with the emulsion.

The processes of washing may be carried out in special washers in which the materials may be left unattended until washing is complete. **Negative Washers.** Roll films processed one at a time call for no special apparatus. Bulk films are transferred from the developing tank and suspended from rods in a similar tank in which jets of fresh water spray on to the films and

PRINT WASHING APPARATUS. Top: *Cascade washer. The prints start off in the bottom compartment, and move up in stages, as further batches of unwashed prints replace them.* Centre left: *Drum washer. The flow of water against the turbine type leaves rotates the drum and keeps the prints in motion.* Centre right: *Washing tank A jet of water keeps the prints circulating, the surplus being drawn off at periodic intervals by a siphon in one corner.* Bottom: *Alternative design of washing tank, with central siphon and drain.*

ACTION OF SIPHON. 1. As the sink or other container fills up, the water level also rises in the open arm of the siphon. 2. As the water level reaches the top, the water starts emptying through the tube. 3. The water goes on flowing out as long as the open arm of the siphon is below the water surface. 4. Beyond that point the flow stops and the cycle starts again.

run down them to waste. The process may be a continuous one in which the films pass through the washing chamber on a conveyor track, or the films may be washed in successive batches.

Special stainless steel tanks are manufactured for washing plates and sheet films in quantity. The negative materials are suspended in suitable hangers from rods across the top of the tank. Water enters through a number of jets at the bottom of the tank and is discharged through an intermittent siphon which empties the tank completely at regular intervals. A typical washing tank of this kind will wash the equivalent of fifteen 8 × 10 ins. plates or films at once.

Print Washers. A print washer is simply a large tank in which batches of loose prints are kept constantly moving in water. The water usually enters in a series of jets around the bottom of the tank. The jets prevent the prints from sticking together and ensure a constant flow of water over the surface of the paper. An intermittent automatic siphon completely drains the tank every few minutes every time the water reaches a certain level.

Washers of this type are used principally by professionals and wholesale photo finishers who keep them in constant use. They are not popular with amateurs because of the space they waste when idle.

Those who only occasionally need an automatic print washer can use a sink conversion unit. This is simply a short vertical length of piping pushed through a plug in the drain hole of the ordinary domestic sink and bent back so that the free end is close to the bottom of the sink.

As the water fills the sink, it rises inside the pipe until it reaches the bend. At that point it spills over and runs out of the drain. This starts a siphoning action that quickly empties the sink. As soon as the water level falls below the open end of the pipe again, air enters, stops the siphon, and the sink fills once more.

For this arrangement to work efficiently, the water should enter the sink with a fair amount of force and at an oblique angle to give a swirling motion to the water in the sink.

Self-Agitating Tanks. These rely on the velocity of the incoming stream of water to keep the prints in a state of constant movement. There are many designs which work on this principle but they all consist basically of (1) a large cylindrical tank, usually of moulded plastic, incorporating (2) a pipe for connecting the tank to the water supply and (3) an overflow which discharges into the sink. The inlet nozzle is set at an angle so that it directs a jet of water around the edge of the tank keeping the mass of water constantly rotating while the prints turn over and over. As the water is moving all the time there is no need to siphon it from the bottom of the tank and a simple overflow is all that is needed. This type of tank has the advantage that it is always full to the brim and there is no danger of the prints being crumpled by the sudden siphoning off of the entire contents. F.P.

See also: *Washing*.

WASHING

After the chemical stages of processing sensitized materials, all remaining soluble chemicals left in the emulsion and support must be washed out. If any sodium thiosulphate or soluble silver compounds are left in the film, they will slowly attack the image. In the course of time the image may turn brown in parts; it may be marred by brown or black spots and stains, or more or less of it may fade. So thorough washing is important.

WASHING NEGATIVES

Films and plates can be washed either in running water or in successive baths of fresh water.

Running Water. Running water is the most convenient means of washing negatives.

During washing the water must renew itself continually to carry away the chemicals diffusing out of the emulsion. So there must be no stationary pockets by-passed by the main

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

WASHING NEGATIVES. Top: *Plates washed in a tilted dish, letting the water flow in at the top, and out at the bottom.* Upper centre: *Alternatively, a siphon may be used to empty the dish periodically, provided it is deep enough.* Lower centre: *One way of washing roll films is to clip the ends to a board.* Bottom: *This board then floats in the washing sink or dish.*

stream. The most efficient washing systems are those where the water enters at one end and has to go through the whole system before it can flow out. Any arrangement is unsatisfactory where the water flows out as it flows in, leaving the bulk of the liquid undisturbed.

Sheet films can be washed lying face up in a dish placed in the sink. The water should flow in at one end of the dish from a rubber tube connected to the tap, and the dish should be slightly inclined so that the water overflows at the opposite end.

Another method is to place the plates or films at the bottom of a deep dish and allow the water to flow in direct from the tap. There should be an outlet near the bottom of the dish, or the water may be drawn away from the bottom through a siphon. Washing tanks of this type are available in a variety of forms.

The stream of water should never flow very rapidly or fall directly on to the emulsion surface, or it may peel the gelatin layer off its support.

Small particles of grit or other solid matter present in the water supply should be caught in a wire gauze filter or a commercial filter unit fitted over the tap.

Continuous batches of negatives are best washed in a cascade washer.

There is no satisfactory way of leaving loose roll films to wash in a dish. The ends of the film may be clipped together to prevent them from curling up and damaging the film surface, but inevitably the rest of the film curls up and gets into a dangerous tangle. Roll films should be either see-sawed through changes of water or left on the spool in the developing tank and washed by passing a continuous stream of water through the tank.

With most types of developing tank, the films or plates can be washed in the tank itself. The water should be directed into the centre of the reel of the ordinary roll film tank so that it has to pass through the turns of the film before it can emerge.

Washing in plate tanks is only satisfactory if the inflow is at the top, and the outflow near the bottom. If there is no outlet at the bottom, a rubber tube from the tap can be made to lead the water in at the bottom of the tank and let it flow out over the top. This will ensure very satisfactory mixing of the water.

With some small plate tanks neither method is possible. In that case the plates are best washed in changes of water, or removed and washed in a dish.

So long as the water is renewed completely at least once every 3 minutes, a total washing time of 30 minutes will be sufficient whatever method is used.

WASHING IN DEVELOPING TANKS. Top left: *Ideally the water should flow into the bottom of the tank and displace the hypo-laden water upwards.* Top right: *Placing the tank under the tap does not renew the lower levels of water.* Centre: *Plate and sheet film tanks often have a bottom drain plug for washing. Otherwise a rubber tube can be used.* Bottom: *Incomplete renewal of washing water.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Changes of Water. Where no running water is available or when water is scarce, negatives can be washed satisfactorily in changes of water.

The dish or tank with the negatives in it is filled with clean water and left for about five minutes. It is then emptied, drained, and refilled with fresh water. The process is repeated every five minutes.

In this way the salts left in the emulsion are diluted up to 50 times at each stage. After about 4 to 5 such changes the amount of soluble matter left in the film or plate is so small that it is harmless.

Miniature tanks holding less than 10 ounces (250–300 c.cm.) of solution need about 8–10 changes.

Temperature Control. Often the washing water is considerably colder than the fixing bath and, as sudden changes of temperature are undesirable, the temperature must be stepped down gradually.

The procedure is the same as for washing in changes of water, but the temperature at each successive change is reduced by about 3° F. (2° C.). When the temperature finally reaches the level of the tap water, the films or plates may be washed in running water, or in changes of water, in the normal way.

The step-down changes count as part of the total washing period.

In Sea Water. If necessary, negatives can be washed in sea water. This actually speeds up the removal of the sodium thiosulphate left in the gelatin, so that the washing time can be halved.

The salt and other compounds in the sea water are harmless. But as they absorb moisture from the air if left in the emulsion, they are best removed by a final wash of 5–10 minutes in running fresh water, or 2 changes of fresh water.

Rapid Washing. Most of the soluble salts in the gelatin are washed out within the first 2–3 minutes. The amount left is not enough to crystallize out. So where speed in processing is essential the negatives may be dried or printed wet after washing for one minute in running water. They can be given a real wash at a later date—up to two or three weeks—without harm.

Testing for Efficient Fixing. To test for complete fixing, a blank test strip should be fixed together with other prints. A drop of a 1 per cent sodium sulphide solution is placed on the strip; if a brownish stain forms, fixing is incomplete. This usually means that the fixing bath is nearly exhausted.

Test for Efficient Washing. There is a simple test for complete removal of sodium thiosulphate. This requires a 0·1 per cent solution of potassium permanganate containing about 0·2 per cent of sodium hydroxide.

First, enough of this solution is poured into a glass of clean water to turn it faintly pink. Then a few drops of washing water are allowed to drain from the washed films or plates into the pink solution. If the colour disappears or becomes fainter, there is probably some sodium thiosulphate left in the negatives. But it should not be forgotten that impurities in the water supply may also discolour the test solution.

Hypo Eliminators. A number of chemicals can be used to remove small traces of hypo (sodium thiosulphate) left in the emulsion. Some of them are sold commercially as hypo-eliminators.

Normally, all chemicals can be removed from films and plates by the usual washing methods. The main use of hypo eliminators with negatives is to shorten washing times. They will render harmless all thiosulphate left in the film after about 5–10 minutes of efficient washing.

Hypo eliminators are more widely used for prints because it is almost impossible to remove the last traces of hypo absorbed by the paper base by ordinary washing.

Neutral salts (e.g., in sea water as mentioned above) also speed up the elimination of hypo from the emulsion.

WASHING PRINTS

Prints can be washed in running water in a dish or bowl; in special print washers or in changes of clean water.

Running Water. The simplest method is to put the prints in a large dish or bowl, placed in the sink with one side slightly raised. A rubber tube is then connected to the tap and arranged so that the water flows in at the raised edge of the dish. When the water fills the dish, it overflows at the lower edge. The rubber tube may be dispensed with and the water allowed to run directly into the dish, but in that case it will probably splash and be a nuisance.

The prints should be washed in this way for at least 45 minutes. Thorough washing demands continual renewal of the washing water, so that it can carry away the chemicals diffusing out of the prints.

This system takes up a comparatively large amount of room, and for large batches of prints a cascade washer, a rotary washer, or a special washing tank with siphon are more convenient.

Changes of Water. This method is more economical in water and is useful where no running water is available, or when water is scarce.

The prints are placed in a large bowl or dish of clean water, and left for about five minutes to allow most of the soluble salts to diffuse out of the prints into the water. The water is then poured out and replaced by fresh water. This dilutes still further the very small amount of soluble salts still left in the paper. After another five minutes, the water is changed again; after eight to nine such changes, the

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

prints will be practically free of harmful salts.

Test for Complete Washing. The washing water can be tested for complete removal of sodium thiosulphate in much the same way as for washing negatives.

Hypo Elimination. The most thorough washing still leaves minute traces of silver salts and sodium thiosulphate (hypo) in the print. These are mainly absorbed in the fibres of the paper.

Tests have shown that the slight traces of harmful chemicals still remaining in the print, even after prolonged washing, may be enough to endanger the permanence of the silver image, particularly the fine-grain images of chloride and chlorobromide papers. The amount of chemicals left behind in a single-weight print is not enough to harm the coarser-grained bromide paper images, but a double-weight paper may absorb enough to affect even these images in time.

Washing is improved by bathing the prints for a few minutes in a 1 per cent borax solution after fixing. This neutralizes the acid of the acid fixing bath—which is one of the harmful chemicals absorbed in the fibres of the printing paper base, and at the same time speeds up the removal of hypo.

A more efficient method is to use a hypo eliminator which renders all chemicals absorbed in the paper harmless by converting them into neutral salts. L.A.M.

Books: *Developing* and *Enlarging*, both by C. J. Jacobson (London).

WASHING SODA. Domestic form of sodium carbonate. It is often too impure for photographic purposes.

WATER. The chief rôle of water in photography is as a solvent for developers and other processing solutions. In its pure state it freezes at 0° C. and boils at 100° C. at 760 mm. barometric pressure, and has a pH of 7·0, which is taken as the reference point of neutrality.

Impurities of Water. Natural and tap water are never pure, and some of the impurities may interfere with one or other of the ingredients of photographic processing baths, in particular:

(1) Calcium and magnesium salts: these may be bicarbonates, or the sulphates, nitrates, etc. Water containing calcium and magnesium salts is generally referred to as hard water; very hard water may contain up to 0·05 per cent.

Hardness caused by the bicarbonates is said to be temporary because the carbonate can be precipitated by simply boiling; with sulphates the hardness is permanent, as it can only be removed by chemical means—e.g., by using sodium carbonate to precipitate the calcium or magnesium carbonates, or adding complex phosphates (sodium hexametaphosphate or Calgon) to prevent their precipitation altogether.

(2) Chlorides of calcium and magnesium: in addition to causing hardness the chloride affects certain silver salt solutions, restrains developers, and may interfere with bleaches.

(3) Dissolved gases: of these oxygen is the most important. Dissolved gases can largely be removed by boiling, though they may return when the water cools.

(4) Sulphides fog emulsions. Copper salts cause development fog, and reduce the keeping quality of colour developers. Iron, manganese, lead, tin, and zinc salts may cause stains.

(5) Other impurities: organic and mineral matter other than mentioned above is normally removed in the purification of the water supply and present in too small quantities to matter.

All mineral dissolved solids and most of the gases are removed from water by distillation, so distilled water is suitable for all, and essential for certain, photographic purposes.

Water equal to distilled water in purity can also be prepared by percolation through certain ion-exchange resins. Suitable units are supplied by laboratory furnishers and simply fit over the water tap. Small purifiers in the form of plastic bottles containing the resin are also sold by photographic dealers. The bottle is filled with tap water and left to stand for some minutes after which the pure water may be poured out. The resin is re-usable several times until a colour indicator shows exhaustion.

Water for Processing. Water for developers: the main impurities that interfere with developers are the calcium and magnesium salts which cause hardness. These precipitate their carbonates or phosphates from developers incorporating sodium carbonate or phosphate or an alkali. The precipitate is chemically harmless, but may be deposited as a scum on films or plates. Developers should therefore be filtered before use. The loss of alkalinity due to this precipitation is usually negligible.

Dissolved oxygen impairs keeping qualities of developers and should be removed by boiling before use. Dissolved carbon dioxide can be ignored, except with developers using caustic alkalies; there it will slightly reduce the activity.

Water for fixers: the normal impurities of tap water do not interfere with fixing solutions.

Water for aftertreatment and toners: in certain cases hardness or chlorides will cause precipitates, especially with solutions containing salts of lead, silver and other heavy metals. Such solutions must be made up with distilled water. Distilled water is also essential for all sensitizers, etc., where impurities may cause unpredictable variations in the characteristics of the sensitive material.

Water for washing: hard water—even sea water—will not appreciably interfere with

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

washing, but may leave scum deposits on drying negatives or prints. The trouble can be avoided by using a final rinse of distilled water, or by adding a trace of acetic or hydrochloric acid to the final rinse.

Negatives and prints intensified or toned by certain processes—e.g., uranium—should be washed in slightly acid water, as traces of alkali will tend to dissolve the image.

Sea Water. Sea water contains appreciable quantities of dissolved sodium chloride and other salts. It is not suitable for making up photographic processing solutions, but may successfully be used for washing negatives and prints. The salt content of the sea water actually aids the removal of sodium thiosulphate from the emulsion and washing times can therefore be reduced. A final wash of 5–10 minutes in fresh or distilled water is, however, necessary.

See also: *Solutions.*

WATER BATH DEVELOPMENT. Method of improving the rendering of shadow detail in a negative or of softening the contrast of a print by transferring the material to a bath of still water after a short immersion in the developer. The result is that the heavily exposed areas quickly exhaust the developer they have soaked up, while the lightly exposed areas go on developing and building up detail. The water merely helps to keep the action of development even.

In practice, the negative or print is developed until a faint image appears. It is then transferred to a dish of water where the action is watched until no further increase in density occurs. If the over-all density of the material is insufficient, it may then be returned to the developer for a short immersion; or, if the contrast is still rather hard, the process can be repeated until the correct contrast is obtained. At no time should the negative or print be agitated when it is in the water; that would help the carried-over developer to diffuse out of the emulsion and so stop its intended local action considerably before the light tones have built up sufficient density.

Although water bath development provides a very useful form of contrast control, if carried to excess it will cause staining on the material. Liberal use of developer improvers and, if possible, a developer that is resistant to oxidation (e.g., glycin) is therefore recommended for this method.

WATERHOUSE, JAMES, 1842–1922. English officer and scientist. Writer on the history of optics and of photography, and on photographic chemistry. Discovered in 1875 that eosin was a green sensitizer for silver bromide collodion dry plates. As chief of the Cartographic Service, Calcutta, developed photographic transfers for photo-zincographic halftone printing and produced in 1894 the first three-colour photogravure prints.

WATERHOUSE STOP. Early form of aperture adjustment consisting of fixed stops in a range of sizes, cut in flat plates so that they could be inserted in a suitable slot machined in the lens mount. The stops were numbered arbitrarily; the figures had no direct relation to the relative aperture.

John Waterhouse of Halifax invented the system in 1858; it is now obsolete, having been replaced by the iris diaphragm calibrated in *f*-numbers.

See also: *Diaphragm.*

WATERPROOF PAPER. Photographic paper coated on stock which has been treated, usually by lacquering both surfaces, so the processing solutions penetrate only negligibly into the support. Hence a print on such a paper dries much more rapidly after processing than a normal paper print.

See also: *Supports for emulsion.*

WATKINS FACTOR. With every developer used for development by inspection, there is a fixed relation between the time of first appearance of the image, and the total time required to give a fully developed image. The Watkins factor is the figure by which the first time must be multiplied to give the second. Its use is now virtually obsolete.

See also: *Developing negatives.*

WATT. Unit of power in electricity. It is the power generated by a current of one ampere acting over a potential difference of one volt. It is used to express the power consumption of electrical equipment such as lamps, etc. The wattage is there obtained by multiplying the voltage at which the equipment is run by the current in amperes taken. (Conversely, the current loading is obtained by dividing the wattage by the voltage.)

For some practical purposes such as high-power lamps, heaters, etc., the watt is too small and the kilowatt is then used. One kilowatt is equal to 1,000 watts.

WATT-SECOND. Unit of energy, numerically equal to the joule. Used to express exposure with artificial light sources (watt-seconds = watts × seconds) and also to measure the energy discharged through the flash tube of electronic flash units. With electronic flash, 1 watt-second corresponds to a light output of approximately 40 lumen-seconds.

WATZEK, HANS, 1848–1903. Viennese amateur photographer from 1890 and prominent Salon exhibitor during the Impressionistic

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

period of photography. Professor Watzek favoured the gum print for his portraits, landscapes and still-lifes.

WAVELENGTH. Distance between corresponding points on two successive waves, applied particularly to electromagnetic radiations. These radiations range in wavelength from miles (wireless waves) down to fractions of a millionth of an inch (X and gamma rays). The wavelengths of visible light are measured in Angstrom units (1 Angstrom unit = one ten-millionth of a millimetre) and range from 4,000 A (violet band limit) to 7,000 A (red band limit).

See also: *Frequency; Light units; Spectrum.*

WAXED PAPER PROCESS. Photography on paper reached its culmination in the 1850s with this variant of the Calotype invented by Gustave Le Gray in 1851. The paper was waxed before iodizing, instead of—as in the Calotype process—merely after exposure to facilitate printing. The wax made the paper so transparent that as fine detail as a glass negative was obtained. The waxed paper process was popular with travelling photographers because the paper could be prepared ten to fourteen days beforehand (instead of the day before as with the Calotype) and did not need to be developed until several days after the picture had been taken (whereas the Calotype had to be developed the same day). Exposures were about the same, but development took one to three hours.

See also: *Calotype.*

WAXING PRINTS. It is often noticed that a print upon a matt or semi-rough surface paper has lost some of the depth and brilliancy it had when wet. The shadow parts of the picture especially seem to suffer.

A thin coating of wax applied to the print will restore some of the wet print quality. All that is necessary is to rub a good quality white wax furniture polish or cream well into the print, taking care to cover the whole surface. The wax must be applied sparingly with a piece of soft fluffless rag or the ball of the finger, and the print must be laid on a smooth surface and be quite dry.

The print is put aside for a few minutes and then polished with a soft dry cloth. It is important to polish off all the surplus wax, as if any remains dust will settle upon, and tend to adhere to, the surface.

As an alternative to the wax the print may be treated by doping the surface, but this method takes longer.

Waxing will not only restore the wet print finish, but it will also help to make any spotting or other hand work in the finishing of the print less obvious. R.M.F.

See also: *Doping prints.*

WEATHER PHOTOGRAPHY. Recording on film the state of the atmosphere. This can range from the size of raindrops and size and form of ice crystals and snow from various altitudes to the detection of hot and cold layers or turbulence over the hot desert. The size and shape of clouds, particularly as they change shape and direction in short periods of time, can best be recorded on film and the results used in forecasting heat or cold, wetness or dryness, calm or storm, clearness or cloudiness and many other meteorological phenomena. The rate of acquisition of data has increased exponentially in recent years and the modes of atmospheric circulation changes are clearly illustrated in the reversal of flow through the seasons. Weather photography also extends to cover photography of icebergs for detection of breakup by darkening, and rocket photography of airglow at 200 km. for atmospheric studies in the ultra-violet.

Observation of the stratosphere, that region of the earth's atmosphere bounded on the lower side by the first temperature minimum (the tropopause) and on the upper side by the first temperature maximum (the stratopause) has revealed that it is not, as first believed, an uninteresting, isothermal, quiescent region. The troposphere jet streams accomplish complete circuits of the northern hemisphere as they circle the cold low pressure region near the North Pole. These have been observed by cameras in the meteorological rockets which have revealed a steady northward flow at 50 km. altitude of appproximately 10 miles per second.

Filters are used for cloud photography and lightning photography and other electrical discharges. The most usual ones are yellow filters to darken a blue sky for cloud effects, and red filters which render red and yellow objects lighter and likewise penetrate aerial haze. High speed aerial films are in use for weather photography because of high contrast and sensitivity.

Until recently meteorologists relied almost entirely on observations or photographs of the atmosphere from balloons, in rockets or on the ground at favourable locations. In regions of sparse observations such as the oceans, tropics or polar areas, the lack of data was a serious obstacle. The use of TIROS (acronym for Television and Infra Red Observation Satellite) was highly successful. Since 1960, satellite observation of cloud coverage has been made by small vidicons which take thirty-two consecutive pictures at intervals of 10 to 30 seconds, transmit these pictures to ground, or store them on magnetic tape. The pictures are then regenerated at ground stations, where they are played out on a kinescope and reproduced on 35 mm. film to produce the positive copies for operational use. The pictures are often rectified by projection through a pinhole on a convex surface representing the curvature of the earth.

CC-0. Arunachalam Digital Preservation Foundation, Chandigarh

These photos are compared with aerial photographs of clouds or radar observations, covering a circular area with a diameter of 90 km. Brightness, texture, structure, pattern shape and dimensions are observed. Water clouds always appear brighter than ice clouds of the same thickness, under similar conditions of illumination. Brightness increases with thickness up to 15,000 feet. Ice reconnaissance was performed by Tiros IV, and also provided some 32,500 photographs for the first U.S. manned orbital flight.

As a typical example of a weather satellite, Tiros contains wide and narrow angle lenses of 5·3 mm. and 40 mm. focal length and short exposures are used because the satellite travels at 7 km. per second. The satellite is space-oriented so that its spin axis changes only slowly in space. The cameras point toward earth a maximum time during daylight hours.

The ½-in. vidicon camera takes 2 seconds to scan at a 1-millisecond exposure at *f* 1·5 from the vehicle that spins once per 5 or 6 seconds, and stores it on a video tape recorder. This stores a sequence of thirty-two pictures, at a resolution of 400 lines per in. Various controls permit the operator to enhance the contrast of the picture on playback. Areas of greatest brightness in clouds are enhanced to identify regions of uniform thickness, moisture content or energy levels. These are of particular value in studying the origin and growth of destructive hurricanes, and several storms have been forecast by this satellite.

Satellite weather photography is occasionally correlated with the photographs of the hemisphere of the sky using Condit's design of a convex mirror which forms a vertical image of the entire sky, reflected on a plane mirror to a 16 mm. cinecamera at 6 frames per minute or more. L.H.N.

See also: *Missile photography.*

WEB PROCESSING. Method of processing continuous lengths of film, for example motion picture film or aerial film, by winding it up in contact with a paper web saturated with a monobath developer-fixer. This makes the finished result available within a few seconds, and also has the advantage of not involving solution flows—useful for processing on board aircraft or missiles.

See also: *Rapid access.*

WEDDINGS

Wedding photography demands a high degree of technical skill, the ability to handle people, and a feeling for the "human angle".

Faultless technique is necessary because the ceremony cannot be repeated. If by mishandling of apparatus or by carelessness in processing the pictures are spoilt there is no second chance to make good the loss.

The photographer's ability to handle people can easily play a decisive part in the success or failure of the ceremony. This is no exaggeration. In a modern wedding the photographer is present at every stage of the proceedings, and his manner and working methods influence everyone around him. His ability to introduce the very desirable human touch into the finished result depends upon his own character and his own personal regard for the occasion.

To many hardened cameramen, a wedding is just another job to be done, often as quickly as possible and with complete lack of sentiment. The established professional, on the other hand, regards it as a special assignment: an intimate glimpse of the lives of two people embarking on a serious undertaking, the uniting of two families. He must not only go to endless trouble to secure the best possible pictures, but he must do all he can to make the event a successful social occasion.

Preparations. On being booked to attend a wedding the photographer first notes the date and exact time the ceremony will take place. Also, in his diary will go the name of the church, where the reception is to be held (with, if necessary, road directions), the bride's future name and address and the date of return from the honeymoon. Then he records the style of photograph or wedding album selected and the sum deposited.

If the wedding is not to be a white one the photographer must find out what the bride will be wearing so that he will be able to identify her quickly. (There have been occasions when the wrong person has been photographed!) He will also want to know how long the reception will last and whether the couple will be going away by road, rail, sea or air.

Then the bridal pair need to be briefed on what is expected of them photographically: arriving at the church, outside the church after the service, (the "official" groups will be taken either here or at the reception), at the cake cutting ceremony and as they leave.

Equipment. Over the last ten years or so the technique of wedding photography has undergone many changes, the major difference being that the posed groups at the studio have been replaced by more informal groups taken either at the church or at the reception. It is also quite common these days to make a complete illustrated story of the occasion.

"Official" group negatives should not be smaller than half plate and should be taken with a stand camera to allow full attention to be given to the arranging and posing. Large negatives are also preferable because they can be retouched. For the remainder of the photographs, the action pictures and the cake cutting

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

ceremony, a coupled rangefinder hand camera or twin lens reflex should be used. Flash will be required for all interior shots, so the shutter should be flash synchronized.

Exposure. With white weddings, exposure can be extremely critical. The brightness range between the bride's white gown and the bridegroom's dark suit can be considerable. So when estimating the correct exposure, preferably with a photo-electric exposure meter, particular care should be taken. If the brightness range is more than the film can handle, exposure should favour the highlights; this is desirable in order to show detail in the bride's gown—more important than the bridegroom's suit.

Arrivals at the Church. The first photographs to be taken are of the arrivals of relatives and friends at the church. As it is impossible to include everyone, the photographer must use his own judgement. Two early arrivals will be the bridegroom and best man and the photographer must be there in time to catch them.

After all the guests have arrived there will be a short lull followed by the arrival of the bridesmaids. They should be given time to get together after the ride and then photographed either actually walking up the path or halted specially for the purpose. There will then be another longer pause.

The next arrival will be the bride who will be escorted into church on the arm of the man who will give her away, usually her father. Here again, they should be allowed a moment or two to compose themselves after getting out of the car before being photographed. Often the photographer will get a better picture by asking them to pause on the church steps.

AT THE CHURCH. Camera positions for various stages and effects. 1. Arrival of bridegroom, best man, bridesmaids. 2 and 3. Arrival of bride. 4. The ceremony, taken from behind the choir stalls. 5 and 6. Groups outside church (facing away from sun). 7. Bride and bridegroom walking to car. 8. Confetti throwing and crowds. 9. Bridal couple driving off.

It is very rare for photographs to be taken inside the church during the service, but if such photographs are requested it is essential that permission from the vicar is obtained first. Time exposures are quite suitable as little movement occurs during most of the ceremony. Care must be taken to avoid making any noise; this applies particularly when using plate cameras with focal plane shutters, which on some models tend to be noisy.

After the Service. While the service is in progress the photographer can be making up his mind on his best place for taking the formal groups. If they are to be taken at the reception then he will only take action shots of the party leaving the church. The light in the porch may not be ideal for photography, but this is undoubtedly the best setting to convey the atmosphere of the ceremony. With a little tact the photographer can usually manage to get rid of any untidy notices together with any unsightly scraps of paper that may be on the ground. If the sun happens to be shining directly into the porch, it will mean screwed-up faces, but the difficulty can generally be overcome by posing the group in one of the other porches where the lighting is more favourable.

Taking the Groups. Whether at the church or the reception the most satisfactory method of working is for the photographer to operate the camera while an assistant—preferably his regular receptionist—sees to the posing by his instructions. This is much quicker and less confusing than when one person keeps running between camera and subjects.

The first photograph to be taken is of the bride and bridegroom, particular care being taken to see that the bride holds her bouquet at a becoming angle and that the bridegroom is upright without being wooden, and that his clothes are free from creases. Spectators should not be visible in the background. Two pictures are normally taken, one with the couple looking at the camera and one looking at each other. Their expressions should be pleasant, but broad laughter is best avoided.

The next photograph is of the bride alone, usually half-turned towards the camera with her face looking straight at the lens. She should hold her bouquet gracefully, smile pleasantly, and have her dress and train well arranged around her feet.

The third photograph is the bridal group—i.e., bride and bridegroom, best man and bridesmaids. Again particular care should be given to bouquets, hats and trouser creases, as a single fault can make the whole group look foolish.

The last picture consists of the previous

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

INDOOR RECEPTION. Camera positions for different groups and activities. Photographed mainly with press camera and synchronized flash. 1. Bride and bridegroom receiving guests (taken from high viewpoint, standing on a chair). 2. Cutting the cake. 3. Making the speeches; should include some of audience. 4 and 5. Formal groups, taken with stand camera and Photoflood lamps. 6. Final departure.

group with the addition of the two families on the respective sides of the bridal couple. Cramping should be avoided and the spectators (and guests not to be included in the group) should be kept tactfully but firmly well out of the way.

Tradition has for so long associated the throwing of confetti with weddings that at least one picture must be secured of the bridal couple undergoing this happy ordeal.

As soon as the last family group has been taken, the photographer should move quickly away ahead of the crowd. He should take up a position from which he can photograph the procession walking down the path to the waiting cars.

For these shots he will of course use a hand camera. Here he will be able to catch the bride and bridegroom covered in confetti entering their car. The photographer should shoot from the "open" side of the car door so that the latter does not obscure the couple. Getting this picture is always a scramble, but it is well worth the effort.

After a final general view for record purposes of the crowd, the church and the cars, the cameraman can follow the bridge and bridegroom and go on to the reception.

At the Reception. There are so many opportunities for securing valuable record pictures at the reception that it pays to carry an electronic flash outfit to save the inconvenience of carrying and disposing of flash bulbs. This should be a powerful portable outfit (100–200 watt-seconds) to provide adequate light even for medium to large size groups.

First the bride and bridegroom are taken receiving their guests; it is as well to take several shots to be sure of getting at least one in which everybody comes out sufficiently clearly and looks happy.

Next, two or three general views of the room should be taken with the guests in their places at the tables.

After the speeches comes the cutting of the cake. This is one of the most popular pictures and the photographer who can be sure of securing one or two happy pictures of this part of the ceremony will be well rewarded. The couple should be carefully posed with knife held by the bride in full view and her hand held by the bridegroom's. It is usual, but not always possible, for the bridesmaid also to appear in this picture. If the table looks untidy a few bouquets placed around the base of the cake will prevent the débris appearing in the pictures.

One or two photographs of the speech-making may next be taken. If group photographs have not been possible outdoors, these should also be taken at the reception; for

OUTDOOR RECEPTION. Camera positions for groups and activities. Photographed mainly with press camera. 1. Bride and bridegroom receiving their guests. 2. General view of assembly and speech making, taken from an upstairs window. 3. Cutting the cake; guests in background. 4 and 5. Formal groups. 6. Final departure, with wing of house as background. Coverage also includes incidental shots of guests at tables.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

these, extra lighting will certainly be needed.

The last indoor photograph to be taken is of the bride and bridegroom leaving the reception. Immediately afterwards, the alert cameraman can often capture an unexpected scoop by making his way outside ahead of the couple to photograph the "decoration" of the car.

Finally comes the last photograph of the series as the couple drive away to the accompaniment of waving and cheers.

The Wedding Album. The experienced professional photographer avoids sending out rough proofs; he prepares a complete set of finished photographs and sends them out in a specimen wedding album.

This in its best form is a well presented album in which the photographs are mounted in the order in which they were taken. The first two or three pages are usually reserved and suitably titled to allow details of the wedding to be entered.

With the album goes a price list of both complete albums and individual copies, all prints being plainly numbered to simplify ordering.

A good set of wedding photographs calls for a surprising amount of planning and organization, but it is too serious a task to justify slipshod or careless work. The sincere photographer never loses sight of the fact that he is recording an occasion that his subjects will treasure as a precious memory. J.Bl.

WEDGE. In photography, a strip of material—such as glass—covered with a layer which is clear at one end and becomes more and more opaque towards the other end.

The layer itself may be dyed gelatin, or a suspension of pigment (such as carbon black) in gelatin, or a developed silver halide emulsion. The increase in density may be smooth and continuous or in regular sections. The latter type is known as a step wedge.

The Goldberg wedge consists of a wedge-shaped edge of dyed gelatin cast between two inclined sheets of glass.

The density range of a wedge is usually from 0 to 5 or 6. On a uniform continuous wedge the increase in density is specified by the wedge constant which is the density increase per cm. of wedge length. Thus a wedge with a constant of 0·3 increases in density by 0·3 every cm.

Step wedges increase by a constant density from step to step, but for really accurate work the wedge is calibrated individually.

Wedges are used mainly for sensitometric tests of emulsions. For this purpose the wedge is laid on the surface of the sensitized material and a single exposure is made through it.

OPTICAL WEDGE. Steps of increasing density hold back progressively more of the incident light. Sensitive material exposed behind wedge thus receives series of graduated exposures at a standard exposure time.

The result is as though the sensitized material had been given a number of separate exposures increasing gradually from one end of the wedge to the other. After development, the test piece can be examined with a densitometer, and the characteristic curve of the material plotted.

If instead of using white light for the exposure, a spectrum of light of different colours is allowed to fall on the wedge so that the whole range of colours crosses each step, the result will indicate the spectral sensitivity of the material because each colour will have registered a range of exposures from one end of the wedge to the other. The developed test piece in this case is called a wedge spectrogram.

See also: *Sensitometry.*

WEDGE SPECTROGRAM. Record of the spectral sensitivity of a sensitized material made by giving it a series of differing exposures to a spectrum projected on to it. In practice the exposure scale is produced by placing a neutral density wedge over the sensitized material in such a way that each step of the wedge lies across the whole projected spectrum. This ensures that the material is subjected to the full range of exposures over every colour.

WEDGWOOD, THOMAS, 1771–1805. English amateur scientist, son of the famous potter, Josiah Wedgwood. Published in 1802, with Humphry Davy, an *Account of a method of copying paintings upon glass and of making profiles by the agency of light upon nitrate of silver.* Was the first to attempt photography and to produce images (e.g., silhouettes and botanical specimens) on paper or leather moistened with silver nitrate solution, and in the solar microscope. But he and Davy were not able to fix their images. Biography by R. B. Litchfield (London 1903).

WEIGHTS AND MEASURES

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

There are three current systems of weights and measures in the English language countries: American, British Imperial, and Metric.

The metric system is consistent throughout the world whereas the British pint, quart and gallon differ from the American measures of the same name. For instance, the British pint is 20 fluid ounces while the American pint is 16 fluid ounces. However, as the latter are American fluid ounces the corresponding British equivalent is something like 16⅔ fluid ounces.

This gives some idea of the confusion encountered when using weights and measures in the British Imperial and American systems. Many people still prefer to use them, however, so conversion tables are necessary.

The metric unit of volume is the cubic centimetre, but the scientifically correct liquid unit of capacity is the millilitre. As the difference between the two (0·0028 per cent) is too slight to matter in photographic formulae, the cubic centimetre is taken here as the equivalent practical unit.

Units of Capacity

IMPERIAL LIQUID UNITS	
60 minims	= 1 fluid drachm
8 fluid drachms	= 1 fluid ounce
20 fluid ounces	= 1 pint
2 pints	= 1 quart
4 quarts	= 1 Imperial gallon
METRIC LIQUID UNITS	
1 litre	= 1,000 millilitres
1000·028 cubic centimetres	= 1 litre
UNITED STATES LIQUID UNITS	
60 U.S. minims	= 1 U.S. fluid dram
8 U.S. fluid drams	= 1 U.S. fluid ounce
16 U.S. fluid ounces	= 1 U.S. pint
32 U.S. fluid ounces	= 1 U.S. quart
4 U.S. quarts	= 1 U.S. gallon

Weights

BRITISH UNITS (AVOIRDUPOIS)	
437·5 grains	= 1 av. ounce
7,000 grains = 16 av. ounces	= 1 av. pound
14 pounds	= 1 stone
28 pounds (or 2 stone)	= 1 quarter
4 quarters	= 1 hundredweight
20 hundredweights	= 1 ton
BRITISH UNITS (APOTHECARY)	
20 grains	= 1 scruple
3 scruples	= 1 drachm
8 drachms	= 1 ap. ounce
12 ounces	= 1 ap. pound
METRIC UNITS	
1,000 milligrams	= 1 gram
1,000 grams	= 1 kilogram
UNITED STATES UNITS	
Use avoirdupois weights up to	1 pound then
2,000 pounds (av.)	= 1 short ton
2,240 pounds (av.)	= 1 long ton

Lengths

BRITISH UNITS	
12 inches	= 1 foot
3 feet	= 1 yard
METRIC UNITS	
10 millimetres	= 1 centimetre
100 centimetres	= 1 metre

WEIGHT PER VOLUME OR VOLUME PER VOLUME TO METRIC

Units A	Units B							
	Imperial Fluid Ounce	U.S. Fluid Ounce	U.S. Pint	Imperial Pint	U.S. Quart	Imperial Quart	U.S. Gallon	Imperial Gallon
Grains	2·3	2·2	0·14	0·11	0·07	0·057	0·017	0·014
Imperial minims	2·1	—	—	0·1	—	0·05	—	0·013
U.S. minims	—	2·1	0·13	—	0·067	—	0·016	—
Imperial fluid drachms ...	125	—	—	6·3	—	3·1	—	0·8
U.S. fluid drams	—	125	8	—	4	—	1	—
Avoirdupois ounce ...	—	—	60	50	30	25	7·5	6·25
Imperial fluid ounce ...	—	—	—	50	—	25	—	6·25
U.S. fluid ounce	—	—	62·5	—	31	—	8	—

To convert Units A per Unit B to grams (or ml. or c.cm.) per litre, trace from the Units A in use on the left to the vertical column corresponding to the Unit B and multiply Units A by the factor. To convert Units A per Unit B to percentages (grams per 100 ml. or volume per volume) convert to grams or millilitres per litre, and divide by 10.

Example—To convert 60 grains per Imperial pint to grams per litre, trace from "grains" on the left to "Imperial pint". The factor is 0·11. Therefore the answer is 60 × 0·11 = 6·6 grams per litre.

METRIC TO WEIGHT PER VOLUME OR VOLUME PER VOLUME

Units A	Units B: Imperial Fluid Ounce	U.S. Fluid Ounce	U.S. Pint	Imperial Pint	U.S. Quart	Imperial Quart	U.S. Gallon	Imperial Gallon
Grains	0·44	0·46	7·3	8·75	14·5	17·5	60	70
Imperial minims	0·48	—	—	10	—	20	—	80
U.S. minims	—	0·48	7·7	—	15	—	60	—
Imperial fluid drachms ...	0·008	—	—	0·16	—	0·32	—	1·25
U.S. fluid drams	—	0·008	0·125	—	0·25	—	1	—
Avoirdupois ounce ...	—	—	0·017	0·02	0·033	0·04	0·13	0·16
Imperial fluid ounce ...	—	—	—	0·02	—	0·04	—	0·16
U.S. fluid ounce	—	—	0·016	—	0·032	—	0·125	—

To convert grams (or ml. or c.cm.) per litre into Units A per Unit B, trace from the Units A in use on the left to the vertical column corresponding to the Unit B and multiply the number of grams by the factor. To convert percentages (grams per 100 ml. or volume per volume) to Units A per Unit B, multiply by 10, and treat as grams or millilitres per litre.

Example—To convert 15 ml. or c.cm. per litre to U.S. minims per U.S. fluid ounce, trace from "U.S. minims" on the left to "U.S. fluid ounce". The factor is 0·48. Therefore the answer is 15 × 0·48 = 7·2 or about 7 U.S. minims per U.S. fluid ounce.

The figures in the above two tables are rounded off, but are accurate to within 4 per cent (which is sufficient for all photographic purposes).

Makeshift Weights. If proper weights are not available certain coins can be used as a substitute. These weights are accurate enough for most practical purposes, but it is important that new or at least reasonably unworn coins should be used.

It is useful to remember that with English and American silver coins weight is directly proportional to monetary value.

EQUIVALENT WEIGHTS

English Coins	Grains	Grams
Sixpence	43·6	2·83
Shilling	87·2	5·65
Two shillings	175·4	11·38
Half-crown	218	14·11
Farthing	43·75	2·84
Halfpenny	87·5	5·66
Penny	145·8	9·44

American Coins	Grains (approx.)	Grams (approx.)
Dime	40	2·5
Quarter-dollar	100	6·5
Half-dollar	200	13
Silver dollar	400	26
Cent	50	3·25
Nickel	80	5

Carefully measured lengths of copper wire, in any standard gauge, will provide very accurate makeshift weights. It is, however, important to ensure that the wire is free from corrosion and has not been stretched.

The following tables show the weight of lengths of copper wire in various gauges:

METRIC WEIGHTS

CC-0. Jangamwadi Digital Preservation Foundation, Chandigarh

WESTON, EDWARD, 1886–1958. American photographer. Started as an itinerant portrait photographer, opened a studio 1911, and until mid-1920s made conventional Salon pictures for exhibitions. Changed his style completely during a three-year stay in Mexico City, under the influence of the artist Diego de Rivera. Weston made portraits for a living, but his reputation rests on his remarkable nature photographs taken from 1927 onward. Founder member of the F.64 Group, 1932. *The Day Books of Edward Weston* edited by Nancy Newhall (1962).

WESTON SPEED. Arithmetical system of emulsion speed classification based on practical tests with reference to the photo-electric exposure meter of that name and now no longer generally used.

See also: *Speed of sensitized materials.*

WET COLLODION PROCESS. Method of making negatives on supports coated with iodized collodion and immersed in a silver nitrate sensitizing bath immediately before exposure.

See also: *Collodion process.*

WET PLATE. Early type of photographic plates which were coated with a collodion emulsion and exposed wet in the camera. They are still used in process work, but even there are being increasingly displaced.

See also: *Collodion process.*

WETTING AGENT. Chemical which reduces the surface tension of water or a watery solution when added in extremely small amounts—about one part in 1,000 or even less.

By lowering the surface tension of a processing solution in this way, the solution is made to spread evenly and quickly over the surface of the sensitized material.

A wetting agent reduces the risk of air bells and makes for uniform development—particularly in daylight roll film, plate, or sheet film tanks.

A trace of wetting agent in the final washing water of films and plates makes the water drain off the surface faster and stops it from drying in tears and leaving marks.

Wetting agents are sold in liquid form, and sometimes even in a solid powder, under a number of proprietary names.

WHEATSTONE, SIR CHARLES, 1802–75. English scientist. Inventor of stereoscopy and of electric telegraphy. Made experiments on stereoscopy (with geometrical drawings) 1832–8, and invented the mirror stereoscope and the refracting stereoscope in 1832. Published his results in 1838.

WHILE-YOU-WAIT PHOTOGRAPHY. The term "while-you-wait photography" applies, strictly speaking, to the work of the itinerant camera operator who plies his trade at country fairs, at the seaside and in places of recreation. He makes his money by supplying finished prints, of a sort, to the customer within a few minutes of taking his portrait.

There are other departments in which prints are produced in minutes—e.g., in newspaper offices and in photo-finish work—but these are not really branches of while-you-wait photography.

There is also a special type of folding hand camera which delivers a positive paper print within seconds of taking the photograph and which lends itself, at least, to use in this particular field.

A fully automatic sitter-operated machine is also made for while-you-wait photography.

Ferrotype Method. A great deal of what is generally accepted as while-you-wait photography of this kind is done by means of the ferrotype or "tintype" method. In this a black enamelled piece of thin sheet iron of the required size of the finished photograph has coated on its surface a sensitive emulsion fast enough to give brief exposure in average daylight. The camera and lens are of the type used in other forms of photography except that the back of the camera is designed to allow the exposed plate to drop directly into a container of developing solution attached underneath. The developer can be poured off and replaced by the fixer. As soon as the plate is fixed, it is brought into the open, rinsed in a convenient bucket of water, waved in the air to dry and clamped into a simple frame. It is usually not quite dry when handed to the customer, but dries completely a very few minutes later. The appearance of the photograph is quite normal because the particular emulsion used forms a milky image and the background is black enamel. This process was invented by a Frenchman and introduced to the French photographic world in 1852. In various forms it has since been very largely used by itinerant photographers and is still practised to-day.

Paper Negative Method. Another method occasionally used is to make the exposure on negative card, which is nothing more than ordinary negative emulsion coated on a cardboard base. This is developed and fixed in the normal way but inside a special compartment in the camera with light-tight sleeves for the operator's arms. It is then re-photographed on to similar material so as to produce a positive. There is no need to dry the negative card before re-exposure, as it does not come into contact with the positive print. The quality of print

produced in this way is not equal to that obtainable from a transparent negative, but it is still quite acceptable for inexpensive portraiture. Quick drying can be facilitated by coating the emulsion on a waterproof based card.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Diffusion Transfer Cameras. A further system of instant photography uses the Polaroid Land camera in which a positive print is produced within about 10 to 15 seconds. The camera is designed mainly for owner use, but is also employed to an increasing degree by while-you-wait photographers and instant picture services both in photographic studios and at fair grounds and similar places. The sitter here receives a positive print which is taken straight out of the camera. With a special colour film, colour prints can also be obtained.

In the camera itself the exposure produces a negative—usually on paper—which is processed in contact with a non-sensitized positive material by spreading a layer of jellified activating solution between the two. This develops the negative and at the same time transfers the unused silver salts to the positive layer where they are reduced to form metallic silver. The colour material works in a similar way, though using a more complex system of dye transfer.

Sitter-Operated Camera. In suitable sites—e.g., the big stores—there are special automatic while-you-wait portrait booths. The user sits in a chair inside a cubicle about the size of a telephone box and adjusts his position to bring his eyes level with a mark on a mirror in the booth. Other mirrors in the cubicle help him to assume the desired expression. When he is ready to be photographed he simply inserts a coin in a slot and the machine goes into action. The photographic lighting switches on, an automatic camera makes the exposure, or series of exposures, and within one minute the machine delivers the finished portrait in the form of a strip of brownish or black-and-white paper prints. Sometimes the prints come singly in a metal frame.

Behind the scenes there is an automatic camera fitted with a wide-aperture short focus lens, and loaded with reversal paper, in rolls. After exposure, the strip of paper with the 4 to 6 pictures on it is cut off from the roll and passes in turn through the various processing solutions.

Alternatively, the paper may be mounted in single pieces in a metal frame. The frame then drops into a horizontal position after exposure and a measured quantity of each of the various processing solutions is squirted in turn on to its sensitized surface. The metal frame acts like the sides of a dish and prevents the processing solution from running off.

The processing routine follows the normal reversal procedure—i.e., develop, rinse, bleach, clear, second exposure, and final development. No fixing is of course required and the print is reasonably permanent without further treatment.

The manipulation and processing are all carried out automatically and the temperature inside the mechanism is kept at 90° F. (32·2° C.) by a thermostat. All processing tanks are fitted with floating lids and the solutions are renewed when necessary. The times of the various operations in the automatic cycle can be adjusted to suit local conditions. P.W.H.

WHOLESALE PHOTO FINISHING

The photographic dealer who operates a developing and printing service for amateur roll films very rarely carries out the work himself. He is much more likely to send the films to a wholesale photo finishing establishment specially organized and equipped to deal with films in large quantities. Such establishments are also known as D. & P. (i.e., Developing and Printing) works. They vary in size from the so-called "one-man" business to huge concerns capable of processing many thousands of films per day.

With the introduction of more automatic processing equipment, small firms—and even some of the larger businesses—have tended to follow the modern trend to merge several small units into one large concern. The main reason for this is that the electronic and mechanical equipment which is now almost essential in providing a profitable output is extremely costly and the small firms usually cannot find sufficient capital, or they cannot in any case justify the outlay. This applies even more to

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

PHOTO-FINISHING LABORATORY. Solid arrows show flow of work for standard developing and contact printing orders, dotted arrows for enlargements. A, stores. B, office. C, film developing. D, enlarging. E, film drying and sorting. F, chemicals and mixing. G, print finishing (washing, drying, glazing) and packing. H, men's cloakroom and toilet. I, contact printing. J, women's cloakroom and toilet.

finishers who handle colour material. Not only each type (negative, reversal) but also every make of material calls for its own processing "line", that is to say a line of processing tanks and replenisher units, together with a temperature control unit, so that each material receives its correct processing treatment. Only the very large concern can provide such facilities and operate them on an economical basis.

The dealer therefore sends colour films to his local finisher; but the latter, instead of carrying out the processing himself, forwards it to one of the large colour processing houses, for which service he receives a small percentage of the retail price.

Organization. When the customer's film is handed to a retail photographic dealer or chemist for developing and printing, it is passed on to the photo finisher who processes and prints it. It is then returned to the dealer with the prints and finally handed back to the customer in as little as twenty-four hours from the time he took it in, or in three or four days in the case of colour films. For acting as the agent of the photo finisher, the dealer receives a percentage of the retail price.

While all work is handled in bulk, each film is recorded separately. The dealer attaches a numbered order form to the roll and this form stays with the film all through the processing and until the finished negatives and prints are ready for handing to the customer. The form is stamped with a dealer's number which tells the finisher to which account the order should be charged. The finisher retains half of the form to enable him to make up his accounts.

Finishers supply their dealers with order pads, price lists and window display showcards and as a rule they run a motor van collection and delivery service to the dealers' shops.

The D. & P. works consists generally of six departments: office, tank-room, drying-room, contact and enprint printing section, enlarging department, and finishing-room. Many works now use automatic continuous processing machines and dispense with the film drying-room, the processed films being conveyed straight into a special drying section at the end of the processing line. Similarly, contact printing is often done on electronic machines. These are designed to make projection prints, one-to-one (or same size as the negatives), as well as the popular enprints (or enlarged prints), so that all this work is done in the one department. There are often several other sections, for instance, those which deal with checking of work, packing and dispatch, miniature film processing, chemical mixing, maintenance, etc.

In the smaller establishments the work is usually handled in ten-minute units, films being divided into batches which will take ten minutes to develop, ten minutes to print, multiples of ten minutes to wash and so on. This standardizes the flow of work through the various departments and maintains an easily controlled and supervised production. In the larger works, where continuous processors are used for films and prints an even flow of production is maintained by the nature of the equipment.

Developing. Films are developed in vertical tanks made of glazed stoneware, stainless steel or hard rubber. These vary in size from 12 to 48 gallons capacity in small works, whereas the larger plants use special developing machines.

In either case the films are stripped of their protective backing-paper and are placed in spring clips by which they are suspended in the tanks from stainless steel rods with the order forms clear of the solution. Solutions are warmed by immersion heaters and the temperature in each tank is maintained at a constant level by a thermostat. Replenishing solution is added to the developing tanks, often automatically, to maintain a constant level and strength so that all processing times can be kept standard. In developing machines the rods of films are raised from one tank and lowered into the next quite automatically, times being controlled by the setting of a time-clock. Once the films have been loaded on to their rods, the operator does not touch them until they are dry.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Printing. After the final wash, the films are dried in heated cabinets at controlled temperatures and passed on to the printers.

There are various types of printing machine —e.g., the old type "judgement printer" with which a skilled operator examines each negative and relies on experience in judging the correct type of sensitive paper and the right exposure time for each print, but these are now little used; the later automatic machine which "reads" the negative through a photo-electric cell.

Finally there is the "roll head" printer on which the exposure is either "read" on a dial and set manually or which may set itself automatically as it "reads". With such machines the exposures are made on sensitized paper in rolls of 250 feet or 500 feet., and these rolls are subsequently placed on continuous strip processors which develop, rinse, fix, wash and glaze the prints without any work from the operator other than a watchful eye. The strips of prints are even cut up into single prints by an electronically operated trimmer. The roll-head printer may also be used by the smaller works without a continuous processor, the prints being then cut off into strips and processed by hand in long trays of solution, and washed in tanks with jets of water. The most advanced machines of this type control the exposure using a single grade of printing paper. The operator's job is then confined to selecting the number of prints per negative, the print size (where adjustable) and making overriding corrections for negatives of special tone distribution which do not yield good results with automatic measurement.

Finishing. After prints have been glazed and trimmed in either of the above processes, they are stacked into piles, one to each order and are placed in wallets after having been identified by "printing numbers" which are stamped on both order forms and prints in the printing-room.

Meanwhile the rolls of film have been cut into separate negatives and placed into wallets to await the prints. Completed orders are passed to checkers who examine the work for good quality and correctness of execution. Faulty prints are returned to the printing department to be reprinted.

Special Services. Orders for high-quality (as distinct from mass-produced) enlargements are handled by skilled operators who use vertical enlargers with automatic focusing and other refinements for fast yet individual work. This includes enlargement of selected parts of the negative, shading and other means of local control, etc.

Some finishers also have a special department for handling subminiature films because of the great care needed to produce satisfactory quality from such small negatives.

Colour. The general arrangements for processing colour films are similar to those for black-and-white materials, though necessarily more complex in view of the extra processing steps involved. Special precautions are necessary for accurate temperature control and standardized agitation. Small-scale colour development is usually carried out in a series of vertical tanks with the films transferred from tank to tank on hangers or reels. Continuous-processing machines are used by larger establishments. Colour processing also requires extensive quality control—often by developing test lengths at regular intervals to check that the development procedure produces results of the correct density and colour quality.

Colour negatives are usually printed on semi-automatic enlargers taking continuous rolls of paper and producing fixed-size enlargements. Operators have to be specially trained, as they must also be able to grade the colour negatives, i.e. select the right filtering for correct colour reproduction. On some printers even this is automatic, but reliable in only about 80 per cent of the negatives printed. A final quality check pinpoints prints of unacceptable colour rendering; the negatives are then sent back to operators for individual reprinting.

High-quality colour enlargements require greater skill and are carried out by specialist operators.

The continuous rolls of colour paper pass through automatic processing machines similar to the rolls of paper from roll-head printers for black-and-white enprints. Individual enlargements on single sheets of colour paper are processed in tank sets which take the prints in special processing baskets, or in small rapid colour processors. L.G.S.

WIDE-ANGLE LENS

Any lens which covers, across the diagonal of the negative, an angular field of view of 60° or more can be classified as a wide-angle lens. This field corresponds to a negative diagonal slightly in excess of the focal length of the lens.

There are many types of wide-angle lens ranging from very simple forms which can only operate at very small relative apertures to complex constructions either operating at large apertures or at extreme image angles.

Design. With the exception of the inverted telephoto system, wide-angle lenses tend to be more symmetrical about a central diaphragm than other photographic lenses and their lens components are usually strongly meniscus in shape with the concave surfaces facing inwards.

Simple wide-angle lenses can be made to cover fields of view of 90° or 100° but at these angles useful results are only obtainable at apertures of *f*11 or *f*16. At such small

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

apertures poorly lighted subjects cannot be focused and composed satisfactorily on a screen in the camera. Some manufacturers choose a lens form which gives, for this purpose, an acceptable visual image at about *f* 6·5. These forms must, however, be stopped down to about *f* 16 before they reach the necessary photographic standard of definition.

There are of course many applications which demand relative apertures more in keeping with modern photographic practice. These needs have been met by modifications to more complex lens constructions to cover fields of view of about 75° at relative apertures up to about *f* 4.

Illumination of the Field. The increased angular field of wide-angle lenses draws attention to the difficulties of providing sufficiently uniform illumination throughout the image.

Even a perfect lens provides a variation of illumination across the negative which varies as the fourth power of the cosine of the semi-angular field measured from the lens axis.

For example, at a point in the image corresponding to 30° of the semi-angular field such a lens can only provide a level of illumination 56 per cent of that in the centre of the image. At an angular field position of 45° the illumination falls to 25 per cent of that in the centre. These percentage reductions in illumination are not affected by change of relative aperture.

Vignetting. Well corrected wide-angle lenses, however, have appreciable axial length and can be considered as hollow cylinders through which axial and oblique beams of light have to pass. Such a cylinder obviously cannot pass an oblique beam as wide as the axial beam because the front and rear apertures of the cylinder vignette (i.e., cut off part of the diaphragm opening as seen from the edge of the field).

This type of mechanical vignetting aggravates to a considerable extent the optical cosine vignetting referred to above. In many cases wide-angle lenses are designed so that their front and rear apertures can be increased beyond those required for the axial beam alone thereby reducing this mechanical vignetting as much as possible.

INVERTED TELEPHOTO LENS. Covers wide angle with long back focus for short focal length. A, diverging lens group. B, converging group F, equivalent focal length. BF, back focal distance.

INVERTED TELEPHOTO SYSTEM. Compared with a normal lens (top) an inverted telephoto system of the same focal length, aperture and angle of view can provide an increased oblique aperture, thus reducing vignetting.

Stopping down a lens of finite length by means of a central iris reduces the diameter of the axial beam and since front and rear apertures are not affected the mechanical type of vignetting will be reduced. It is usually completely removed at intermediate apertures leaving a lens which approximately obeys the cosine law.

Inverted Telephoto System. Entirely different forms of wide-angle lenses are based on what is known as the inverted telephoto system. In these the lens comprises a front dispersive component of relatively large diameter widely spaced from a rear collective component. The arrangement results in a distance between the rear surface and the focal plane which can exceed the focal length. This is particularly advantageous in small cameras in which the focal length has to be small and shutters or other mechanisms are situated between the lens and the film.

Thus wide-angle lenses for single-lens reflex cameras are almost invariably of the inverted telephoto design. This permits the lens to be mounted sufficiently far forward of the film plane to accommodate the movable reflex mirror. At present inverted telephoto systems of this kind are available with the back focal distance up to twice the nominal focal length.

Owing to this property, inverted telephoto lenses are also known as retrofocus systems.

The inverted telephoto wide-angle lens is largely restricted to these small cine and miniature cameras since it is a very bulky form of lens relative to its focal length. Distances between the front lens surface and focal plane of up to five times the focal length are quite common and diameters, especially at the front, are correspondingly large. This large bulk and obvious departure from symmetry make inverted telephoto lenses readily recognizable.

The inverted telephoto lens has also gained appreciably in importance with the development of interchangeable lens systems for cameras with a diaphragm shutter. Since the

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

TYPICAL INVERTED TELEPHOTO LENS. This construction is characterized by a large diameter diverging element in front of a more conventional lens system. The effective focal length is shortened, but the back focus remains long, making this lens suitable for single-lens reflex cameras which require plenty of space between the lens unit and the film for the mirror system.

shutter is permanently built into the camera, the lens has to be mounted in front of it. Alternative lens systems must therefore all have the same back focal distance within fairly narrow limits.

An alternative method of obtaining a range of focal lengths on a camera with built-in shutter is to split the lens itself and have the rear component also built-in behind the shutter. Alternative focal lengths are obtained by interchangeable front components—a construction which permits short focal lengths to be obtained only by a use of inverted telephoto designs.

This form of lens has other very desirable characteristics. It can be designed with greatly improved vignetting and achieve, simultaneously, wide angle and large aperture. Angular fields of about 75° can be covered by this form at apertures greater than *f* 2—a performance not yet equalled by more symmetrical lens forms.

The better vignetting characteristics result from both the greater back focal distance and the large front component. The increased focal distance reduces the obliquity of beams of light forming off-axis images. The front dispersive component has to be large enough in diameter to accommodate the increased width of oblique beams that can be transmitted by the rear component. This leads to an increased oblique aperture for this lens design, and hence less vignetting.

Distortion. Provided the object lies solely in a single flat plane at right angles to the lens axis and also that the sensitive emulsion is at right angles to the lens axis, a wide-angle lens corrected for distortion will record, throughout its field of view, a correct geometrical reproduction of the object.

Although distortion in the aberrational sense may be absent from the lens itself, there are independent geometrical factors affecting perspective which, under certain viewing conditions, can be distorted to an objectionable extent.

Perspective. When wide-angle lenses are employed it is often impossible to maintain the ideal conditions for rendering perspective. In wide-angle photography it is likely that the camera viewpoint will be too near the object and also that the focal length of the camera lens (multiplied by the enlarging factor, if any) will be less than the viewing distance of eye to photograph. Both these factors introduce an unusual perspective which appears as a disproportionately large variation in the scale of foreground objects to background objects.

This violent variation in size between near and far objects apparently increases the depth dimension in the photograph to an unnatural degree. Since the wide-angle lens has a good view of the sides of objects at the edges of the field, this increase in depth is more apparent there than at the centre.

Thus the distortion in three-dimensional objects at the sides of the photograph is such that they appear to be too large in the direction parallel to the lens axis.

Perspective can be restored to some extent by viewing the photograph from such a distance that it subtends the same angle at the eye as the original scene subtended at the camera. It should be realized, however, that this can only be achieved for monocular vision and that, although the eye then sees exactly what the lens saw, different mental processes are employed in viewing a real scene and in viewing a single plane reproduction. G.H.C.

Books: *Photographic Optics* and *A System of Optical Design*, both by A. Cox (London).

WIDE-ANGLE RACK. Supplementary focusing rack on the baseboard of a stand camera which allows the lens panel to be racked back from the normal infinity stop so that a wide-angle lens may be focused. This is necessary because the short focal length of the wide-angle lens brings it closer to the plate than a normal lens.

Sometimes the sliding member on the baseboard of a stand camera can be racked right out and reversed to bring the lens closer to the plate.

Occasionally the dimensions of the camera are such that the front edge of the baseboard would cut off the foreground when a wide-angle lens is used. To overcome this on some cameras—more especially folding Press type and technical cameras—the front half of the baseboard hinges down when the lens panel is racked back to work with a wide-angle lens.

See also: *Camera movements.*

WIDE SCREEN PROJECTION. Motion picture projection on to a wider-than-normal screen. The screen is usually slightly curved towards the audience who, in consequence, experience a sensation of participation in the action of the film.

There are various systems for achieving more or less similar effects.

WILLIS, WILLIAM, 1841–1923. English engineer, bank employee and photographer. Patented the Platinotype process in 1873 and founded the Platinotype Company which manufactured platinum development paper from 1878 onwards. Later worked out the Satista (silver-platinum) and the Palladiotype papers. Received the Progress Medal of the Royal Photographic Society in 1881.

WILSON, GEORGE WASHINGTON, 1823–93. Scottish professional portrait and landscape photographer in Aberdeen from 1853. Was among the earliest to take instantaneous street scenes, 1859. Appointed photographer to Queen Victoria in Scotland, *c.* 1860. Built up an extensive business in publishing photographs of all countries. The firm was also the largest producer of lantern slides in Britain.

WINTER SPORTS. Snow scenes can be taken with any camera, but for winter sports a small camera is best. Any size, from 35 mm. to 2¼ × 3¼ ins. is suitable, but the miniature is preferable for long ski tours and similar winter sports; it reduces the problem of carrying film and does not weigh down the photographer, who is already loaded with his gear and sufficiently tired by the exertion of ski-ing. The lighter the camera and the handier its controls, the better the results will be when fingers are stiff from the cold.

For sports photographs a long focus lens will be found useful, to fill the negative with figures which would otherwise be disappointingly small—e.g., a ski-jumper coming down a steep slope. Experts usually prefer a frame finder as it shows everything in its natural size and makes it easier to follow fast movement.

Miniature cameras are also to be preferred for another reason: they can be carried under the outer clothing and so kept warm in colder weather. Old shutters give slower exposure times in lower temperatures, and the 1/100 second setting may easily become a 1/50 second or more. With a camera that cannot be protected from the cold, the slowing down may have to be corrected by selecting a shorter exposure.

If the camera is to be carried on the chest whilst ski-ing or climbing, a length of elastic around the camera and chest will prevent it from swinging or bouncing.

In dazzling snowscapes a lens hood is an essential accessory and also, above about 3,500 feet, a light or medium yellow filter and a U.V. filter.

Film and Filter. A glance at any winter resort brochure shows how effectively colour film can record winter sports. The faster and less contrasty films are best for snow scenes, and the excess blue in the shadows must be filtered out. At altitudes up to about 3,500 feet, a colourless U.V. filter will be sufficient on sunny days, but on sunless days and at higher altitudes a skylight filter is necessary.

For black-and-white pictures, too, the medium to fast films are best able to deal with the high contrast of scenes with people and/or objects in the snow. When using black-and-white material, in addition to the above-mentioned filters, filters of various colours may also be used to achieve desired effects,—e.g., yellow, orange or even red.

In the lower reaches, a medium yellow filter will generally improve the sky tones and snow texture; at medium heights, a light yellow filter is all that is necessary. At altitudes from 3,500 feet up a U.V. filter is essential. The U.V. filter is practically colourless glass, which removes a large amount of the ultra-violet rays always present in the light at great heights. For pictures in the mountains, filters must be used with caution. If the filter is too deep, the photographs will lack the characteristic atmosphere of the mountain scene.

Deeply tanned faces produce a filter problem of their own. Correct filters show the tanned faces and the deep blue sky in nearly the same grey tones. Stronger filters make the faces lose their deep tan and render the sky too dark. Light filters make the faces too dark against a very light sky. The final choice must be a compromise depending on the conditions and the photographer's taste.

Light and Exposure. Snow photographs are only effective when taken in sunshine. Without sun, snow scenes always look flat. Early morning and the afternoon, when shadows are strong and clear, are the best times for photographing.

Good photographs can be obtained with side lighting; but the best are almost always taken against the sun, when it is high in the sky. Only strong sidelighting or clear light shining towards the lens can give the snow its true sparkle, and this sparkle is essential for conveying the optical effect of snow.

The exposure times must be correct; there is little or no margin one way or the other. Fully exposed photographs have a tendency to lack detail in the highlights with normal development. It is preferable to expose fully and curtail development to about two-thirds normal.

With the abnormal amount of general reflection coming off the snow, the exposure meter can only be relied on up to a point. The readings are correct for the snowscape by itself, but as soon as the foreground includes

shadow detail the exposure must be doubled. For near shots close-up lens attachments are useful.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The Subject. A picture taken on a slope lying diagonally across the light or illuminated from the side by the sun, so that it sparkles with reflected light, should generally have one interesting item sharply defined in the foreground to provide a base for the composition.

Ski photographs come out best when there is freshly fallen powder snow about. This sweeps up on both sides with the movement of the skis, and the cloud of powdered snow, taken when it is a little windy and against the sun, can make a most impressive picture.

When taking photographs of skiers or ski-jumpers the choice of the correct positioning is everything. The shadow side of a hill, with the sun shining across the crest will always make a good vantage point for photography. As the skier moves downhill, the clouds of snow he raises are brilliantly illuminated against the sun. Under these conditions a long focus lens and frame finder are particularly useful accessories.

Pictures of skaters are generally easier to take because they can if necessary be rehearsed and repeated. The most interesting subjects are undoubtedly figure skaters, and the light is generally bright enough to allow exposures of 1/200 to 1/500 second which is short enough to arrest the movement. Pictures of racers are only interesting if they are taken close enough to catch the tense expressions of the competitors and at an instant when the grouping is dynamic. Mere speed as such does not register convincingly.

The last rule holds good also for pictures of toboggan and bobsleigh races. These should be taken on the corners where the racers mount high up the banking and thus convey an impression of their speed. At such points there is also a chance to photograph a spill. Zone focusing and a shutter speed of 1/500 second (less if the camera is swung) are the best combination for such subjects.

Curling is a game that moves more slowly and is usually played by individuals of a more assorted and characterful type. Their gestures and antics aimed at guiding the "cheese" make amusing pictures. No great shutter speeds are called for; near or medium zone focusing at about 1/125 second should give good results.

In ice hockey the most profitable area for the photographer is the area in front of the goal. This is where nearly all the shots for goal are made and where the most exciting incidents happen. As the puck can be a dangerous missile, it is wiser to work at a distance with a long focus lens. Action shots will require exposures of about 1/500 second and shots of players taking a corner or free hit, no more than 1/100 second.

Making the Print. The negative must be well graduated but not too thin, or the print will lack vigour. On the other hand, if the negative is too hard the result will look more like white plaster than snow. It is true, however, that no print on paper can truly reproduce the sparkling brilliance of a snow scene. A transparency is much more likely to produce the desired effect.

For the best results from paper prints all snow pictures should be printed on highly glossy paper with plenty of contrast and clean highlights.

Chloride papers generally give better results, as their tonal range is greater than that of bromide paper; the blacks are deeper and the half-tones richer. R.K.

WIRING. The electrical wiring of a building carries the mains supply to the various lamps, heaters, and other pieces of equipment that make up the permanent installation. It also supplies convenient points to which items of portable or movable equipment can be connected by flexible leads.

Permanent Wiring. Permanent wiring consists of copper conductors insulated with vulcanized indiarubber (V.I.R.), or nowadays more often in plastic. These insulated wires may be run in metal conduit, sheathed with lead, sheathed with tough rubber, or simply supported away from the wall surface on porcelain cleats.

The thickness and number of the copper wires is always arranged to be more than sufficient to carry the heaviest load that the circuit is likely to impose, and the insulation is always tested to withstand many times the supply voltage.

The installation or extension of the permanent wiring of a building calls for a qualified contractor; amateurs and handymen who insist on treading on such dangerous ground should at least consult the I.E.E. regulations on the subject.

Flexible Wiring. The wiring to standard lamps may be made of twin twisted insulated flexible wire; all other portable equipment must, by regulations, be connected to the supply through three-core circular braided flexible cable. This cable consists of three insulated conductors, coloured red, black and green, laid up with hemp worming into a circular section and covered with either indiarubber, braid, or both.

The colours indicate how the flex is connected to its plug and to the equipment: red, to the live pin of the plug and the switch on the equipment; black to the neutral pin of the plug; and green to the earth pin of the plug and all exposed metal parts of the equipment. (At one time, the earth wire was coloured brown, but green is now the approved colour.) This colour scheme applies to Britain only.

The current rating of flex should never be less than the maximum working current of the

equipment to which it is connected, to avoid overheating and danger of fire.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Socket Outlets. The supply points to which equipment is plugged in are known as socket outlets. There are three standard sizes: 2 amp, 5 amp and 15 amp. Nowadays two-pin sockets are no longer fitted; all sizes are of the three-pin type. The socket for the large pin is connected to earth and when the socket is looked at with this hole at the top, the hole on the left (marked N) is connected to the neutral (black) wire, and that on the right (marked L), to the live (red) wire.

When the outlet is controlled by a switch, the assembly is known as a switch socket outlet. The better types of socket outlet have an automatic shutter that covers the live and neutral sockets when the plug is withdrawn. The shutter is released by the earth pin on the plug so that the arrangement prevents two-pin or non-standard plugs from being used.

Plugs. The plugs by which the equipment is connected to the socket outlet are made in 2, 5 and 15 amp sizes. Most plugs nowadays incorporate some type of clamp which firmly anchors the flex to the body of the plug and prevents any strain from being taken by the wire at the terminals.

Three-pin plugs are wired in this way: looking on the back of the plug, with the earth pin at the top—brown or green wire to the earth pin; black wire to the left pin (marked N); red wire to the right pin (marked L).

Distribution. The main supply cable is connected to a pair of fuses as close as possible to its point of entry into the building. These fuses fix the total amount of current that can be drawn from the mains by the equipment in the building. The main fuses are there to protect the supply cable; they are sealed in their own fuse box and if they "blow" they must be replaced by the supply authority.

The cables that emerge from the main fuse box pass via the meter (which measures the number of units used in the building) to one or more distribution boxes. These distribution boxes hold sets of fuses which are connected to the various sub-circuits of the permanent wiring. Each sub-circuit supplies its own group of points—lamps, heaters, etc.

THREE-PIN PLUG AND SOCKET. E, earth pin, connected to green wire of cable or flex. N, neutral pin, connected to black wire. L, live pin, connected to red wire.

STANDARD DISTRIBUTION NETWORK. The current supply reaches the meter through the service fuses, and is then distributed to subsidiary fuse boxes and hence to permanent lighting and power circuits

The maximum safe load that the sub-circuit wires will carry fixes the type and amount of equipment that can be connected to it. It also fixes the value of the fuses in that outlet.

In planning the distribution it is assumed that only a proportion of the equipment on any sub-circuit will be switched on at one time. So if the maximum safe current that can be carried by the cable in a sub-circuit is 15 amps, the capacity of the fuse must also be 15 amps. But the circuit could include enough equipment to impose a load that, if it were all switched on at the same time, would be more than 15 amps.

The idea of dividing the distribution network into sub-circuits is to make the system safe. In a correctly planned system, as soon as any distribution cable, flex, or piece of equipment carries substantially more than its rated current, a fuse blows and that part of the system becomes dead.

This is why it is not good practice to connect a piece of equipment that only takes a small current—a 25 watt safelight, for instance—to a power point. A short circuit in the thin flex of the safelight could carry enough current to heat it up and start a fire without blowing the 15 amp fuse of the power circuit. If the safelight is connected as it ought to be, to a circuit reserved for lightly-rated equipment, the current need rise no higher than two or three amps before blowing a fuse.

Ring Main Distribution. Until recent years there was no alternative to the sub-circuit system of distribution. Nowadays, however, there is a new system—Ring Main Distribution—which may in time become universal. This method employs a single heavy-duty cable in place of the multitude of sub-circuits. The only fuse in the wiring is the main fuse, rated to carry the entire current of all the equipment in the building.

All the heating, and power connexions are provided by 13 amp socket outlets connected directly to the main cable. These 13 amp socket

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

RING MAINS. The mains supply reaches the meter through the service fuses, and thence goes along the ring main all round the building. Outlets wired as required, used with fused plugs.

outlets will accept only the special flat-pin fused plugs designed for them, and each piece of equipment carries its own fuse in the plug that connects it to the ring main.

The size of the fuse depends upon the current rating of the equipment, but the plug is always the same size, whether it belongs to a 3 kW. heater or a 25 watt safelight. All fuses are of the cartridge type and the plugs are designed to allow the fuse to be changed easily. F.P.

WOLCOTT, ALEXANDER, 1804–44. American instrument maker and daguerreotypist. Designed a camera without a lens which the light entered to be reflected by a concave mirror on to the plate (which was turned away from the subject). On the 7th October 1839 probably took the first successful portrait ever made. In March 1840 opened the world's first photographic portrait studio in New York.

WOLLASTON, WILLIAM HYDE, 1766–1828. English physician and scientist. Made many improvements to optical instruments, especially the microscope and the camera obscura, for which he invented the meniscus lens in 1812. Invented in 1807 the camera lucida. In 1802 observed the blackening of silver chloride in the ultra-violet part of the spectrum. Also observed the dark lines (better known as the Fraunhofer lines) in the solar spectrum.

WOODBURY. WALTER BENTLEY, 1834–85. English professional photographer. Invented in 1864 the Woodburytype process of printing with pigmented gelatin from lead moulds which had been obtained from chromated gelatin reliefs. The process was widely used as it produced prints with all half-tones, high definition, and without any grain or screen. It was superseded in the late 1880's by Collotype and other processes whose prints did not need trimming and mounting. Invented stannotype 1879. Woodbury also worked on balloon photography, on rotary printing and on stereo-projection. Received the Progress Medal of the Royal Photographic Society in 1883 for his stannotype process.

WOODBURYTYPE. This obsolete photomechanical printing process produced magnificent reproductions in monochrome and was probably the only photo-engraved method which had absolutely no grain or half-tone dot formation. It was named after its inventor and was used from about 1864 until the turn of the century.

A high gelatin relief was made on special carbon tissue by printing from a continuous tone negative. The relief was dried and pressed into lead in an hydraulic press. This lead cast provided the "printing plate".

A warm solution of pigmented gelatin was poured into the lead mould, allowed to set and then transferred on to a sheet of paper pressed into contact with it. Woodburytype was a true continuous tone intaglio process, but, although its results were beautiful, it was superseded by other more rapid processes.

Woodburytype prints can always be identified by their complete lack of any grain and by the fact that they are always trimmed flush and mounted separately into the page.

WOOD PRINT. Wood and similar materials can be treated so that they can be printed with a photographic image. The printing may be carried out by contact printing by daylight or artificial light, or by enlarging.

After the surface of the wood has been sealed and, if necessary, coated with a white base for the image, it may be printed on by any of the following methods:

(1) The surface may be brushed over with a sensitized coating or emulsion, exposed under the negative by contact or in the enlarger, and then developed.

(2) It may have the image transferred to it by the method of transfer coating.

(3) It may take the place of the final support in the carbon or carbro processes.

See also: *Printing on special supports.*

WOOD'S LAMP. Source of ultra-violet radiations consisting of a high pressure mercury vapour lamp with an outer glass envelope incorporating a filter layer of nickel oxide.

The lamp is named after Wood, the physicist who introduced this type of filter in 1913. The filter cuts off practically all visible radiations, leaving only a deep violet glow visible when the vapour tube is looked at directly. Although the very short rays are absorbed by the glass envelope, the lamp emits a useful band of ultra-violet rays. Commercially, lamps of the Wood type are used as a source of "black light"—e.g., for shop window display novelties—and for rendering visible laundry marks printed in colourless fluorescing ink. For photography by reflected ultra-violet rays, it is

more convenient to filter out the unwanted rays by placing a suitable filter in front of the lens instead of over the source as in a Wood's lamp.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Lamps of this type must be used in conjunction with a choke since the internal resistance is not constant. For this reason the lamp cap has three pins to prevent its being accidentally inserted in an ordinary two-pin bayonet holder. As the lamp does not give its full efficiency until the temperature has reached a certain value (which varies according to the lamp's construction and characteristics) it must be switched on five or ten minutes before it is wanted. Once switched off, the lamp cannot be switched on again until cold enough to allow the arc to strike again.

See also: *Discharge lamp; Ultra-violet and fluorescence photography.*

WORKING APERTURE. Largest aperture at which a lens will give a satisfactory negative, as opposed to the largest aperture to which the diaphragm can be opened. A wide-angle lens may have a large aperture to give a bright enough image on the focusing screen to allow the picture to be arranged, but its standard of definition at this opening may be unsatisfactory. Such a lens needs stopping down to its known working aperture before makingt he exposure.

WOTHLYTYPE. A printing-out paper invented by J. Wothly of Aachen, 1864. The paper coated with collodion containing uranium and silver nitrate, was considerably more sensitive than the albumen paper then in general use, but the claim for permanence, due to the uranium, was not fulfilled, and after a couple of years the Wothlytype was abandoned.

WRATTEN, FREDERICK CHARLES LUTHER, 1840–1926. English photographic manufacturer, founder (1878) of the firm of Wratten and Wainwright, Croydon. Invented in 1878 the "noodling" of silver bromide gelatin emulsions before washing, and manufactured silver bromide gelatin dry plates in 1878. Produced the first panchromatic plates in England in 1906 and became a famous manufacturer of photographic filters.

X

XENON. Rare gas used in a variety of discharge lamps and in most present-day electronic flash tubes. Xenon discharge lighting has an energy distribution sufficiently similar to daylight, so that xenon discharge lamps can be used for colour photography with daylight type colour films.

See also: *Discharge lamp.*

XEROGRAPHY. Electro-photographic system involving the image-wise discharge under the influence of light of an electrostatically charged selenium plate. The areas that remain charged attract oppositely charged pigment particles during subsequent "development". This image of pigment particles is then transferred on to paper and fused into the paper support. The system has wide applications in photo-copying.

X-RAY CRYSTAL ANALYSIS. Method of deriving information about the structure of a crystalline substance by means of diffraction patterns produced when a beam of X-rays is passed through a single crystal or powdered crystals of the substance.

X-ray Diffraction. When X-rays traverse a crystalline substance, the regular network of atoms of which the substance is composed acts as a three-dimensional diffraction grating and the X-rays are scattered according to certain rules. The diffraction effects are most simply interpreted in terms of reflection by planes in the atomic network and this leads to the well-known Bragg relationship

$$2d \sin \theta = n\lambda$$

where d is the interplanar spacing, θ the angle of incidence of the X-rays on the "reflecting" planes, λ the X-ray wavelength and n an integer.

The diffracted X-rays cannot, however, be focused by lenses to form a direct image of the crystal structure. All that can be done is to make a record of the diffraction pattern. The problem of X-ray crystal analysis then lies in postulating or calculating the positions and distribution of atoms in the structure cell that have given rise to the intensities of spots or lines found in the diffraction pattern.

The discovery of X-ray diffraction provided an enormously powerful method of advancing our knowledge of the structure of matter. Besides the solution of crystal structures there are many other industrially important applications of X-ray analysis. The precise identification of a substance, the study of alloy formation, and the investigation of the causes of strain in the crystal lattice are just three examples of such applications.

DIFFRACTION CAMERA SET-UP. Production of X-ray powder diffraction pattern. A, beam of incident X-rays. B, powder specimen to be examined. C, cone of diffracted X-rays. D, cylindrical film surrounding specimen.

Photographic Recording. X-ray diffraction patterns are commonly registered photographically. It should be remembered, however, that one of the original methods by which crystal structure determinations were made was the Bragg spectrometer in which an ionization chamber was used to detect and measure the intensities of X-ray reflections. Today the basic principles of the Bragg spectrometer are incorporated in the so-called counter diffractometer instruments. In such instruments the ionization chamber has been replaced by one of the three well-known types of counter, Geiger-Müller, proportional, or scintillation.

Many different types of camera have been designed for the photographic recording of X-

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

X-RAY DIFFRACTION. Different planes of crystal lattice reflect X-rays. Diffraction takes place when incident and reflected angles are equal, and 2d sin θ is a multiple of the X-ray wavelength, and produces patterns on the film.

ray diffraction patterns. In the simplest arrangement the crystal is mounted on a goniometer device which allows easy choice of different orientations towards the incident collimated X-ray beam. The diffracted effects are intercepted by a flat film held in a cassette mounted behind the crystal. When the specimen consists of a multitude of small crystals instead of one crystal, and the incident X-rays are monochromatic, the diffracted beams travel along the surfaces of a set of coaxial cones and the diffraction pattern registered on the film comprises a series of concentric rings. For some purposes it is sufficient to record only small parts of these rings, and then a strip of film is held on a narrow cylindrical surface with the powder specimen at its centre. The resultant line diffraction patterns are commonly described as "powder photographs". The powder photograph is widely used for identification, crystal size measurement, and other applications of practical importance.

Single crystal photographs are generally required for the complete solution of crystal structures. Interpretation is assisted by recording the patterns with specially designed cameras in which during the exposure the photographic film is moved in synchronism with rotation of the crystal. Movement of the film effects a separation of reflections which would otherwise overlap.

The X-ray film normally employed is similar to the non-screen double-coated film used in industrial radiography. In the majority of applications a large part of the incident X-ray energy is absorbed in the front emulsion, but the second coating adds something to the over-all density obtained.

Exposure times range from a few minutes to many hours in some single crystal work.

A special fine-grain high-contrast film is advocated when fine detail is of primary importance, but there is the accompanying disadvantage of a three- or four-fold increase in exposure time. In certain techniques, involving thirty times enlargements of a single X-ray reflection, Lippmann type plates are necessary.

If the X-ray reflections are likely to be incident obliquely on a flat film, it is occasionally desirable to use single-coated X-ray film. This avoids ambiguities arising because of lack of register between the front and back images on a double-coated film.

Counter Diffractometers. The counter diffractometers which were referred to above are commonly coupled to pen recorders, which enable for example an X-ray powder diffraction pattern to be recorded on a chart as a continuous trace. Peaks on this trace register clearly both the positions and intensities of the "reflections" which comprise the pattern. The instruments also incorporate means for studying selected "reflections" in detail by time counts. Such equipment lends itself to automation. Thus applications of the X-ray diffraction method to the monitoring of production processes in which phase identification and concentration must be controlled become possible. Other types of diffractometers have been developed for recording automatically the intensities of the multitude of "reflections" from single crystals, thus enormously increasing the speed of collection of data from which atomic arrangements have to be computed.

Interpretation. To evaluate the information on an X-ray diffraction pattern, both the intensity and the position of the X-ray reflections have to be determined.

The intensities of the reflections are obtained by comparison of the densities of lines or spots comprising the pattern. Visual estimation may sometimes give acceptable results, but photometric measurement is often required.

As the relation between X-ray negative opacity and reflection intensity is not linear, a wedge or series of spots corresponding to known relative intensities should be imprinted on each film. To place the measurements on an absolute scale, it is necessary to calibrate by means of reflections of known intensity from a standard crystal.

Special travelling microscopes are advocated for determination of line or spot positions on X-ray diffraction negatives.

Many of the problems of reflection-intensity measurement may be minimized by use of counter diffractometers.

Much of the laborious computation involved in complete structure determination may be reduced by an experimental approach involving optical diffraction methods. One optical arrangement that has been suggested is known as the "fly's eye". A plane mask or pattern is constructed to correspond to the proposed crystal structure viewed from some chosen direction. The optical diffraction pattern, obtained when monochromatic light from a point source is passed through the mask, is compared with the X-ray diffraction pattern to determine whether the proposed atomic arrangement is correct. The masks are prepared by a photographic reduction method, since the element of a pattern must be reproduced perhaps two or three hundred times in any given mask.

Attempts have also been made to produce directly an optical image of the crystal structure or key projections of it. The masks then have to imitate particular features of the X-ray diffraction pattern, and a section of what is termed the reciprocal lattice, which can be readily derived from it, is constructed. The problems of adjusting the intensities of the X-ray beams and of determining their phases are both dealt with by taking advantage of the polarizing properties of mica. By covering the holes in the mask with sheet mica in various orientations the transmitted light beams can be modified in appropriate ways, and different possibilities examined by trial and error. The development of this so-called diffraction spectrometer has provided a powerful new tool for the structure analyst. H.P.R.

X-RAY DIFFRACTION. Coherent scattering of X-rays by the atoms of a chemical substance. Where the arrangement of the atoms is regular, e.g., in a crystal lattice, a beam of X-rays produces a diffraction pattern which is recorded photographically and this pattern yields substantial information about the crystal structure of the substance.

See also: *X-ray crystal analysis.*

X-RAY FILM. Sensitive material designed specifically for radiography. X-ray films consist of a safety base carrying an emulsion on both sides, thus utilizing the penetrating power and absorption of X-rays in both emulsion layers. Double coating gives increased speed and contrast over a single coating.

Direct and Screen X-ray Films. X-ray films are exposed either to X-rays directly or in conjunction with a pair of intensifying screens. The purpose of the latter is to reduce to exposure time which would be required without screens. There are essentially two types of screen: salt and lead screens. X-ray films differ in characteristics according to whether they are determined for direct exposure to X-rays and in combination with lead screen or for salt screen exposure.

Salt screens consist of a support of cardboard or other flexible layer coated with calcium tungstate or barium lead sulphate. Both substances emit bluish fluorescent light when exposed to X-rays. An X-ray film is sandwiched between a pair of such screens. Although excited by X-rays the image obtained is essentially due to the action of bluish light.

Lead screens consist of a flexible support provided with a thin lead foil which emits electrons when struck by X-rays. The X-ray film is sandwiched between a pair of lead screens and the intensification achieved is due to the action of electrons on the photographic emulsion.

Direct X-ray films have an emulsion highly sensitive to X-rays and to the electron emission from lead screens. The screen type emulsion is highly sensitive to the blue light emission from salt screens and may have a relatively low X-ray sensitivity. The spectral emission of the calcium tungstate screens with a peak of about 4,300 A. almost coincides with the natural spectral sensitivity of an X-ray silver bromide emulsion later. The emission of barium lead sulphate screens is shifted slightly more towards the U.V. radiation, to which the emulsion is still very sensitive.

Exposure Characteristics. In direct X-ray exposures it has been found that one X-ray quantum absorbed per silver halide grain renders this developable, whereas this is not so for screen light exposures. Hence for direct X-ray exposures there is no reciprocity failure and results are independent of the rate of exposure. In the initial part of the density-exposure curve the number of grains rendered developable is proportional to the number of quanta absorbed, hence there exists proportionality between exposure and density which holds until more and more grains receive several X-ray quanta hits. Then the proportionality ceases and the density-exposure curve gradually leads to saturation at higher densities. In some non-screen X-ray films this proportionality holds up to densities of 2 and 3 and may be utilized in scientific applications, such as X-ray crystallography.

In screen exposures where the image is produced essentially by light, reciprocity failure may occur, particularly in long exposures using low X-ray intensities. The intensify-factor is defined as

$$\frac{\text{exposure required without screens}}{\text{the exposure required with screens.}}$$

CC-0. Approach Digital Preservation Foundation, Chandigarh

in order to obtain the same density on the same type of film. The intensifying factor may reach values of up to 100 and even more depending on the quality of radiation and the rate of exposure applied.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

Medical Radiography. In medical use most exposures are made with screen films. Most intimate contact between screens and film is required to obtain optimum resolution. As the individual crystals of screens emit light in all directions the resolution obtainable with screens is limited. Hence exposures of extremities, where high definition of bone structure is expected are usually taken with direct X-ray films. Lead screens are not used in medical applications, as the screens would not permit any reduction of exposure time within the range of kilovoltage applied in medical radiography.

Industrial Radiography. Most exposures for industrial radiography are made on non-screen X-ray film, usually in conjunction with lead intensifying screens. The latter become useful only at kilovoltages above 140 kV. Resolution is not impaired when using lead screens if these are in perfect contact with the film. In contrast to medical radiography, where exposure times range from fractions of a second to seconds, industrial radiographic exposures run to minutes and even hours. Hence the use of screen film with screens is very limited owing to the reciprocity failure of the film.

For both medical and industrial radiography a range of X-ray films is manufactured covering different requirements of speed, contrast and definition. Dental films which are of the non-screen type are individually packed, often with a thin lead foil behind the film to reduce scattered radiation originating from the gum. Screen and non-screen films are usually supplied folder wrapped, but non-screen films are also obtainable in individual envelopes. These permit the handling of films in daylight without the use of special cassettes.

X-ray films are preferably stored in lead lined containers to protect them from accidental exposure to X-rays.

Processing. X-ray films are normally processed in tanks using strict time and temperature control. During processing the films are supported by stainless steel hangers which also permit inspection after processing whilst the films are still wet. In hospitals and industrial laboratories where a great number of radiographs are taken per day, the use of automatic processing units has become an essential feature of a national operation R.H.H.

See also: *Antoradiography; Industrial radiography; Medical radiography.*

X-RAY MICROGRAPHY. Technique for examining the internal structure of thin opaque specimens not normally revealed by photomicrography. A specimen of the material—e.g., a metallurgical section—1 mm. thick, or less, is placed in contact with an extremely fine-grained sensitized emulsion and a radiograph is made.

The radiograph is then examined or photographed under the microscope. By this means the internal structure of specimens may be seen at magnifications of up to 300×.

See also: *Microradiography.*

X-RAYS. Rays discovered and so named by Röntgen in 1895. They are able to penetrate solid matter and to produce a developable image in the photographic emulsion. X-rays were shown to be electro-magnetic waves by von Laue in 1912. They occupy the region of the spectrum between gamma rays and the ultra-violet, having wavelengths from about 0·05 A ("hard" rays) to over 100 A ("soft" rays). Hard rays are more penetrating; rays of more than a few A wavelength have no practical application.

X-rays are generated by the impact of high-velocity electrons on matter. In the original tubes an electric discharge in a rarefied gas (cathode rays) was used. Modern tubes (Coolidge tubes) are evacuated as completely as possible; the electrons are emitted by a hot tungsten filament, and are accelerated by a potential of several thousand volts to strike the anticathode or target, which emits the X-rays. The tube also contains parts designed to focus the electrons on to a small area of the target. The material used for the target depends upon the type of radiation desired, but it must be very infusible and/or a good conductor of heat, as the impact of the electron beam has an intense heating effect; for the same reason the target is always water-cooled. The target is frequently made of tungsten, but copper, molybdenum, iron, cobalt, chromium, silver or rhodium are also used for special purposes.

Very hard X-rays, in the production of which potentials of up to 1 million volts are employed, are used therapeutically, in the treatment of cancer, etc. Photography is not concerned at all with this use.

The other uses of X-rays employ their penetrative powers. These depend upon the density of the material under examination, bone being more opaque than the surrounding soft tissues, blowholes and other faults in castings more transparent than the surrounding sound metal, etc.

The records of X-ray examinations of these types are normally made photographically on radiographic films.

The photographic recording of X-rays is used in: medical diagnosis, for which comparatively soft rays are used; industrial radiography. Very hard and penetrating rays (wavelengths 0·05–1 A) are used to reveal the internal structure of castings, etc. A new

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

development is micro-radiography, which uses soft rays to reveal the structural details of comparatively transparent materials such as paper, plastics, etc.; a fine-grain maximum-resolution emulsion is exposed behind the sample, and the developed image examined under a microscope. X-ray crystallography, which uses rays of 0·5–2 A wavelength, is the most important scientific, as distinct from technical, application of X-rays. It depends upon the diffraction of the rays by the regularly-spaced atoms in crystals (analogous to the manner in which visible light is diffracted by a grating), and is a most powerful tool in the exploration of molecular structure. The chemical constitution of penicillin was elucidated in this way, for example.

Although X-rays act on photographic emulsions, they are less effective in this respect than light, since their penetrative power allows them to a large extent to pass through the emulsion without affecting it. X-ray film is therefore always coated on both sides, in order to increase the total emulsion thickness. Coarse-grained emulsions are also used wherever possible, since these are more sensitive to X-rays than fine-grained ones. H.J.Wa.

Y

YARD (YD.). Unit of lineal measure equal to 3 feet or 36 ins. Originally the yard was based on the ell (from Lat. ulna, the forearm) which, in England was standardized as the length of the arm of King Henry I. The present standard is given by the distance between two gold inserts in a bar of platinum in the Exchequer Offices, London.

See also: *Weights and measures.*

YELLOW. The red-green colour reflected or transmitted by a surface which absorbs blue, also known for this reason as minus blue. One of the three primary colours used to form the image in subtractive colour processes, the other two being minus red (cyan), and minus green (magenta).

YLLA (Camilla Koffler) ?–1955. Hungarian-born photographer, settled in Paris in 1920s and trained as photographer. Her talent for photographing animals manifested itself during her student days. She emigrated to U.S.A., 1940, and after the War her picture stories of animals won international reputation. She had a fatal fall from her truck while photographing big game in Africa.

YUGOSLAVIA. At the time photography was invented, the people of present-day Yugoslavia were either under foreign rule as Croatians and Slovenes, or were just creating their state as Serbians, after five centuries of Turkish occupation. In spite of this, besides showing keen interest in photography the Yugoslavs also contributed to its development.

History. Daguerreotypes were being made by numerous workers between 1840 and 1850, among them being Novaković and Boš in Zagreb and J. Kapišeri and A. Dajč in Belgrade. It was the Slovenian Catholic clergyman Janez Puhar and the Serbian Anastas Jovanović, however, whose work made an impact beyond the boundaries of Yugoslavia.

Puhar (1814–64) found it difficult to procure the necessary material for daguerreotypes, particularly the silver plates which would have been somewhat expensive for a young clergyman of limited means, in the small Austro-Hungarian town of Kranj. He began using glass plates as early as 1842—five years before Niépce de St Victor, who is officially considered the inventor of photographs on glass plates—and made transparent pictures by means of sulphurous, iodine and chromium vapours. Puhar's invention was registered by the Viennese Academy of Science but was forgotten, in spite of his being elected a member of the French Academie Nationale, Agricole, Manufacturiere et Commerciale in 1852, and being awarded a diploma in which he is referred to as inventeur de photographie sur verre (Inventor of photography on glass plates). Puhar exhibited his photographs at the World Fair in London in 1851, and also in New York in 1852. Anastas Jovanović (1817–99) was first a printer in Belgrade, and later the first Serbian lithographer. He went to Vienna on a state scholarship to study art at the Art Academy of St. Anna. There he saw the first daguerreotypes, and became so enthusiastic about them that he immediately bought a camera with a Petzval objective. He first made talbotypes and was the first to take stereophotographs of Vienna which he exhibited at a show organized by the Viennese optician Prokesch in 1854. Jovanović made a complete portrait gallery of eminent Serbian personalities in the first half of the nineteenth century, using the talbotype method.

Clubs and Associations. The photographic section of the Croatian Art Society, founded in Zagreb in 1890, is doubtless the oldest amateur photographers' organization in the country. The Slovene amateur photographers had two clubs at the beginning of 1900. The Belgrade photo club was founded in 1901, and was the

first in the Kingdom of Serbia. The Balkan War and the First World War interrupted photographic activities over a long period, and they were continued only after the unification and creation of a common state in 1918. The *Fotoklub Zagreb* (Zagreb Photo Club) was established in 1923, Belgrade founded its club in 1928 and the club in Ljubljana also resumed its activities at that time. Amateur photographers were extremely active within the photo-sections of mountaineering societies, and these often developed into independent clubs later.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

The first amateur photographers' organizations after World War II were founded in Belgrade, Zagreb and Ljubljana. Interest in photography having become far keener in the post war years, the membership of these clubs grew rapidly.

The Federation of Yugoslav Amateur Photographers was founded in 1949 with the aim of raising the standard of technical training, and of promoting photography generally. Since 1950 the Federation has been a member of the Federation Internationale de l'art Photographique (F.I.A.P.) Photo clubs have been established throughout the country with the help of the Federation, photography courses have been organized, and instruction- and work-schedules drawn up for newly established photographic organizations. By 1950 there were 63 clubs, with a total of 9,835 members. The Federation also directed its attention to amateur cinematographers, who were operating under great financial difficulties, and by 1956 seven cine-clubs were in operation. News reporters and press photographers are organized within the Federation of Journalists' Associations of Yugoslavia.

The Photographers and Cinematographers Federation of Yugoslavia (FKSJ) consists of six separate associations, each of which operates independently on its territory. Each association co-ordinates the activities of the clubs on its territory. Both amateurs and professionals are eligible for membership. The Federation has introduced the ranks of Master of Photography and Candidate Master, these titles being conferred by the Arts Council.

In order to operate as a professional photographer it is necessary to pass specified examinations. The general standard of work is not as yet as high as in most Western countries. At present there are no photographic schools in Yugoslavia although there is a photographic section within the School of Applied Art, this being the only centre of photographic learning in the Balkans.

Industry. The Yugoslav photographic industry is still young, and the first films and plates were manufactured as recently as 1947. A Zagreb factory, the only one of its kind in the Balkans, is producing a wide assortment of photographic materials including 35 mm. films, papers, X-ray materials, positive 16 and 35 mm. cine films, photostat materials for copying and registration, photographic chemicals, optical gelatin filters and lantern plates. The manufacture of materials for colour photography is currently in preparation. Photographic materials are exported to several countries such as the U.S.A., Holland, Austria and the Scandinavian countries, as well as to India, Egypt, Lebanon and Turkey where demands are very great. Twenty-five per cent of the roll films produced in 1962 were sold to the U.S.A. Brazil is beginning to show an interest in Yugoslavia's photographic products. High quality motion picture projectors for 16 mm. film are being manufactured in Kranj, as well as slide projectors and other equipment and accessories for photo-laboratories. The optical glasses for these are manufactured in Ljubljana. Cameras and accessories, motion picture cameras, colour films and optical glasses are all imported into the country. High quality cameras come mostly from West Germany, while the less expensive models for the average amateur are supplied by East Germany, Czechoslovakia and the Soviet Union. During the past three years cameras and other photographic materials and accessories have also been imported from Japan on a fairly large scale.

Exhibitions. The country's first photographic exhibition was held at the Arts and Crafts fair in Zagreb in 1891. The Serbian amateur photographers held their first exhibition in Belgrade in 1901, and the Slovenians had their first exhibition in Ljubljana in 1911. Foreign exhibitors took part in exhibitions held in Zagreb in 1910 and 1913.

After 1935, when the International Exhibition of Slavic Photography was held, the Zagreb photographers club organized five international exhibitions before the beginning of World War II. The Ljubljana photo club also organized international exhibitions in 1934, 1936 and 1938. The Zagreb amateur photographers club exhibited at the Royal Photographic Society in London in 1938, and also in Argentina and Holland. The newly formed Association in 1949 resumed the activities cut short by the war with still greater enthusiasm, and so far twelve all-Yugoslav exhibitions, with about 4,000 photographs, have been held. Today the all-Yugoslav shows are always accompanied by lectures and discussions at which the individual problems and aspects of Yugoslav photography are examined in detail.

International exhibitions have been held since 1951 and apart from this, small-scale exhibitions are being organized by the individual clubs. Yugoslav amateur and professional photographers are taking part regularly in shows and competitions abroad and some artists have held one-man shows in various European countries. One-man shows within Yugoslavia received a vigorous boost at the

beginning of 1962 through the inauguration of the exclusive Photographic Gallery in Belgrade, whose aim is to acquaint the public with the work of individual Yugoslav photographers and distinguished foreign amateurs and professionals.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Publications. Although the first publication, the review *Fotografski pregled* (Photographic Survey), appeared in Belgrade in 1911, Yugoslav photographic literature is limited. There were ten photographic reviews published in Yugoslavia from 1911 to 1940, and of these the international review *Galerija*, (*die Gallerie*) published in 1933, was perhaps the most noteworthy. *Fotozevija*, which specialized mostly in technical problems of photography, appeared from 1931 to 1940. The review *Savremena fotografija* (Contemporary Photography), was founded in 1941, but was forced out of existence by the war. In 1948 the Yugoslav Federation of Amateur Photographers founded *Fotografija*, a universal review of photography which is now published under the title of *Fotokino revija* (Photographers and Cinematographers Review). Apart from this, professional photographers published their own review *Naša Fotografija* (Our Photography), from 1947 to 1951, and the Belgrade amateur photographers published *Beogradski objektiv* from 1952 to 1958 as well as the young photo-amateurs' review *Oko* (Eye). Foreign books and publications on photography are widely read, and two years ago a Zagreb publishing house began issuing books devoted to the art of photography.

Artistic Trends. At the beginning of the century, photography in Yugoslavia, as in the rest of the world, tended to take its inspiration from the field of painting and thus portrayed such subjects as idyllic village scenes and artificial genre. There was a lack of any definite objective criteria. In the 1930s, the Neue Sachlichkeit (New Reality) movement and the Bauhaus experiments emanating from Germany, had a brief influence, but served in the long run, only to confirm belief in the silver bromide process.

The most active groups between 1930 and 1940 were the Fotoklub Ljubljana (Ljubljana Amateur Photographers Club) and the Foto-Klub Zagreb (Zagreb Amateur Photographers Club). The Ljubljana school of photography was based on pictorialism and emphasized fine technique and craftsmanship, and much use was made of the soft focus lens to gain an impressionistic effect. The Zagreb school, on the other hand, favoured portrait and genre. They aimed for realism and simplicity and regarded the negative as inviolable, retouching only to remove blemishes.

Towards the end of the 1930s the Klub Fotoamatera Beograd (Belgrade Amateur Photographers Club) practised the same style but with greater originality and freshness owing to their comparative remoteness from international exhibitions. Their activities were stopped by World War II.

After the liberation of the country, life in all its forms and manifestations was the basic theme of the new Yugoslav photography. International exhibitions are inspired by a new spirit and new concept of photography with which the Yugoslav amateur has become gradually acquainted through foreign publications. Subjective photography and Italian neo-realism may also be considered to have had a noticeable influence on the development of Yugoslav photography. The *Family of Man* exhibition made a particularly great impact, as Yugoslav photographers have for a long time had a strong affinity for this kind of work.

Photography plays a prominent part in business publications, prospectuses, and catalogues; in publications on tourism and on art: in the numerous lavish presentations of the Yugoslav publishing house; and in the prominent monthly magazine, *Review*.

After World War II, and under the new social conditions, photography acquired a status equal with the other arts, and photographers were able to join the Association of Visual Artists alongside painters and sculptors. As the impact of photography on the country grows efforts are being made both to spread interest in this field to those more remote regions where it is as yet little known, and also to introduce photography and photographic facilities into the schools, as an optional subject. Z

ZEISS, CARL, 1816–88. German optical manufacturer. Founder of an optical firm in Jena. With collaborators and successors (especially Abbe and Rudolph) designed or improved microscopes, field-glasses, optical instruments, photographic lenses (anastigmat, Tessar) and cameras. Biography in *Zur Geschichte der Zeissischen Werkstätte* by M. von Rohr (Jena 1936).

ZINCOGRAPHY. Photomechanical printing process in which the negative image is printed on zinc to produce a litho plate from which reproductions can be taken in printing ink.

ZIRCONIUM LAMP. Concentrated arc lamp used in projectors and enlargers.

The electrodes are a ring-shaped metal anode surrounding a tiny tube of zirconium oxide, and the arc occurs in the narrow annular gap (a few thousandths of an inch) separating them. At the high temperature of the arc, the oxide becomes coated with molten incandescent zirconium which gives a brightness comparable with that of a carbon arc at a colour temperature of about 3,000° K. All the light is emitted through the hole in the anode in a forward direction, so it is a highly efficient source.

A 2 watt lamp (37 volts) has a light source of 0·003 in. diameter and a 100 watt type (15·4 volts) about 0·059 in.

The electrodes are enclosed in a glass bulb.

See also: *Point source lamp.*

ZOËTROPE. Device invented by W. G. Horner of Bristol in 1833 and named Zoëtrope in 1867. It consisted of a light sheet metal cylinder about a foot in diameter, mounted on a central pivot so that it could be spun around by hand. The top half of the cylinder was pierced with a series of slits, and around the inside of the lower half was fastened a paper band. This band carried a series of pictures on the lines of an animated cartoon, creating the illusion of moving pictures when rotated.

The number of pictures around the band was equal to the number of slits in the cylinder, and the whole series covered a complete action sequence—e.g., a boy leap-frogging over another's back, or turning a cart wheel.

When the drum was set turning, an observer looking through the moving slits at the pictures on the opposite side of the drum caught a glimpse of each picture at the instant when it reached the opposite side of the drum. Before and after that instant, his view of the picture sequence was cut off by the side of the drum.

So the observer's eye received a series of impressions of still pictures, each successive picture showing another step in the progressive development of the action. Because of persistence of vision, all the separate impressions added up to a moving picture, repeating the action at each revolution of the cylinder.

The popularity of this form of entertainment fell off abruptly with the introduction of cinematography.

Other types of apparatus on the same principle in one form or another were variously called a wheel of life, a phenakistoscope, stroboscope, a phantascope, and a kaleidorama.

The earliest and simplest form was invented simultaneously by Plateau of Ghent and Stampfer of Vienna in 1832.

ZONE FOCUSING. For fast-moving subjects, sports events, children at play, and animals, there is no time to focus and set the aperture before each exposure. Under these circumstances the experienced photographer sets his lens to cover the entire depth of the zone in which the subject is likely to be moving. Then, so long as the subject keeps inside the zone, there is no further need for focusing, and the photographer can concentrate on making exposures.

Once he has decided on the near and far limits of the field he has to cover, he con-

The heavy figure in each group gives the distance on which the camera should be focused. The lighter figures give the limits of the depth of field. The zones assume that the lens is in each case the normal focal length (i.e., neither wide angle nor telephoto or long focus) for the negative size it is used with.

sults the depth of field tables for the lens he is using to find what focused distance and lens aperture will give him the required depth. This will then cover the particular subject or a series of subjects (e.g., a picture sequence) within the selected zone.

Next he finds what shutter speed he must use at this lens aperture to give him the correct exposure.

If this shutter speed is fast enough to arrest movement of the subject, he can make the necessary adjustments of focused distance, aperture, and shutter speed, and fire away with that fixed setting.

ZONE FOCUSING. Focusing zones for miniature camera with interchangeable lenses. Top: *Near, medium, and distant zones covered by 5 cm. lens focused on 4, 8, and 15 feet respectively, and stopped down to f8.* Centre: *Corresponding zones with 7·5 cm. semi-long focus lens.* Bottom: *Corresponding zones with 10 cm. long focus lens at same settings.*

But sometimes the shutter speed will not be fast enough to arrest movement of the subject at the range of distances included in the focused zone.

There are two ways out of the difficulty, according to whether sharpness to arrest movement or the subject depth covered is more important:

(1) He can move farther away from the subject. At a greater focused distance, the depth of the zone of sharpness is also greater. As the photographer will then have more depth than he wants, he can sacrifice some of it to allow him to open up the lens aperture and speed up the shutter.

Unfortunately when he moves farther away from the subject, he is forced to make do with a smaller image.

(2) He can use a bigger aperture which will in turn let him give a faster shutter speed. This has the disadvantage of narrowing the zone of sharp focus.

Both expedients carry penalties; the final choice is bound to be a compromise that will vary with the circumstances and the photographer.

Zone Indicators. Many cameras show the settings for one or two focusing zones on the distance scale.

This may take the form of special symbols to which the scale is set; such a setting, combined with an appropriate aperture (sometimes marked in red on the aperture scale) then yields one or two useful focusing zones.

A number of modern simple cameras dispense with the focusing scale or else use in addition a scale of symbols indicating the most suitable zone for portraits, groups and more distant views. (This is in fact substantially the same thing as the two point or three-point focus settings on older simple cameras.)

Occasionally the lens mount clicks into place at specific focusing zone settings. With some cameras the viewfinder may even indicate a selected focusing zone by a suitable signal (for example 1, 2, or 3 coloured dots or some symbols and a movable pointer).

See also: *Depth of field.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

ZOO. Photography at the zoo calls for patience above everything else. The photographer has no control over the animal and so he must be prepared to wait for it to take up a suitable position. It is sometimes possible to exercise a certain amount of control by tempting the subject with food, and a slight noise will often make it look more alert. But beyond this, there is little that the photographer can do except wait—for hours, if necessary. It is better to wait for one really good picture than to hurry away with a batch of second-rate snaps.

The beginner will usually find it easier to start with the larger and tamer animals. Deer, camels, zebras and the like are easier to get at and offer fewest technical difficulties. With wild animals there are the bars to contend with from the outside of the cage, and the risk of attack when taking photographs inside the cage. And smaller animals are very much more difficult to photograph; it is considerably easier to make a good picture of an elephant than a mouse.

Camera. Almost any type of camera can be used to make zoo pictures, so long as the photographer works within its limits. A box camera will take satisfactory photographs of any animal from an elephant down to a goat. But it is quite unsuitable for the smaller animals and birds.

Close-ups of small subjects call for a camera that can be fitted with a long focus or telephoto lens; this will allow the photographer to work at a comfortable distance and still get a big enough image. Long focus and telephoto lenses are useful in open-air zoos where the animals are generally seen a long way off. Under such conditions a camera with a normal lens gives a picture in which the animal comes out as a tiny speck in a wide expanse of uninteresting landscape.

Two very suitable cameras for zoo photography are the 35 mm. miniature and the single-lens reflex, both taking interchangeable lenses.

Tripod. A tripod is often more of a handicap than a help. Most zoos discourage the use of cameras on tripods because they obstruct the public pathways at the busiest points. Then a tripod is useless when the camera lens has to be pushed between the bars of a cage. And finally, most animals are frightened by a tripod; to them it is a stick, and they know that sticks can hurt.

Flash. A flash outfit can be useful for taking pictures in dark surroundings and for lighting up strong shadows, particularly on dark fur or feathers. But it is always necessary to ask permission of the keeper first. Some antelopes, for instance, are so timid that they would dash themselves against the fence and break their limbs if they were startled with a flash.

Backgrounds. One of the greatest difficulties in zoo photography is to avoid an ugly or uncharacteristic background. Too often the photographer has to make the best of existing and unalterable surroundings. When this happens—as when the animal is in a cage or other confined space—it is best to coax the animal away from the background, or wait until it moves away from it, and then focus sharply on the subject at a wide aperture. This technique throws the background out of focus so that it is blurred and very much less assertive in the final photograph.

Another useful way of separating the subject from its background is to choose a time of day when the background is in shadow and the animal can be caught in sunshine.

Dealing with Bars. Zoos without bars are to be preferred for animal photography, but even in the conventional type of cage there are plenty of opportunities for making good pictures.

It is often stated that if the camera lens is pushed right up against fine wire mesh, the wire will not show in the photograph. This is not true, and wherever possible the lens should be poked through the mesh or between the bars so as to be quite clear of them. Before going as close as this, however, the photographer should always be sure that it is safe. When the animal is dangerous, there is always a notice on the cage saying so, and in that case there is nothing to be gained by experimenting.

When a photograph is taken with the lens pushed through the bars in this way, there is a danger that the animal will be too close. In these circumstances a friend—or the keeper for preference—should throw pieces of food to tempt the animal away from the bars. The photographer himself should never let the animal see him with food or it will probably come right up and lick his lens.

On the whole, better pictures result from simply waiting until the animal moves naturally over to the right spot; food should only be used as an incentive when time is short.

The shadow of the bars is always a potential nuisance as it tends to turn all animals into zebras. If the cage is so situated that the sun always lays the shadows of the bars across the animal and its background, the only solution is to wait for a bright sunless day.

Finally, if the bars cannot be kept out of the picture by any of the methods described, it is important that they should be shown absolutely vertical—i.e., parallel to the sides of the print.

Behind the Bars. The keeper can often be persuaded to allow the photographer to take photographs inside the cages of the tamer animals. Photography at such close quarters and with no bars or wires in front of the subject offers much greater scope for individual work.

The photographer who is lucky enough to get permission to enter a cage must learn to move slowly—this is necessary not only when approaching the animal, but for all movements. Often even the act of drawing out a dark

zoom lens. In this way the focusing movement equally affects the system at all focal length settings.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

In terms of lens performance, zoom lenses inevitably represent a compromise of greater tolerance than is accepted with a high class lens of fixed focal length. This is because the various lens aberrations, normally corrected for specific inter-element separations, have to be kept constantly low over the whole optical movement range. This involved compensating aberrations which must cancel between the fixed and the moving components of the lens. For this reason also high-class zoom lenses are usually complex, containing anything from eleven to twenty elements, and correspondingly expensive.

The complexity naturally increases the greater the zooming range required. For cine and television lenses this varies from about 3 : 1 up to 10 : 1; for still camera zoom lenses 4 : 1 is more or less the maximum ratio and for projection lenses requirements rarely go beyond 2 : 1 or 3 : 1.

Cine and Television Zoom Lenses. Low price (comparatively) zoom lenses for amateur narrow gauge cine cameras start with a zooming range of 3 : 1 and maximum apertures of *f* 1·8 or *f* 1·9. For an 8 mm. camera the range might thus cover from 9 to 27 mm. or 10 to 30 mm., going from a slight wide angle lens to a 2½× telephoto. Frequently the zooming range can be changed by a fixed afocal attachment, which might bring the lower limit of the focal length range down to about 6·5 or 7 mm., correspondingly reducing also the tele end of the zooming movement.

For 16 mm. cameras a corresponding zooming range might be 20 to 60 mm.

High class cine zoom lenses come with a focal length range of 1 : 4 to 1 : 6. For 8 mm. cameras this might cover focal lengths from 7·5 to 35 mm. or 8 to 48 mm., the latter extreme being nearly a 4× telephoto focal length and the longest ever likely to be required for amateur purposes. For 16 mm. cine and television purposes (with vidicon cameras) a typical zooming range might be from 17 mm. to 70 or 85 mm., in other words from a normal wide angle to a 3½× telephoto position. Lenses of extra long zooming range are however available, covering focal lengths from 12 to 120 mm. and are principally used in professional cinematography, newsreel work, etc. In addition there are also zoom lenses of specially long focal length, covering a telephoto range from 1½ to 2× up to 6×. Some types of this kind go up to very extreme focal lengths.

Zoom lenses for 35 mm. cameras may have a focal length range from 35 to 40 mm. up to 150 mm. or more. For image orthicon television cameras the focal length range usually starts at 60 or 70 mm. and may extend to 200 mm. or more. Again telephoto zoom lenses, mainly for newsreel work, are also available.

Viewfinder Systems. Early cine cameras with zoom lenses used to have (and less expensive ones still do) a separate zoom finder coupled with the zooming movement of the lens. This shows the variable field of view at different focal lengths.

More modern cameras usually have a through-the-lens reflex finder. There a beam splitter within the lens system diverts part of the light into a second optical system which is the viewfinder. It may incorporate a ground glass screen or a clear image plane for aerial focusing, or some sort of split-image rangefinder system. Sometimes part of the finder beam is further split with a proportion of the light diverted to a photo cell for exposure automation.

Alternative beam splitting systems utilize a reflex shutter or an oscillating mirror which also acts as the shutter. In all these cases the finder image corresponds to the view seen through the lens.

Professional cine and television cameras nearly always have reflex finders of this kind.

Automatic and Remote Control. On amateur cine cameras the zooming movement is usually controlled by a lever or ring around the circumference of the lens, or by a fore-and-aft lever connected with a sliding lens barrel through a gear. On some cameras a knob in the camera side changes the focal lengths.

On a number of amateur cameras, and most professional ones, the zooming movement is motorized. A small motor drives the focal length adjustment in either direction on pressing one or other of two zooming buttons on the camera. The motor may be a spring motor wound up at the same time as the main camera motor or it may be electric. Some zoom lenses can be used with an attachable supplementary power zooming motor, fed by separate miniature batteries.

Where the zooming motor is electrically driven, remote control is also possible. This may be linked with the other remote control functions of the camera. On television cameras remote control operation may extend also to the distance setting of the lens and the aperture control. Lenses with these features usually have up to three miniature motors mounted around the lens barrel, and geared to the appropriate setting ring. The various functions are then operated from a control panel at the end of an appropriate cable.

Remote control is useful wherever television or cine cameras have to be mounted in comparatively inaccessible places (for example traffic control, etc.) or where it would be dangerous for the operator to be next to the camera —as in the case of radiation risks.

Zoom Lenses for Still Cameras. Variable focus lenses are available for 35 mm. miniature cameras from a number of manufacturers. They are primarily intended for reflex cameras, where the finder permits a direct and con-

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

ZOOM LENS FOR MINIATURE REFLEX CAMERA. The front element serves for focusing. The two elements shown solid move in unison for changing the focal length.

tinuous check on both the subject area and the picture sharpness at the different focal length settings. Constancy of focus for zoom lenses of this kind is still regarded as desirable, though there are one or two types where the lens needs refocusing whenever the focal length is changed.

Where the zooming range includes the standard focal length, it usually extends from about 35 to 45 mm. up to 80 to 100 mm. Zoom lenses of this kind are only moderately popular, mainly because of their bulk as compared with that of a normal camera lens or even a couple of interchangeable lenses.

Tele-zoom lenses with a focal length range from about 80 up to 200 to 300 mm. are also available. Since a tele lens of 135 mm. or over is mostly used with the camera on a tripod, the extra bulk of the zoom lens is less of a handicap and the availability of several focal lengths in one lens is here a real advantage.

Projection Zoom Lenses. Variable focus lenses for still and cine projection—especially the latter—are becoming a standard feature of many better-class projectors. Here the availability of a variable focus lens permits the projector to be used with a range of screen sizes at a given projection distance, or adapted to a range of projection distances for a given screen size. It thus eliminates the need for moving the projector about to get a required image size.

With multi-size slide projectors (for example half-frame 18 × 24 mm. and 24 × 36 mm., or 24 × 36 mm. and $2\frac{1}{4} \times 2\frac{1}{4}$ ins. transparencies) a zoom lens provides a neat way of quickly changing over from one transparency size to the other while ensuring a constant screen image size.

The most usual zooming range for 8 mm. cine projectors is 15 to 25 mm., and for 16 mm. projectors about 40 to 60 mm. For still projectors the zooming range frequently extends from 80 or 90 mm. up to 110 or 120 mm.; projection zoom lenses with a 3 : 1 range however also exist.

Book: *Optics*, by A. Cox (London).

ZOOPRAXISCOPE. An instrument devised by Eadweard Muybridge in 1880, based on the phenakisticope of Joseph Plateau and the stroboscope of Simon Stampfer, both invented in 1832. The zoopraxiscope was the first instrument in which drawings based on photographs were projected on a screen in quick succession to demonstrate, by means of persistence of vision, the phases of movements which had been instantaneously photographed. It was a forerunner of cinematography.

THE FOCAL ENCYCLOPEDIA

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

MANY VOICES BUT ONE OPINION ON THE FOCAL ENCYCLOPEDIA

"the outstanding photographic book of our time." *The New York Daily Mirror*

"the most important reference book of its kind." *Modern Camera Magazine, London*

"the most important work on photography ever published." *World's Press News, London*

"truly a mammoth work in size and coverage." *The Amateur Photographer, London*

"a whole photographic reference library in one volume." *The Journal of the British Film Academy, London*

"the first encyclopedia of photography in the true sense of the term." *Photorama, Antwerp*

"There have been other encyclopedias . . . but never one of the calibre, the scope, or the thoroughness of this single volume." *Photo Developments, Jackson, Michigan, U.S.A.*

"an enormous storehouse of reliable material." *The New York Times*

"It would be most difficult to name any subject of photographic interest which has been left out." *The Librarian, London*

"a prodigious undertaking . . . the result of a magnificent piece of team work." *Photography, London*

"everything in photography that carries a name has its own entry, and everyone that has a name in photography is there to provide the authority." *Photographic Retailer, London*

"This is a book to stagger the imagination of the photographic expert, to encourage the curiosity of the less-than-expert, to enlarge the horizons of both . . . this masterwork answers all of the hows and whys and whats and whos and whens that are photography." *Popular Photography, New York*

"There can be no more useful volume than this." *The Journal of the Royal Photographic Society, London*

" . . . an arbiter that can be trusted." *The Journal of the Royal Society of Arts, London*

"a cultural feat." *Foto Prisma, Düsseldorf*

"fabulously comprehensive." *Amateur Film Maker, London*

"truly formidable." *De Periscoop, Brussels*

"a tremendous work." *Art Direction, New York*

"a tremendous contribution." *Photo Methods for Industry, New York*

"of absorbing interest." *The Times Educational Supplement, London*

"most interesting and well worth-while." *British Kinematography, London*

"lucid, concise, infallible, and interesting to read." *The Publishers' Circular, London*

"an outstanding work, fascinating, readable, comprehensive." *Industrial Photography, New York*

"The book is a must." *Film World, New York*

"A monumental work and one of great and continuing value." *Journal of the Society of Motion Picture & TV Engineers, New York*

"Unquestioned value." *American Cinematographer, Hollywood, California*

"of immense value." *Discovery, London*

"Invaluable." *The Times Literary Supplement, London*

"Invaluable." *U.S. Camera, New York*

"The most intelligent book on photography in a long, long time." *Aperture, Rochester, U.S.A.*
